
which are 1¼in. apart, be substituted for the pins, they in like manner appear to unite at 10in. behind the stereos. As the size of the stereo prints increases, the distance at which they unite also increases, and the necessary amount of squint becomes less, till with the full-sized pictures 2½in. between the centres, a very slight inclination of the eyes is required, the natural accommodating power of the eyes being sufficient to cause them to unite. They seem, in fact, to coalesce without effort.

Pictures taken with the lenses of the camera the same distance apart as the eyes give the least trouble to unite, as one sees the pictures under the same aspect as the objects they depict.

I have shown at Q in the diagram the effect of uniting the pictures in the way mentioned by "R. S. D." It will be seen that the amount of squint requisite is greatly in excess of the way I described, and more trying to the eyes.

I know that some people find a difficulty in uniting the pictures; but, on the other hand, many do so quite easily. I have photographed and mounted a very great number of stereos during the last forty years by the method described, and have never found any trouble in doing so. I recently looked at the stereoscopic pictures in the *Royal Magazine* without a stereoscope, and, with one exception, had no difficulty. Some of them were excellent—much better than I should have thought possible from mechanical printing.

Lavant. **L. Paxton.**

HEAT AND GASES—MICRATOMIC ETHER.

[42894.]—I FEAR that, owing to the brevity of my previous letter (42817), I have not pointed out with sufficient clearness the exact fallacy in the formula which Mr. Tanton deduces. Using his notation, we have—

$$M = V r^n \text{ and } r = 1 + a,$$

$$\therefore \quad M = V (1 + a)^n.$$

Now, the correct formula, using the same notation, is

$$M = V (1 + a n).$$

It is obvious that, as in Mr. Tanton's formula the expression $(1 + a)$ is raised to the nth power, and in the correct formula the term a is multiplied by n, the first formula will give results in excess of the truth. Let me point out that the correct formula is nothing more than the algebraic expression of Charles' law.

The proof of the accepted formula is given perfectly correctly in "W. B. M. M.'s" letter (42819, p. 115), if we take into account the obvious slip of $V t = V (1 + a t)$ for $V_t = V (1 + a t)$, where V_t represents the volume at $t°$ C., and V that at 0° C.

Mr. Tanton's criticism of Mr. Webb's letter (42818) is perfectly justified. It must be remembered that the equation given above only holds with absolute exactness for a "perfect gas"—i.e., one that obeys Boyle's law, and for which R in the equation $P V = R T$, and γ, or the ratio of the two specific heats, are really constant. All gases diverge from Boyle's law to a greater or less extent, the differences decreasing with decreasing pressure. Small irregularities also become apparent as the temperature falls. Both these deviations become more marked the nearer the gas approaches its liquefying point.

I do not think that the coefficient of expansion of any gas has been determined for each degree between 0° and 100° C. The variations within these limits would be excessively small. It being still vacation, I have no great reference library with me; but all Regnault's results I am acquainted with are the mean values between 0° and 100° C., or some such range of temperature. They vary from ·0036613 in the case of hydrogen to ·0039028 in the case of sulphur dioxide. If we were acquainted with any substance which even within a limited range of temperature behaved exactly as a perfect gas, it would be quite easy and also correct to extend its indications by extrapolation, and thus to determine with accuracy the absolute zero, from which we could reckon an absolute scale of temperature.

This would, of course, be independent of the peculiarities of any thermometric substance whatever. As it is, one particular substance is chosen as the standard, and all other thermometric substances standardised by comparison with it. Nitrogen gas is perhaps the most suitable; but it is evident that the more this standard substance departs from the behaviour of a perfect gas, as regards expansion by heat, the more inherently vitiated will our observations of temperature be. However, fortunately for us, nitrogen or hydrogen departs so little from the behaviour of a perfect gas, within wide ranges of temperature and pressure, that these errors vanish almost entirely.

Lord Kelvin has succeeded in determining the "absolute freezing point of water" by a thermodynamic method, and finds it to be 273·14. According to the indications of the gas thermometers, it is 273° C. The difference is trifling. Mr. Tanton seems to find some difficulty in arriving at the physical interpretation of the term "absolute zero." It is safe to look on it as a point where all motion of the molecules and atoms ceases; and, consequently, as a temperature below which we cannot go.

I am afraid I do not quite see the meaning of Mr. Tanton's penultimate paragraph (letter 42872). If he would kindly explain his difficulty, I might possibly be able to help him. In conclusion, let me recommend Preston's "Theory of Heat" to Mr. Tanton. He will find it very interesting reading; it requires, however, an elementary knowledge of the calculus in a few places. The price is, unfortunately, rather high.

With regard to "Lucretian's" remarks (letter 42871), he is quite right in saying "I scarcely think 'J. M. W.' imagines the ether to be mere motion," for I have always carefully avoided crediting the ether with any specific structure. There is, however, a great deal to be said for the idea that matter is merely motion of the ether—i.e, for the vortex atom theory. This theory I recommend to "Lucretian's" close attention; I am sure he will find its study profitable and instructive, and afterwards he will not speak so disparagingly of it as he does in his letter of last week.

Trin. Coll. Oxon. **J. M. W.**

THE MISTAKES OF AUTHORITIES—A HINDRANCE TO PROGRESS — THE AURORA.

[42895.]—SCIENTIFIC literature contains examples of theories that were once venerated as orthodox explanations of natural phenomena in the scientific ranks, which have since been ruthlessly shattered by the criticisms and influence of modern research.

The introduction of a rival theory to supersede one that has been sanctioned by custom is usually regarded as an unwelcome intrusion in the camp of

prejudice, and is destined to face opposition, sometimes acrimoniously conducted, in passing through the various debatable positions, until common sense prevails over objections more sentimental than sensible, and it eventually becomes accepted as an established principle in the scientific canon.

Similarly prejudicial opposition operates now, and has operated during the past half-century, as an obstacle in the formation of a correct apprehension, or an unbiased judgment of the evidence elicited in a class of phenomena of a quasi-astronomical character, whose hypotheses are founded on mistakes and sustained by misapplied facts. These references comprise the faulty methods employed in dealing with the Aurora Borealis, Zodiacal Light and Band, the Gegenschein, and certain aspects of meteoric phenomena.

In examining the methods of investigation adopted in the first of these subjects, it will be noticed that no preliminary attempt is made to ascertain the nature of the phenomenon to be investigated—whether the luminous objects forming the aërial picture are material or spectral, whether the proposed problem is possible or impossible; but without any justification the requisite conditions for treating it as possible, and the objects as concrete bodies, are assumed, then submitted to comparison with similar objects seen elsewhere, and upon their supposed identity computations are based, in the vain endeavour to reach tangible results, a difficulty further increased by the unscientific method of selecting the facts to suit the assumptions and rejecting the rest. Necessarily, the results obtained by the adoption of such unsound principles are extremely divergent and worthless, whilst the publicity given to them, without comment, in periodicals devoted to exact science, gives them a fictitious importance tending to their perpetuation rather than their solution. An example of this kind is furnished in the monthly notices of the Royal Astronomical Society, Vol. LVII. p. 73, and is by no means an isolated instance of errors possibly sanctioned by that learned body, whose decisions and dicta in such matters are generally supposed to be unquestionable. In *Nature*, Vol. V. p. 422, Mr. Backhouse recommends "some rules to be attended to" in recording observations appertaining to this subject, and directs attention to the necessity of noting the astronomical positions of these luminosities as particulars of paramount importance; whilst discouraging the notification of the position of the radiant point of the streamers "because it is of no value in determining their height, for it is merely an apparent phenomenon." What effect this unfortunate advice has had in delaying the solution of the question, it is impossible to say; but certain it is that the omission of such an indispensable factor from the records vitiates their utility, whilst the retention of the rest serves very little purpose.

The requisite observations and the method of dealing with them to prove the fallacy of the current ideas in relation to this subject are collected and discussed in the ENGLISH MECHANIC for April and May, 1894.

The conclusions there arrived at have recently been confirmed by Prof. Cleveland Abbe, in a paper read before the American Philosophical and Physical Society, who states that "the aurora, like the lightning, may be entirely confined to the lowest stratum of the atmosphere. That its origin must be placed at or below the level of the clouds within a few thousand feet of the ground, and that the assumption that the observed beams have an individual existence is negatived, and that the observers do not see the same object."

An impartial scrutiny of the observations, studied with the view of obtaining all the information derivable from them, is calculated to produce many facts which will materially assist in placing the question on a philosophical basis conducive to its solution.

There are sufficient already in hand to show that it is in the domain of experimental physics that this desirable result may be accomplished. It seems fairly deducible, for instance, that the beams are semi-luminous hollow cylinders, resting on bases some 150 yards in diameter, thickly studded over a surface three or four miles in diameter, with cyclonic movement from east to west round a centre, constituting an auroral system. The arch, which shows no perspective effects, connects two terminal points, separated by the diameter of the magnetic field, a connection which is sometimes established by moving objects taking the same course when the arch is absent. A display seen from various places is due to the multiplicity of such systems, apparently traversing the country from east to west simultaneously; the rate of progression along certain lines of force was noted in one instance at 9¾° of longitude in 2¼ hours.

The conditions of visibility are among the mysteries connected with this peculiar light, whose power of penetration is of a very limited kind, analogous to light reflected from films or thin plates, and may be due to the action of the vertical currents on the mechanical structure of the cylinders, the tint being observed to change with their change of position relatively to the observer situated in the plane of reflection, their visibility being, apparently, within narrow limits in direction and distance.

Birmingham, Sept. 24. **W. H. Wood.**

USEFUL AND SCIENTIFIC NOTES.

A GAS and Allied Trades Exhibition will open on December 31, 1899, at the Royal Aquarium, Westminster, London, and terminate on January 23, 1900.

OBSERVATIONS have been taken of the rise of temperature at different depths in a mine at Bendigo. At 454ft. the rise was 1° Fahr. for each 110ft.; at 1,294ft. it was 1° for each 182ft.; at 1,750ft., 1° for each 173ft.; at 2,295ft., 1° for each 152ft.; at 2,701ft., 1° for each 137ft.; at 3,110ft., 1° for each 110ft.; at 3,250ft., 1° for each 111ft.; the mean result being 1° for each 137ft. in depth. The mine in question was through Silurian rock.

AN American firm of locomotive builders ascertains the weights on locomotive wheels by means of an apparatus whereby the weight on each pair of wheels is measured by a separate scale. The scales used are portable, being mounted on small truck-wheels. Each scale is capable of registering a weight of 60,000lb. They are about 7ft. 6in. long by 2ft. 6in. wide. All locomotives are weighed with a full tank, and the gauges three-quarters full.

COKE is to be used as a locomotive fuel on the Boston and Maine Railroad, says an American contemporary. The locomotives using coke are to be fitted with water-grates. About a dozen have now been changed, and it is expected to have 100 locomotives ready to use coke by the end of the year. Besides the saving of smoke, it is expected that the coke will prove advantageous in reducing the number of fires caused by locomotives; and, owing to the low price of coke hereabouts as compared with coal, should prove much more economical.

PROF. MOSSO has been recently experimenting on smoke prevention in a long tunnel not far from Genoa, through which some 200 trains pass a day. Two methods were tried:—First, large steel cylinders, 5ft. by 2ft., were filled with air at 750lb. pressure, and placed in a locomotive tender. The air was allowed to escape in the tunnel, with the object of blowing out the smoke. The second method was with compressed oxygen, which was supplied to the furnaces of the engines with the idea of improving the combustion. Both methods are reported to have been successful.

Cost of Railway Working.—The Board of Trade report on the working of the railways of the United Kingdom points out that the average expenditure per train mile has been increased by over one penny in two years, and that the expenditure cannot be expected to diminish much during the next year or two. Before 1890 the total expenditure of the companies per train mile stood for some years at about 2s. 6d., whereas from 1891 to 1897 it was about 2s. 8d. Last year it was 2s. 9½d. The number of third-class passengers in 1885 was about 603¾ millions, while last year it had risen to over 963¼ millions. This is a total increase of 359½ millions in the thirteen years, or on an average about 27¾ millions annually.

The "Ivernia."—The new steamer built for the Cunard "carrying" line was successfully launched on Sept. 20. The vessel is the fourth largest in the world, being about 400 tons smaller than the *Kaiser Wilhelm der Grosse*. Among British steamers there is only one larger, the recently built *Oceanic*. The *Ivernia*, which was christened by the Countess of Ravensworth, is intended for the company's line between Liverpool and Boston, and is designed mainly for the carriage of cargo, third-class passengers, and cattle, although a few first and second-class passengers will be carried. Stalls will be fitted for about 800 head of cattle and 80 horses. The leading particulars of the vessel are:—Length over all, 600ft.; length between perpendicular, 580ft.; beam, extreme, 64ft. 6in.; depth, moulded to upper deck, 41ft. 6in.; depth, moulded to shelter deck, 49ft. 6in.; gross tonnage, about 13,900 tons; speed, on trial, 16½ knots. There are four complete steel decks—lower, main, upper, and shelter; also a steel orlop deck from the boiler room forward to the stem, and a bridge deck 280ft. long above the shelter deck. The space between the orlop and lower decks forward is insulated for carrying chilled beef. Three large refrigerating engines are fitted in a house on the upper deck, and also a smaller one for the ship's own stores. The whole of the space forward of the engine-room on the main deck is utilised for the accommodation of the third-class passengers. On the same deck aft are the stalls for the cattle. These stalls will be fitted on the latest approved principle to pass the American cattle regulations. On the upper deck at the forward end is a clear covered promenade for the third-class passengers. It is expected that the vessel will take up her station on the Liverpool and Boston service early next year.

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[96439.]—**Quadratic.**—Solutions to this are not satisfactory; all partake of the guess and trial method. As for that of H. T. Burgess, any little boy can reduce it to a bi-quadratic, which is not re present question. The way I took is as follows, but was not satisfied, and thought to get a better from some of our readers. Mr. H. C. Donnithorne says, rather airily, that if he spent half an hour he could, by quadratics, find a in $a^2 - x - 3 = 0$. 'Tis a pity his half-hours are so precious.

$$\sqrt{x+3} + \frac{\sqrt{x-2}}{\sqrt{x+3}} = \frac{11}{3}$$

Let— $$m = \sqrt{x+3}$$

Then— $$m + \frac{\sqrt{m^2 - 5}}{m} = \frac{11}{3}.$$

$$11m - 3m^2 = \sqrt{9m^2 - 45}.$$

As $9m^2 - 45$ is a square number, we can take its square root, which is $3m - 3$, and remainder is $18m - 54 = 0$, from either of which we have $m = 3$ and $m^2 = x + 3$. Therefore $x = 6$. ONTARIO.

[96452.]—**Meal-Powder.**—When I was a boy, I made fireworks of all sorts, from crackers to shells, and even yet I do something in that way now and again. For a long time the most unpleasant part of the work was the grinding of the meal-powder. At last, however, I found an old disused coffee-mill. Into this I put the big-grained powder (quarry-powder, we used to call it), and a few turns of the handle brought it out as fine as snuff. I ground stones weight of powder in this way, and there is not the slightest danger. The mill will not get hot if it is not turned too quickly. These mills have usually a means of regulating the degree of fineness. Run the powder first through so that the grains are only crushed, then tighten the machine and grind a second time. Charcoal may be ground in the same way. POWDER.

[96503.]—**Shire.**—The use of the suffix "shire" seems to be purely arbitrary. If the meridian of Canterbury is taken (that is the mother city, the real metropolis of this country), all the shires lie west; but, so far as I know, no one has been able to explain why "shire" should be added to the names of counties. On the east side of England there is Lincolnshire, Yorkshire, Cambridgeshire, Hertfordshire, but on the west there is Cornwall, for example. The term "shire" seems to be used in a very arbitrary manner, for while it is generally applied to the Scotch counties, it is very rarely appended (if ever) to the Irish counties. I have looked up this matter, and cannot find any definite information at all, nor why there should be, amongst others, such a term as "Hallamshire." TOPOS.

[96555.]—**Equations.**—Mr. Harding is quite right; the reply given by Mr. Burgess cannot be called a solution of the problem; it is impossible to say how he has hit upon "the answer," as there is nothing in the equations to justify him in saying "we may assume" x to be so and so. In the three equations here reproduced—

$$\left.\begin{aligned} \text{(i)}\ \tfrac{2}{3}x^2 + \tfrac{8}{5}yz &= 6\tfrac{3}{4} \\ \text{(ii)}\ \tfrac{8}{5}y^2 + \tfrac{5}{7}xz &= 7\tfrac{1}{2} \\ \text{(iii)}\ \tfrac{5}{7}z^2 + \tfrac{7}{9}xy &= 11\tfrac{2}{3} \end{aligned}\right\}$$

It will be noticed that the coefficient $\frac{8}{5}$ occurs both in (i) and (ii), also that the coefficient $\frac{5}{7}$ occurs both in (ii) and (iii). Now eliminate $\frac{8}{5}$ between (i) and (ii), and the same for $\frac{5}{7}$ between (ii) and (iii), and we get two equations; it will be found that x^2y appears in both of these equations; eliminate this, and we get the equation—

$$\tfrac{81}{8}y - \tfrac{425}{28}z - 15x = \tfrac{87}{35}y^2z - \tfrac{15}{14}xz^2$$

Now, I want to get rid of the z's except the term involving z alone. From I., we have—

$$yz = \tfrac{45}{4} - \tfrac{10}{9}z^2,$$

and from (iii.)—

$$z^2 = \tfrac{42}{5} - \tfrac{49}{45}xy.$$

Substituting these and reducing, we get—

$$z = \tfrac{9}{16}y + \tfrac{14}{9}x - \tfrac{182}{945}x^2y,$$

and from (i.)—

$$z = \frac{\tfrac{45}{4} - \tfrac{10}{9}z^2}{y}$$

Equating these, we get an equation from which y can be found in terms of x, or x in terms of y by solving a quadratic equation. Taking the former, I find on solving the quadratic—

$$y = \frac{\sqrt{\left(\tfrac{3644}{1701}z^4 - \tfrac{57713}{4462}x^2 + \tfrac{81}{8}\right)} - \tfrac{7}{8}x}{\tfrac{9}{16} - \tfrac{182}{945}x^2}$$

Now, in order that this equation may hold good, the terms under the radical sign must form a square

number: otherwise we should have an inexact number = an exact one, which is impossible. Then, confining our attention to the radical term, we may equate the terms under that sign to $\frac{m^2}{n^2}$, m and n being the whole numbers. And it will be seen that any number, either whole or fractional, can be represented by $\frac{m}{n}$ where m and n are whole numbers. Now bring the terms under the radical sign to a common denominator, and write it in this form:—

$$\frac{x^2}{3402}\left(728\,x^2 - 8715 + \frac{34445{\cdot}25}{x^2}\right) = \frac{m^2}{n^2}.$$

Now we have to make x^2 = a square number, which will make the left hand of the equation of the form $\frac{m^2}{n^2}$. To do this, it is necessary that x^2 should divide 34445·25 exactly without a remainder. The only square values of x^2 which will do this are $x^2 = {\cdot}25$ and $x^2 = 2{\cdot}25$. The latter makes the last term 15,309. With this value of x^2, the whole expression after reduction reduces to $\frac{49}{9} = \frac{m^2}{n^2}$, which is the square of $\frac{7}{3}$. Substitute $\frac{7}{3}$ for the radical term and put $x^2 = 2{\cdot}25$ or $x = 1{\cdot}5$, and we get $y = 2{\cdot}5$; then from the other given equations $z = 3{\cdot}5$.

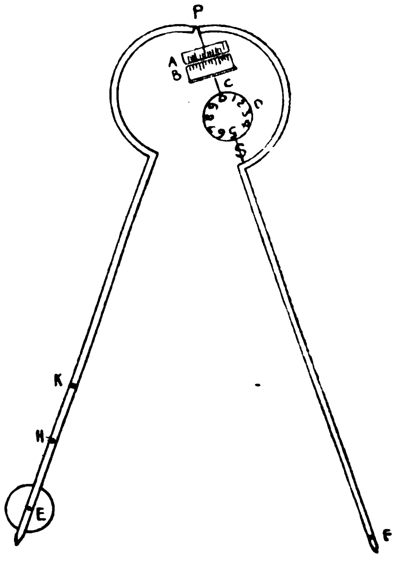
Bath. M.I.C.E.

[96555.]—**Equations.**—As Mr. Harding has had the kindness to mention my name in this connection, I can only say that the direct solution is beyond me. The elimination gives rise to an equation of the eighth degree in the remaining unknown, and some works on algebra say that it has been "conclusively proved" that any general solution of equations of a higher degree than the fourth is "impossible." Personally, I fail to see how any negative can be "conclusively" proved, as the possibilities of a science are infinite.

Oystermouth. SCORPIO.

[96556.]—**Oil and Gas-Engines.**—Thanks to "965" for correction—my mistake. Theoretically you are right; but if you fit a pressure-gauge on a tee-piece so that you can use side outlet for relief-cock, you will find compression actual—generally comes out somewhat higher. Fit a cock also between gauge and engine if running, as it plays havoc with any steam gauge, which should never be subjected to sudden violent shocks. Turn engine sharply by hand and watch gauge. MONTY.

[96587.]—**Speed Indicator.**—(1) Yes, the principle is that of a centrifugal governor. The centrifugal force of the rotating spindle causes a needle to indicate upon a dial graduated to give direct readings in miles per hour. I have seen another form containing a watch movement. On pressing a stud the movement is wound up and the hand set to zero. On releasing the stud the indicator starts counting revolutions, and continues so for 60 seconds. When the watch movement throws the mechanism out of gear, the diameter of the wheel being known, a simple calculation gives the speed. (2) I inclose a rough sketch of a planimeter drawn somewhat



out of proportion in order to render the working parts clear. A, fixed vernier; B, wheel; C, worm gear actuating disc D; S, spindle; E, fixed point; F, tracing point; P, hinge. The total revolutions are read on the disc D, the tenths on the wheel itself, and the hundredths on the vernier. The weight E which anchors the fixed point may be placed at different positions, as shown at H and K, thus enabling the ratio between the two arms to be varied, in order to simplify the reduction of the readings when working to different scales. The theory of the instrument depends upon the fact that while the free end traces out the area of any closed figure the hinged end oscillates to and fro along a curve, but traces no area. If "Scorpio" can refer to "Williamson's Integral Calculus," or "Minchin's Uniplanar Kinematics," he will find the theory of the instrument fully elaborated. As a matter of fact, the planimeter is simply a mechanical integrator. There are several different forms of the instrument. The form I have sketched, with which I am practically conversant, is that commonly used by civil engineers for checking areas and similar calculations. A more elaborate form is used by naval architects in calculating metacentres, displacements, &c., which measures the moments of inertia of areas. W. J. G. F.

[96615.]—**Brown Boot-Polish.**—Yellow wax 1oz., palm-oil 1oz., oil turpentine 3oz., oil mirbane 15 drops. Make into paste. Colour may be heightened by judicious use of butter, colouring made from annatto. Russet leather shoe polish: yellow wax 2oz., linseed oil 3oz., oil turpentine 10oz. Dissolve by means of a water bath in closed vessel, and add hard yellow soap, finely shaved, 1½oz. Dissolve soap in 14oz. of water, add solution to solution of yellow wax and flax-seed oil formed in first instance. A nice russet brown colour may be imparted by incorporating about three grains of Bismarck brown to each ounce of polish. Oil turpentine 10oz., yellow wax 5oz., soap ½oz., boiling water 10oz. Dissolve wax in the turpentine by aid of water bath, and soap in the boiling water. Mix and stir until cold and smooth. Soft soap 1oz., linseed oil, raw, 1½oz., annatto 4oz., yellow wax 1½oz., gum turpentine 4oz., water 4oz. Dissolve soap in water, and add annatto. Melt wax in linseed oil and turpentine, and gradually add the soap solution, stirring till cold. All these articles should be easy to get. REGENT'S PARK.

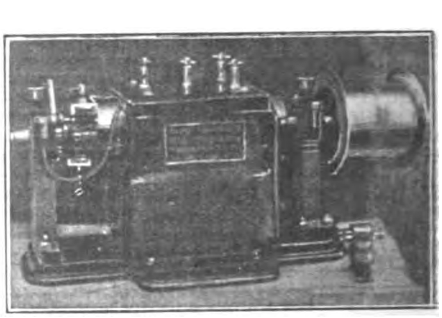
[96619.]—**Electric Organ.**—Thanks to "Diapason" for reply. I should still like to connect American-organ keyboard with that of pipe-organ by electricity, if he will kindly give a few hints how to manage it. In a rough way I had previously connected the keys with laths, but found the leverage too great to play easily. With regard to the pitch, the pipe-organ has its own bellows, and can be weighted according to pressure required. Would "Diapason" also state publisher and price of work referred to. J. S. Z.

[96624.]—**Etching Ground.**—White wax 30, gum mastic 30, asphaltum, 15. White wax 30, gum mastic 15, asphaltum 15. White wax 60, gum mastic 30, asphaltum, 60. White wax 3, black pitch 1, asphaltum 4, rosin, 1. Callot's ground: Linseed-oil varnish, mastic, heat until wax is melted, filter, apply with brush, and heat plate until varnish stops smoking. White wax 2, black and Burgundy pitch each ½, add by degrees powdered asphaltum 2, boil till a drop taken out on a plate will break when cold by being bent double two or three times, pour into warm water, and make into balls. Soft: Soft linseed-oil 4, gum benzoin and white wax each ½, boil to two-thirds. REGENT'S PARK.

[96628.]—**German Yeast.**—As you live so far away, perhaps an inspection of W. Jago, on Bread-making, who is a consulting specialist in London on the subject. The publishers are Simpkin, Marshall, and Co., Ltd., London. He informs us that compressed yeasts from France, Holland, and Germany are not successfully made except on a large scale, and cannot be imitated by small bakers; mostly distillers yeast working chiefly for spirit, largely used for perfumery, &c. However, if you care to try your hand, this is what he gives. Have not written all, as you may suppose. Malt and rye taken together, mashed at a convenient temperature to transform into maltose. Mash allowed to stand in tubs at temperature most suitable for lactic acid or about 35° C. Lactic acid germs on skin of malt rapidly develop and marked acidulation ensues, perhaps 1·5 per cent. of acid. Mash is then cooled by immersion therein of cooling coils of copper tube, through which cold water passes. When at desired temperature, without filtering of the grains (husky fibre of grain used), pitching yeast is added, fermentation allowed to proceed for 10 to 14 hours, according to temperature. Next the raw grain, principally maize, first cooked by high-pressure steam in special steam-cooking vessel (cuiseur) until thorough gelatinisation has been produced. From this vessel cooked maize passes into saccharification tun, there mashed, first with rye; afterwards malt is added, and saccharification continued until the hydrolysis of the carbohydrates to maltose is as complete as possible. The finished wort passes to refrigerators; then conveyed to fermentation vats and pitching ferments added. Air is drawn through the wort by mechanical means until, or found, necessary. Grains in mash rise to surface and act as non-conductor of heat. In three or four hours after pitching the carbon dioxide forces itself up in a sort of cauliflower head through the grounds and bursts or breaks. Fermentation is allowed to continue from 10 to 12 hours from commencement, and then the yeast is skimmed off with a long lath and lay up whole of yeast at one end of vat and then ladle it off in scoops into wooden gutter for conveyance away for washing and purification. Skimming is practically carried on for 12 hours. The skimmed yeast first mixed with water; then passed through a series of mechanical sieves to separate the grains. Yeast then washed by decantation two or three times, and then sifted through finer sieves, &c. REGENT'S PARK.

[96629.]—**Linoleum Polish.**—A paste of beeswax and turpentine, made by melting the wax and stirring in the turps, afterwards stirring carefully in a pot on a kitchen-stove, answers well. Take care not to let the turps catch fire. It is used cold. GLATTON.

[96630.]—**Fifty-Volt Overtype.**—I inclose a photo., of one of our drum-armature shunt-wound overtype dynamos, that perhaps our Editor, with



his usual willingness to oblige, will insert. Subjoined are the principal dimensions:—Armature, built up of 4in. punchings, 3⅝in. long and 4in. diam. before winding. Shaft 2ft. long, 1¼in. diam., turned down to 1in. where it enters bearings. Base of dynamo 23in. long by 13¾in. at widest portion, 1¾in. thick. Field-magnet cores 8in. wide, 1in. thick, by 6¼in. high. Pole-pieces 3⅞in. high, 9⅞in. long, 7¼in. across the tunnel, which is bored out to take the wound armature to about 4¼in. diameter. Armature to be wound with 3lb. No. 18 in 24 sections of 5·625 yards each. Field-magnets to be wound with 10lb. No. 22 d.c.c. on each limb, connected up in shunt. Output at 1,800 revs. per minute 20 ampères, 50 to 55 volts. Will light easily from fifteen to twenty 50v. 16c.p. lamps, or two arcs taking 8 ampères each in parallel. S. BOTTONE.

[96631.]—**The Eight Queens Problem.**—There is nothing "vague" about this problem, as stated by "Q. R." To arrange the eight queens in this manner is an old puzzle, well known to most chess-players, and the fact that the eight queens command the whole board has no bearing on the question. Examined analytically the problem is resolved into the following arithmetical puzzle:—Place the first eight natural numbers in such an order that the inequality $a_m \sim a_n \neq m \sim n$ shall hold generally, where a_m and a_n denote the mth and nth numbers in order. Such an arrangement is 7, 5, 3, 1, 6, 8, 2, 4. If we place immediately to the left of each number the figure representing its place in order, we get 17, 25, 33, 41, 56, 68, 72, 84, and these are the eight squares on which the queens are to stand, expressed in Kieseritsky's notation (where 11, 12, 13 . . . 18 represent the squares of the first rank, 21, 22, 23 . . . 28 those of the second rank, and so on). In the common English notation the above solution gives the squares Q R 7, Q Kt 5, Q B 3, Q sq., K 6, K B 8, K Kt 2, K R 4. The problem, as quoted by "Q. R.," requires *the number of different solutions*, and in giving an answer to this question we must first decide what we shall call a different solution. In general, any arrangement of the pieces can be presented in eight different aspects. We may turn the board on either of its sides, or upside down, thus giving four different views, and each of these may be duplicated by reflection in a looking-glass. I am not aware of any published solution to the above arithmetical problem, and have been forced to consider it *de novo*. The analysis is much too long and complicated for publication here, but the result, which "Q. R." may take as correct, is as follows:—If we consider the eight aspects mentioned above as *different* aspects, then there are 92 arrangements which satisfy the required conditions. If, on the other hand, we do not consider them as different, there are only 12 satisfactory arrangements. The reason why the first value is not eight times the second is that one of the latter 12 arrangements is semi-symmetrical, and can only be shown in four different ways. Of the twelve solutions, six belong to one family, and can be converted one into another by equal displacements; the other six are monads. C. P.

[96631.]—**The Eight Queens Problem.**—This interesting problem is a particular case of the more general one—viz., to place n queens on a board of

n^2 cells, so that none can take any other. In 1874 Dr. Günther suggested a method of solution by means of determinants. Thus, if we take 64 cells we can obtain the possible positions by expanding the determinant—

$$\begin{matrix} h_1 & g_2 & f_3 & e_4 & d_5 & c_6 & b_7 & a_8 \\ k_2 & h_3 & g_4 & f_5 & e_6 & d_7 & c_8 & b_9 \\ l_3 & k_4 & h_5 & g_6 & f_7 & e_8 & d_9 & c_{10} \\ m_4 & l_5 & k_6 & h_7 & g_8 & f_9 & e_{10} & d_{11} \\ n_5 & m_6 & l_7 & k_8 & h_9 & g_{10} & f_{11} & e_{12} \\ o_6 & n_7 & m_8 & l_9 & k_{10} & h_{11} & g_{12} & f_{13} \\ p_7 & o_8 & n_9 & m_{10} & l_{11} & k_{12} & h_{13} & g_{14} \\ q_8 & p_9 & o_{10} & n_{11} & m_{12} & l_{13} & k_{14} & h_{15} \end{matrix}$$

Each symbol representing the corresponding cell of the board. Now pick out each term in which neither the same letter nor the same number appears more than once. Each such term gives a solution. There are 92 such terms in the above determinant, and "Q. R." may like to find them for himself; for his benefit, however, let him remember that there are |8 or 40,320 terms to investigate. Dr. Glaisher (*Phil. Mag.* Dec. 1874, pp. 457-467) has shown how to shorten the process by deducing the solutions for a board of n^2 cells from one of $(n-1)^2$ cells. In this way he finds twelve fundamental solutions given by—

4 6 1 5 2 8 3 7, 6 1 5 2 8 3 7 4, 3 5 8 4 1 7 2 6,
6 8 4 1 7 2 6 3, 7 2 6 3 1 4 8 5, 5 7 2 6 3 1 4 8,
3 5 2 8 1 7 4 6, 1 6 8 3 7 4 2 5, 4 8 1 5 7 2 6 3,
5 1 4 6 8 2 7 3, 4 2 7 5 1 8 6 3, 5 1 8 6 3 7 2 4.

In these the 1st, 2nd, 3rd, &c., digit represents the number in the 1st, 2nd, 3rd, &c., column of a queen. For futher information on this subject the reader is referred to *Phil. Mag.* 1874, as above, and to a short article on pp. 85-88 of that excellent little book "Mathematical Recreations and Problems," by W. W. R. Ball (Macmillan), guaranteed to cure inventors of perpetual motion machines, lunar non-rotationists, &c. J. T. G.

[96635.]—**Solder.**—The inquiry was for a solder more fusible than tinman's solder. Five of tin to one of lead is a low-melting solder, or one of tin to one of bismuth melts nearly 100° lower. It is a general rule, the lower the melting-point the weaker the solder, but soft-solder is much stronger than is generally supposed, especially if the joint is well fitted and the layer of solder very thin. Don't mind "Regent's Park's" answers. He once gave one for brass-coloured solder to use with copper bit. I spent several hours in testing, thinking it was possible that "R. P." had made a discovery, though I should have known better. I would willingly give £5 for recipe for brass-coloured soft-solder.

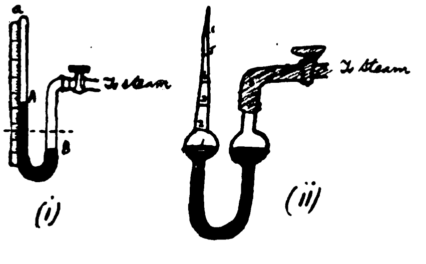
West Didsbury. M. COLE.

[96636.]—**Accumulator.**—Page 142, last sentence, for "two parts of water" read ten parts of water to one of sulphuric acid. W. J. G. F.

[96648.]—**Mercury Gauge.**—I remember experimenting some years ago with a patented gauge consisting of a glass tube filled partly with fluid and partly with air, the latter being near the closed end of tube. Steam pressure forced more of the liquid up the tube, compressing the air. Equal divisions were obtained by varying the section of the tube. I did not think it satisfactory, as the amount of air required adjustment from time to time. The fluid used was water, but mercury would be better, as it would not absorb the air.

GLATTON.

[96648.]—**Mercury Gauge.**—The simplest form of such a gauge is shown in Fig. 1, and consists simply of a bent U-tube, with its longer limb, A, closed at one end. In this tube is a quantity of mercury, A B, which thus shuts off from all communication with the external air the air A *a* in the



longer closed limb of the tube. The gauge is so made that when the pressure on the mercury at B is equal to that of the atmosphere, the mercury is at the same level in both limbs of tube. If the pressure be increased, the mercury in B will be forced into A, thus causing the air in A to be compressed, as shown by the rise of the mercury in A. Equilibrium will be established when the pressure in A, together with that exerted by a column of mercury whose lift is the difference between the levels of the mercury, equals the pressure on B. It will be seen that decreasing rises in the mercury in A will correspond to equal rises in pressure at B. Hence for very high pressures the accuracy and sensibility of the instrument are not very great. This difficulty is overcome in some instruments by making the tube A conical. Thus, when the mercury rises in A, increasing changes in length of the mercury column correspond to equal changes in volume and pressure. (See Fig. II.) Such instruments are in practice graduated empirically by subjecting to varying pressures and comparing with a standard mercury column or pressure gauge. Unless access can be had to a standard gauge and compressed air or steam to act on, both so as to graduate gauge by experiment, I think the manufacture should not be attempted, as, although the distances on the scale for equal increments of pressure can be determined by calculation, the formula is fairly complicated and the chances of error, owing to differences in volume of different lengths of tube, &c., are not a few. The glass tube, of course, should be stout steam and water-gauge tubing, such as is used on boilers for water-gauges, and should be without flaws. J. BENNETT.

[96656.]—**Bookbinding.**—By all means take the books to a printer, and have them cut by machine. I have done my own bookbinding for 30 years, and never could cut edges to give good appearance. In gold lettering you can use ordinary-type, which need not be very hot. You can usually buy for 4d. or 6d. at the bookstalls most beautiful specimens of binding—of course, the worse for wear, but good as specimens to copy from.

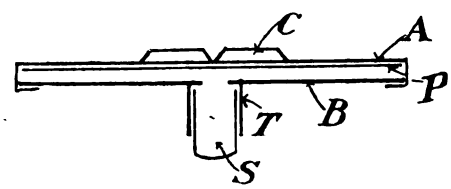
West Didsbury. M. COLE.

[96658.]—**Rheumatism.**—I have been suffering from what the doctor calls gouty neuritis since June, and, getting tired of taking salicylate of soda, unusual exercise, and the other things recommended, I began three weeks ago to take Bishop's citrate of lithia, as recommended by "Edwards," on p. 72. The results are most encouraging; the pain has practically gone, and so has the crackling of one of my hip-joints, which I experienced when getting up in the morning. GLATTON.

[96660.]—**Ringing Anvil.**—A lump of wood stuck on the horn reduces the noise, but is in the way.

West Didsbury. M. COLE.

[96661.]—**Regulating Capsules for Incubators.**—I have two incubators—one on the atmospheric principle, which is regulated by what is called a J-tube regulator; and the other machine is on the hydro principle, regulated by the capsule-regulator. I have used the machine on the atmospheric principle which is regulated with the J-tube, and find the regulator to work very well. The other machine, with the capsule-regulator, I have not yet worked, so cannot say how it works with use. I got mine made at a tinner's from my instructions, which are as follows:—In Fig. 1, to



A, Top plate; B, bottom plate; C, metal ring soldered in centre of top plate; T, tube to pour ether in; S, plug to fit tube; P, sheet of blotting-paper.

make it clear, I give a section of the capsule. The upper plate, marked A, should be 2½in. square and No. 33 gauge, and the lower plate, B, 2in. square, and rather stronger—say No. 30 gauge. A small round metal plate, C, about ⅝in. diameter, is countersunk in the centre; the lifting-rod works into this countersunk hole. This metal plate is soldered into the top plate marked A (Fig. 1) in the centre, thus spreading the weight over the whole plate. In the centre of the bottom plate B (Fig. 1) solder a very small piece of brass tube, T (Fig. 1), and turn a brass plug to fit tightly in it, which is afterwards sweated or soldered in (see S, Fig. 1). Now, to commence putting the capsule together. Have both the plates perfectly flat, then bend the edges of the top plate A over the bottom plate B, and solder round, and be sure to put a 2in. square of clean blotting-paper, P, between the two plates. Now fill the tube with ether (prepared for the purpose), which is made of sulphuric ether 2 parts, methylated spirit 1 part. Allow it to soak into the blotting-paper until it will soak no more. Then sweat or solder in the brass plug S (Fig. 1). The capsule is then complete, and I think the various plates, &c., will be understood from the vertical drawing of the same. The capsules are generally made of thin sheet brass to the sizes given above, though I had mine made of thin sheet steel; but, of course, cannot tell how it will work until I have given it a trial. I trust the information will be found useful by your correspondent, "Poultry Breeder," and I might just say that a good book on the subject is "Incubators: How to Use and Make Them," published by Carvell and Co., Ludgate Hill, London, E.C., price 1s. 2d. I have, I may say, from the instructions therein, made the two incubators as above, and here he will find all information required, though I shall be pleased to answer any further questions if desired to do so. The specially-prepared ether for the capsules can be obtained from incubator makers at about 6d. per small bottle. I find I have not any left, or would have sent you a bottle in care of the Editor. W. H. B.

[96661.]—**Incubator Capsules.**—Get some thin sheet-brass, cut out two discs 2⅞in. and 3in. diam., and harden well by planishing with hammer on smooth block (a flat-iron will do), hammering slightly more in the middle to raise same about $\frac{1}{16}$in. or so. Now clean and tin each round about ⅛in. from edge. Place same together and solder round with the exception of about ⅛in., allowing solder to lap over edge of top plate. This forms shell which, when compressed, should spring and cockle. Pour about 20 drops of sulphuric ether in a saucer, compress shell, forcing the air out between the plates; apply unsoldered part to ether and release, and the ether is sucked up or, rather, forced between the plates. Close up, keep capsule cool with a piece of wet rag on the other side to prevent ether from evaporating, and solder up remaining ⅛in. This will boil and lift at 98°, but by weighting lever boiling-point is raised easily to 108°. If a higher temperature is required on capsule, owing to position of capsule and tank, a mixture of alcohol (rectified spirits) one part and S. ether three parts can be used. You will find this gives a good result if directions are carried out. SOCIALIST BRUM.

[96662.]—**Thunderstorm.**—It probably makes little or no difference whether the coat of the man or animal be wet or dry. Animal bodies are good conductors of the electricity of high potential difference of which lightning is an example. The hair, wool, or fur of animals, however, are protective, being in varying degrees insulators; but when wet, water being a good conductor, they to some extent lose their protective or insulating properties. This rule also, of course, applies to woollen clothes worn by man. Clothes of cotton or vegetable material are conductors of electricity even when dry. Men, therefore, or other animals, are more likely, *cæteris paribus*, to be struck by lightning when their clothes or skins are wet. However, this wet condition generally implies that it is raining, and when this is the case there is less likelihood of an object being struck, for the electrified clouds are being dissipated, falling harmlessly as rain to the earth, and the damp air affords an easier path for any high electrical discharge from cloud to cloud, or from cloud to earth. Trees are good conductors of electricity, some kinds being better than others. This is owing perhaps to the large number of points which their leaves or branches present; and it is therefore obviously, as well as notoriously, dangerous to stand under a tree during a thunderstorm. It is said to be safer, however, to stand near a tree, at a distance from the trunk equal to the height of the tree, than in an open field. These statements are perhaps mostly founded on theory; but since the Russian, Prof. Richmann, of St. Petersburg, was killed by the lightning which he had drawn for experimental purposes from a "thunder" cloud, comparatively few people seem to have practically investigated the subject. H. E. SEYMOUR.

[96662.]—**Thunderstorm.**—I remember, at a lecture at the Royal Institution, seeing a waterproof boot exhibited which had been torn to pieces by a lightning flash, which had passed over the wet parts of the wearer without injuring him. I cannot find this mentioned in the *Proceedings* however. Prof. Lodge's experiments showed that, dry or wet, it is dangerous to stand near a tree in a thunderstorm. A horse (and probably cows and bullocks) is killed very easily by an electric shock. An electric-tram cable, if it it falls on a horse's head, will generally kill. What would be merely a severe shock to a man will kill a horse. In this week's *Engineering*, p. 338, a new method of experimentally imitating ball lightning is described, which is interesting. GLATTON.

[96666.]—**To J. Dormer.**—Your paper does not seem sufficiently sized. Try treating it with gelatine solution before applying iron. J. D.

[96669.]—**Mercury's Mass.**—In Ball's "Elements of Astronomy," 1883 edition, four determinations of this are quoted:—

A.D. 1841	Encke	$\frac{1}{4865751}$	of the sun's mass.
„ 1861	Leverrier	$\frac{1}{5310000}$	„ „ „
„ 1861	„	$\frac{1}{3580000}$	„ „ „
„ 1876	Von Asten	$\frac{1}{7636440}$	„ „ „

Probably there are later estimates. GLATTON.

[96671.]—**Solvent for Gum.**—Benzine, chloroform, ether, or petroleum ether are solvents.
REGENT'S PARK.

[96673.]—**Aluminium.**—As this is now only about 15d. per pound in the ingot, it is not worth while to go to much expense about it. To reduce to fine powder machinery is required. Send it to a board school to put in their cabinet of specimens.
West Didsbury. M. COLE.

[96677.] — **Voltage.** — It is quite immaterial whether the source of current be a dynamo or a battery. The softer the iron of the rod the more powerful will be the magnetisation. The size of wire will depend entirely upon what current you use, the result will depend upon the number of ampère-turns—i.e., 10 ampères going once round the rod will produce the same effect as 1 ampère going ten times round. You may, therefore, use a small current with high voltage to force it through the resistance of many turns of wire, or a large current with small voltage going round comparatively few turns. W. J. G. F.

[96677.] — **Voltage.**—The question as to the gauge of copper wire best adapted to wind an electro-magnet is decided by a knowledge of the current in ampères required to magnetically saturate the iron. Remembering that the "free" magnetism which can be evoked is dependent upon sectional area of poles (independent of length), and on the number of ampère turns, and also that the limit of useful magnetising force is reached when the ampères (or ampère turns) flowing round the iron amount to about 14,000 per square inch of section, there will be no difficulty in calculating out the best winding, provided the E.M.F. and internal resistance of the proposed source of current is also known. An example is here given. Suppose we have an iron rod of 1⅛in. diam. (equal very nearly to 1in. square sectional area), we should require to cause to flow around that 14,000 ampères. Such a large current is not practical, so we will use ampère turns instead, and content ourselves with six ampères. Now 6)14,000(2,333 very nearly, so that if we can wind our rod with 2,333 turns of a wire that will safely carry six ampères, we shall get the desired magnetising force. No. 16 copper wire meets the requirements. Hence, if we wind our rod with about 2,333 turns of No. 16d.c.c., we shall do very well. No. 16 lies 14 turns to the inch, so that we can wind 168 turns on a rod 12in. long: $14 \times 168 = 2{,}352$, so that 14 layers will give us the desired number of ampère turns. As the average length of each turn is about 5⅛in., so the total length of wire needed is 12,042in., or, say, 335 yards, or 14lb. very nearly. Now the resistance of No. 16 copper wire is 0·2 to the pound, so that the total resistance of our coils is 2·8 ohm. To push six ampères through this resistance, we should require a battery, dynamo, &c., capable of giving at least 16·8 volt, since 2·8)16·8(6. But since there is no battery or dynamo that has *no* internal resistance, allowance must be made for this. Supposing we used accumulator cells, each giving two volts, with an internal resistance of 0·04 ohm each, then ten such cells in series, when coupled to the electro-magnet, would give us $\frac{20}{2\cdot8 + \cdot4}$ 6·21 ampères. From this it is evident that a dynamo giving 18 to 20 volts, with an internal resistance not exceeding 0·4 ohm, would answer equally well in this case. S. BOTTONE.

[96678.]—**Spark Coil.**—If you have not put the condenser in connection with the contact-breaker of the coil you can form no criterion of the behaviour of the coil. Try it again, with the condenser properly connected, and with a good battery, capable of giving about eight volts and six or eight ampères. (Four freshly-charged accumulator cells are the most satisfactory for this purpose.) If the nine sections do not give at least ¾in. spark under these circumstances, there must be something radically wrong in the insulation.
S. BOTTONE.

[96678.]—**Spark Coil.**—If the insulation and connections are right, one would expect much more than $\frac{1}{16}$in. spark from 1lb. of wire. Querist does not mention the break. If not already tried, a mercury break might be found to improve results; a bit of platinum wire dipped by hand in the mercury does for a test. The core and primary are, however, in my opinion, too small for 6lb. of secondary. Judging from the dimensions of noted coils given in a table which I published in "E. M.," No. 797, the core might be 1¼in. to 1⅜in. diameter by 15in. to 18in. long, and primary three layers of No. 12 to 14. The present core and primary might suit for 3 to 4lb. secondary No. 36, and give 3in. to 4in. spark.
Belfast. J. BROWN.

[96678.]—**Spark Coil.**—The reason for your coil not working seems to be that you didn't connect up the condenser. A 6in. spark coil without a condenser will give barely 1in. spark. Are you sure that the sections are properly connected up? You should be able to get 5in. spark or more from this coil. W. E. G.

[96680.]—**Temperature.**—If Perkins's "Arktos" refrigerator is still on the market, it would perhaps suit. A few pipes, partly filled with ammonia, led round the room like heating pipes, are practically all it consists of. A fire has to be lit about once a day in a fireplace where part of the pipe is coiled. No other attention wanted, I believe. GLATTON.

[96683.] — **Cycle Motors.** — Endurance motor seems a crude adaptation of oil-engine taken from gas-engine practice. It is English make and design, and Early English at that, though they may run well enough; but look to me more in keeping with a wheelbarrow or hand-truck than a tricycle. You cannot do better than follow on lines described by writer; but make your inlet valve pipes and gauze in carburator half as large again. It is a great deal easier to choke a high-speed oil-engine than people are generally aware of. I do not like in writer's design the sunk nuts on flywheels. Any special work like that is bad in practice. Otherwise, all would-be makers are indebted to him. MONTY.

[96686.]—**Cycle Motor.**—You can pump petrol in if you wish. Pennington used to run his in by gravity three or four years ago; and they worked well; but I believe had a tendency to choke up near small inlet into cylinder. I do not think he uses it on his present engine, from which you can draw your own conclusions. MONTY.

[96687.] — **Black Straw Hat Polish.** — "Milliner" will find nothing better than black sealing-wax dissolved in methylated spirit. Some things that are used for black straw are intolerable—they either have a horrible smell which is never got rid of, or in the least rain they become clammy, and come off on the hand. Sealing-wax and methylated spirit are free from any objection. M.

[96688.] — **Oil Engine.** — You do not say if yours is a stationary engine or not. Electric ignition will enable you to fire at best point and therefore get better results! Certainly you would get better results from petrol than common paraffin with less objectionable smell, and no tarry deposit in cylinder and vaporiser. Power is merely a question of speed; compare difference between yours and one described. You can easily test the brake H.P. before and after alteration. Double the speed of your present engine if you want more power. MONTY.

[96690.]—**Dynamo.**—To MR. BOTTONE.—Premising that at 65v. pressure you will not be able to draw a large current from so small a dynamo, I should advise you to wind the armature with about 130 yards, or, say, a little over 1½lb. of No. 20 d.c.c. in not less than 16 sections, and the field-magnets with about 10lb. No. 22 d.c.c. If the iron of the F.M.'s is soft and of good magnetic permeability, you would probably get better results by using as much as 13lb. of No. 22; but if the iron is at all hard the machine would possibly not "build" with so much wire on the fields. Using wire of the above gauges, which correspond to 0 89mm. and 0·75mm. respectively, you may reasonably expect to get four ampères at 65 volts when driving the machine at about 2,500 revs. per minute.
S. BOTTONE.

[96691.]—**Acetylene Gas**—The statement that this gas can be made at a cost of 2s. 6d. per 1,000c.ft. is ridiculous. Calcium carbide cannot at present be bought by consumers at a lower figure than 20s. a cwt., to which must be added the cost of its carriage. A pound of good carbide is supposed to give 5c.ft. of acetylene; but the querist may consider himself lucky if he can get carbide to give 4c.ft. in practice, and at this rate his 1,000c.ft. would cost over £2, without taking into account cost of carriage. One has not the least faith in the statements made in the catalogues of people connected with the acetylene business if one has had experience in the matter. Under the most favourable circumstances, the amount of light would work out thus:—112lb. $CaC_2 \times$ 4c.ft. = 448c.ft. = 60 candle-power for 448 hours, or 448c.ft. × 60c.p. = 26,760 candle-power for one hour. The acetylene light is a brilliant one, and could not be beaten; but I should say that coal-gas at 3s. 9d. per 1,000 with incandescent mantles (with fair care) would be a great deal cheaper. FIAT LUX.

[96692.]—**Liquid Nitrogen.**—The querist asks a question, and assumes that liquid nitrogen would be above its critical temperature, and "therefore must be in gaseous state." How can nitrogen or other "gas" be in a gaseous state when it is under such a pressure as compels it to be liquid? It appears to me that this is an examination question, and should be left alone by readers of the "E. M." Some of these examination questions are useful no doubt, because they test the real knowledge of the students, and some candidates have the courage to write against them that they are incomprehensible, others, perhaps more daring still, write "silly."
JUSTUS.

[96693.]—**Colouring White Metal.**—What does for brass will probably do. If so, as a lacquer dissolve dammar 2 parts in oil turpentine 4, add to solution siccative 1 and boiled linseed-oil 2. By adding gamboge, dragon's blood, and Syrian asphaltum, red or brown-yellow to golden tones given; or ruby shellac 10, copaiba 3, siccative linseed-oil 3. Melt together when cold, dissolve mass in 100 to 150 of spirits of wine, according to desired consistence. Or dissolve fused copal 1 in oil turpentine 2 to 3. Black (amber) varnish for metals: melt amber chips in iron vessel, and same quantity by weight of best asphaltum in second vessel; heat both resins till they evolve heavy vapours. Then add to each resin half its quantity of boiling linseed-oil of the resins originally used; stir oil roughly into resins, then combine both fluids. Heat the article first, and apply varnish in hot state in very thin layer. Copal may be used instead of amber, but not so durable. Brown and every shad to black: water 1 pint, nitrate iron 5dr.; water 1 pint, perchloride iron, 5dr. Brown and every shade to red: water 1 pint, nitrate iron 16dr., hyposulphite of soda 16dr.; water 1 pint, hyposulphite of soda 16dr., nitric acid 1dr. Brownish red: water 1 pint, nitrate copper 1dr., oxalic acid 1dr., nitric acid 3dr. Yellow to red: water 1 pint, tersulphide arsenic 30gr., pearlash solution 6dr. Blue: water 1 pint, hyposulphite soda 20dr. Steel grey: water 1 pint, muriate arsenic 1oz. Black: water 1 pint, permuriate iron, 2 pints, muriate arsenic 10oz. REGENT'S PARK.

[96694.]—**Circular Saw.**—"R. T." could buy a small horse-gear, such as farmers use for chaff-cutting, &c., for about £8, and an intermediate gear for increasing the speed, and with pulley for belt for about another £5; or, if very high speed is not required, could drive direct from gear with a rod and universal couplings. But only a small saw could be driven by a donkey, and even horses soon get sick of these contrivances and require continually prodding to keep them at it, so that the proverbially stubborn donkey would probably refuse to go at all in a short time, and then no amount of ill-treatment, however barbarous, would make him (or her). OPTICAL L.

[96696.]—**Cycle Motor.**—I would advise "Fiat Lux" not to attach a motor to his bike; $\frac{1}{10}$H.P. would be useless, it wouldn't drive the machine along the level, even without a rider. A suitable motor and accumulators would be very heavy, and oil-motor bikes are no good except for side-slipping, which they do rather well. GIBSON.

[96697.]—**Lime-Water.**—Take some well and newly-burnt limestone, and pour water over it as long as the stone seems to absorb, and allow it to stand; if not breaking down freely, sprinkle a little more water over it. A small quantity is best done in a vessel, such as an old cask, so that it can be covered with a board or bag. After being slaked, add about 1lb. of it to every 10 gallons of cold water, then stir, and allow to settle. The clear liquor is what is used for dyeing. Lime-water attracts carbonic acid from the air, which tends to weaken solution. Or, take 2oz. of lime, 2 quarts of distilled water. Slake lime with a little of the water, pour on the remainder of water, and stir them together; then immediately cover the vessel, and let it rest four hours. Keep the solution with the undissolved lime in glass-stoppered bottles, and when wanted for use pour off the clear liquor—anti-acid, of course. REGENT'S PARK.

[96699.]—**Purification of Well.**—The "slightly reddish colour" may be due to iron; but there is one thing certain: if there is any reason to suspect the purity of the water it should not be used until certified to be free from contamination. I must have consumed some quarts of water from Aldgate pump, the late pump in Cornhill, near the Royal Exchange, and also from that in Postern-row, Tower-hill; but they have all been condemned, and I should not wonder if the water companies somehow managed to get the water from the well in the Bank of England condemned. That will probably be a tough job; but the charge for water on the Bank would be a nice little sum. The breweries in London use water from wells—deep ones, in the chalk. S. R.

[96700.]—**Shaving.**—Very few put the razor into hot water. My father did so, and I am the youngest of thirteen children, and in my 80th year; but none of his sons ever used hot water for the razor, although we all used hot water to soak the beard.
G. A. H.

[96702.] — **Glue.** — The addition of a little glycerine tends to prevent cracking, making it elastic. REGENT'S PARK.

[96703.]—**Cycle Chain.**—One of the leading cycle papers a few weeks ago advised a correspondent to take off his chain, soak it in paraffin and then boil it in Russian tallow. After letting it cool in the tallow, wipe off the superfluous grease, and it will then run 700 or 800 miles "without further lubrication." I have tried this for some 200 miles with excellent results, as it runs now as smoothly as when first put back. I have also rubbed it occasionally with "grapholine." It keeps beautifully clean in contrast to the nasty mess made by oil in dusty weather.
Oystermouth. SCRIPIO.

[96703.]—**Cycle Chain.**—The noise is probably due to chain or hub gear-wheel, or both, being worn out of pitch. The only remedy is a new chain or gear-wheel, as the case may be.

N. E. E. S.

[96703.]—**Cycle Chain.**—Take chain off, put it in an old pot, cover it with cold water, put a handful of common soda in, and boil hard for about fifteen minutes. Take chain out whilst boiling, and it will dry in a few seconds. (Don't wait until the water gets cold). Then rub all dirt off with dry rag. Now thoroughly clean chain wheels, and put chain on. Next put a good drop of oil on chain, and run it round so as to thoroughly work oil between blocks and rivets. Wipe all oil off outside of chain, so that no oil will get on teeth of chain wheels, and put some good blacklead on, or, better still, some dry lubricant (which is obtainable at any cycle shop), and keep chain well lubricated with it.

Syrl.

[96704.]—**Ivory Polish.** — Putty-powder and water, by rubber made of old hat. Or, set in turner's wheel, take rushes and pumicestone powder and water, and rub till smooth; then heat by turning it over piece of linen or sheepskin, and when hot rub it with a little whiting diluted with olive-oil; then rub with a little dry whiting, and finally with a soft piece of white rag.

Regent's Park.

[96706.]—**Cutting up Slate.**—After getting perfectly level surface on slate, coating of colour of shade required is applied. Slab baked in oven at 130° to 250° Fahr. for 12 to 48 hours according to size. The colours floated on to the surface of a cistern of water over which they float naturally into shapes of streaks of colour seen in marble. The slate with its black ground (tar varnish is used with good effect) burnt in is dipped into surface of water and receives thin coat of colour. It again goes into oven, and when hardened a coating of enamel is applied. Another baking to harden the enamel. The slab is then pumiced to get level surface. Baked again, once more pumiced, and then goes into oven with pumice wet on surface. If necessary this last operation is repeated. Slab ready for polishing. As regards cutting, have you heard of De Winton's patent hydraulic feed circular saw, driven by pulley and belt arrangement for independent travel by hydraulic pressure to table carrying slab to be sawn. Table connected on underside by a bracket and nut to the piston-rod head of hydraulic cylinder, bolted underneath table to framing. Supply pipe leads to both ends of cylinder from valve-box with pressure of 60lb. to square inch, &c., &c. Fast or slow movement, according to thickness or hardness of slate, quick return of table obtained. Small quantity of water to work feed; 3in. main pipe enough for twelve pairs of saws. Feed very steady, and prevents slate being jagged, saw forced, as is sometimes the case with chain or rack feed. See Powis Bale on "Slate and Stone Cutting."

Regent's Park.

[96708.]—**D.Sc. Degree.**—To Mr. Bottone.—Nearly all the Italian universities are absolutely free to students, *id est*, no fee is required for admission to the classes and lectures. But fees are demanded for entrance to the examinations themselves, and no diplomas are granted unless the candidate has thus entered himself and passed the exams.

S. Bottone.

[96709.]—**Hovis Bread.**—1. Quantities: 3½lb. Hovis flour, 1oz. of compressed yeast, such as D.C.L. (dissolved in two tablespoonfuls of warm water), 1 quart water (about as warm as the hand can bear it); use no salt. 2. Method: Take about three parts of the flour and mix it thoroughly with the water, then pour in the yeast and mix again—this time using also the remainder of the flour. 3. Baking: Let it rise 20 to 40 minutes, and bake rather longer than ordinary bread (say 15 to 20 minutes longer). 4. Caution: Do not attempt to knead or mould it in the ordinary way (it will not be firm enough for these operations to be possible); but put it in the tins direct from the mixing.

The Hovis-Bread Flour Co., Ltd.
Hovis Flour Mills, Macclesfield.

[96709.]—**Hovis Bread.**—Take, say, 14lb. Hovis flour, 4oz. compressed distilled yeast, one gallon of water; break down yeast in 4oz. of water. Take temperature of Hovis flour, say 50° Fahr. water must be 130° Fahr., or if it is 70° Fahr. water must be 110° Fahr., the two added always making 180° Fahr. Dough should be 90° to 95° Fahr.; mix 10lb. or two-thirds of meal with the gallon of water till it is a very smooth batter; stir in the dissolved yeast, complete the mixing with remaining 4lb. of flour, weigh off and tin immediately. It will require from 20min. to 40min. proof (according to temperature of bakehouse, &c.) and should be thoroughly well baked, say 10min. or 15min. more than white bread. Use no salt. Dough should be thin and somewhat unpleasantly sticky; no other flour to be used but Hovis flour, not even for dusting, &c., &c. See "Jago" on "Bread-Making."

Regent's Park.

[96713.]—**Test for Arsenic.**—Scrape off the paper as much of the colour as you can. Boil this in a test tube with pure hydrochloric acid. Now divide this into two portions in separate test-tubes. In the first place a strip of clean bright copper, and boil up for a few minutes. If arsenic be present the copper will become covered with a grey metallic deposit. In the second add a few drops of ammonia nitrate of silver. The presence of arsenic will be shown by the production of a yellow precipitate. There is yet another test, which is extremely delicate, but which requires special apparatus and a little dexterity. It consists in placing the acid solution in a well-corked bottle, fitted with a tube drawn out to a fine aperture. A few pieces of pure zinc are then placed in the bottle, which is to be immediately corked. A little of the gas is allowed to escape from the tubes, so as to avoid explosion. The issuing gas is ignited, and a piece of clean white porcelain (such as a broken plate) lowered upon the flame. A *brilliant* metallic stain will be produced on the porcelain if arsenic be present.

S. Bottone.

[96713.]—**Test for Arsenic.**—Heat a piece of glass tube and draw it out to make a jet. Insert the tube through the cork of a medicine-bottle, with the jet outside. Place in bottle a little pure zinc, sulphuric acid, and water. Light the hydrogen gas which is evolved at the jet. Inserting a cool surface, as a china cup, in the flame, will cause a black mirror to be formed on it if arsenic be present in the bottle. If no mirror be formed, place some scraps of paper in the bottle, and notice if then formed. This arsenic mirror is soluble in sodium hypochlorite almost immediately; if not, it is due to antimony.

Clara.

[96713.]—**Test for Arsenic.**—Take fragment of the paper and put it into a solution of ammonia. If arsenic be present the liquid will assume a bluish colour. For further test, pour a little of the ammoniacal solution on crystals of nitrate of silver, and arsenic, if present, will leave a yellow deposit on crystals.

Regent's Park.

[96714.]—**Electrophorus for Wireless Telegraphy.**—Yes; an electrophorus answers perfectly well, with one proviso, and that is that you have some device for producing a "surging wave." The neatest way to do this is to make a small Leyden jar with a ½oz. medicine phial, and fasten this bodily to the shield or cover of the electrophorus, and take the sparks from the knob of this little jar with a brass ball.

S. Bottone.

[96716.]—**Solenoid.**—To Mr. Bottone.—The iron would now carry less than before boring, because the magnetic force is a function of the superficial area of pole-piece. The rod would not travel up the iron cylinder at all, because the said iron cylinder would shield it almost entirely from the magnetic lines set up by the solenoidal wires.

S. Bottone.

[96717.]—**Shaving Cream.**—Veal suet, 60; lard, 20; cocoa-nut oil, 20; potash lye, 36°, 50. Melt grease in kettle or jacket with double bottom heated by steam, kettle of tinned copper, or by means of a steam jacket. Divide alkali into two parts, and dilute one with water to mark 21°, and place it so that it will run gently into melted grease. When grease is about 112° Fahr., turn on the lye, keep stirring, and regulate the temperature below 100°. In about two hours soap will begin to form, and will separate in grains, then add the other portion of lye at 36°, and continue the constant stirring until it becomes too stiff to work, when remove the fire, and beat it, while cooling, into as smooth a mass as possible, when cover the pan or remove it into any suitable wooden vessel. The pearly appearance has to be given by beating in small portions in marble mortar or by running it rapidly through the stone rollers of the mill. To make almond cream, perfume with oil of bitter almonds and a little bergamot. To make rose cream, colour with fine French vermilion of proportion of a drachm to 1lb. of cream, and perfume with oil of roses and rhodium. To make ambrosial, colour with tincture of archil and perfume with tinctures of ambergris and musk, oil of cloves and bergamot. The colours are mixed at the time of milling or rubbing in the mortar.

Regent's Park.

[96718.] — **Bonetti-Wimshurst.** — I do not suppose P. H. Calcis will find any description of such machine, for Mr. Wimshurst at the very early stage showed the sectorless machine at several of the prominent institutions; but, as they are practically not self-exciting, he has never recommended them. The best machine for all purposes should have from 10 to 20 sectors upon each glass. So fitted, the machine is freely self-exciting in any atmosphere.

I. W.

[96719.]—**Gauging Tanks.**—How does this suit? The capacity of a cylinder in imperial gallons = the square of the diameter × the length (all in inches) × ·0028325; for U.S. gallons, × ·0032. Or if the terms are in feet, × 4·9 or 4·89469 for imperial gallons; for U.S. gallons, × 5⅞.

Regent's Park.

[96720.]—**Hotel Problem.**—The two visitors who pay £2 3s. 4d. each per week pay 6d. each less than the weekly average of the whole number. But if any large proportion of the 34 visitors pay three guineas each per week, or anything approaching that sum, it is certain that those who pay no more than the general average of £2 3s. 10d., and necessarily all below it, must fail to yield any profit to the hotel.

A. E. P.

[96721.]—**Launch.** — Your neighbours in the States are very prominent with steam (by spirit) launches. Very well illustrated in C. P. Kunhardt's "Steam Yachts, &c.," published by Forest and Stream Co., New York, 1887. Nothing to prevent making if you have the skill; but otherwise cheaper to buy of firms like Colt Co., at Hartford, Conn.

Regent's Park.

USEFUL AND SCIENTIFIC NOTES.

The popularity of the "penny-in-the-slot" gas-meters is increasing in Sydney, the number in use at present being over 3,000.

Birmingham is about to experiment with the bacteriological treatment of sewage, and the Drainage Board have authorised the expenditure of £1,000 in the construction of experimental beds. Works are now in course of construction at Saltley.

A firm in America is said to be turning out large quantities of paper tiles which are used for roofing. They are reported to be hard and tough, and the glazing appears to be of the nature of Japanese lac. They are said to be exceedingly cheap, and can be fashioned in any colour or shape to suit the purchaser.

Loss Through Smoke.—Someone has calculated that the "smoke nuisance in London" represents a loss of four or five millions of pounds per annum in London alone, and no man can estimate the human suffering it entails by shutting out the invigorating sunshine and by poisoning the air we breathe. The article concludes with a suggestion that the appointment of a Royal Commission to investigate the question should be urged on the Government; but it is not quite clear whether pounds weight or pounds sterling represents the loss, and, of course, there is no suggestion as to a remedy.

At an auction held recently at Torquay one of the lots put up was a very curious clock, made in 1635. Besides chiming on 37 large bells, tuned by semitones, and consequently extending to three octaves, it can be played upon by means of an "organ keyboard." The whole is inclosed in a handsome walnut pedestal case, with dial, over 10ft. high in all. The original cost is said to have been £200, but £73 10s. was the price it fetched under the auctioneer's hammer.

Insect-Trapping Orchids.—"The Story of the Orchids" is a theme on which the Rev. Alexander S. Wilson, M.A., B.Sc., discourses in the September issue of *Knowledge*. "One of the Australian orchids, *Pterostylis longifolia*, has a sensitive labellum which acts as a spring trap. When an insect alights it instantly flaps up, and the unwary visitor is entrapped in the flower. There is only one opening above by which escape is possible, and, as happens in Cypripedium, the stigma and anther are encountered on the way out. An irritable labellum also occurs in species of Megaclinium, Bolbophyllum, Drakea, and others. In the vanilla orchid, the pods of which supply the well-known flavouring, an arrangement of hairs, somewhat resembling the mouse-trap hairs of the birthwort, induces visitors to enter and depart in the manner most favourable to cross-fertilisation."

The Social Instinct in Protoplasts.—Sir Edward Fry still continues to advance curious facts about the mycetozoa in *Knowledge*, and in the current issue he says: "The life-history of all these Acrasieæ presents many very curious points. It seems to bring before us the fact that separate protoplasts, without ever uniting into a plasmodium or ever becoming part of a single organism, may nevertheless acquire as it were the social instinct, and live for the good not of themselves but of the whole organism, and for that purpose may submit to a division of labour; for whilst some of the protoplasts assume the function of only supporting their fellows, the others avail themselves of the support, raise themselves from the level of their original surface, and devote themselves to the function of reproduction. And, moreover, certain aberrant and sessile forms of the *Dictyostelium* seem to show that this elevation of a portion of the protoplasm is not necessary to reproduction, though it may well be that the greater exposure to the ripening influences of the atmosphere and the sun may render it beneficial to the organism, and so more than compensate for the withdrawing from the function of reproduction of a certain part of the protoplasm, and applying it to the purposes of support alone."

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered, are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[96722.]—**The Preservation of Indiarubber.**—I recently had a conversation with a scientific acquaintance on this subject, with special reference to cycle tires. He said that, especially in the case of a machine being laid by for the winter, the best thing is to smother the tires with flowers of sulphur, which he had experimentally proved to be a valuable preservative. This is contrary to all I had previously heard. But my friend's scientific attainments were such that I could not lightly dispute his opinion. Thousands of "ours" must be interested in this question. Will some of our chemical friends give their experience?—CH. ROBINSON.

[96723.]—**Electrical.**—Will Mr. Bottone advise on the following case? I have a dynamo of 45 amps. and 110 volts, compound wound, which at present lights nothing but incandescent lamps. On one section of the circuit I wish to place two or three arc lamps in place of six incandescent lamps. Can I do this with present wiring, which is capable of carrying 12 amps.? And, if so, what lamps would be best to use, and how fixed, so as to retain a few incandescent lamps on the same circuit?—S.

[96724.]—**Oil-Engine Castings.**—To THE BOGEY MAN.—Will you kindly give a few hints on fitting up a set of castings of 1½H.P. oil-engine? If so, please say what is necessary to be done to the castings to complete them, or what would be the probable cost of having them done by a maker?—ROBUR.

[96725.] — **Geometrical Progression.** — Five numbers are in geometrical progression, their sum is 62, and the sum of their squares is 1364.—CANADA.

[96726.]—**Induction Coil.**—Will Mr. Bottone please give me a little information on the above? I have a ⅝in. charcoal iron core, 6in. long, and, when wound, I want to get the longest spark possible. Must I wind the primary directly next the core, and then insulate for secondary? Kindly give sizes of wires, and also thickness of insulation. I have heard something about winding the secondary in sections. Is it advisable, and will Mr. Bottone kindly explain? The size of a suitable condenser and the manner of connecting will much oblige?—LUCIO.

[96727.]—**Elementary Optics.** — If the rays of light from an object, after passing through a lens, proceed in diverging straight lines, why cannot the reversed image of an object, as viewed on the focussing-screen of a camera, be seen with equal distinctness at all distances? Why is it necessary, after adjusting the distance from lens to screen to get the size of picture, to have to make another alteration, frequently quite minute, to get perfect sharpness?—W. A. G.

[96728.]—**Gold.**—W. Howse speaks of the difference between Australian and Californian golds as atomic, and not molecular? What differences are there between golds from different sources?—W. A. G.

[96729.]—**Grindstone.**—What pressure will a grindstone bear without breaking, running at n revolutions per minute, and doing its ordinary work of grinding castings, &c., the tensile strength of the stone being s pounds per square inch?—GRIT.

[96730.]—**Curl in Photo. Films.**—Will any reader kindly tell me how to take the curl out of photo. films, as they always seem to curl up after developing?—CURLY.

[96731.]—**Power of Boiler.**—Can any of our engineering friends say what power can be got from a boiler, size as follows?—12in. diam., length over all 28in., tubes are 19in. long, copper 130 in the boiler, size of tube ⅜in. The boiler is tested 330lb. I propose having a 3 by 5 engine. Would it drive a larger one, speed 600?—MOTOR CAR.

[96732.]—**Paint.**—Could some readers of the "E. M." give an idea how to mix house paint, as I am told the paint bought already mixed has very little white-lead in, and has no lasting power. Is there any book published on this subject?—POOR MAN.

[96733.]—**Gas and Oil-Engines.**—Why is the trunk form of piston always used in gas and oil-engines? Why cannot a double-action cylinder, as used in steam-engines be employed so as to obtain an impulse every revolution, instead of every alternate one?—J. E. L.

[96734.]—**Nerve in Tooth.**—Can any reader say what the dentists use for killing the nerve in a tooth previous to stopping it? I refer to a brown, rather bitter, substance. Is any patent preparation recommended?—NEW CENTURY.

[96735.]—**White Paint.**—Will some reader give me good recipe for white paint? I have whitelead, turpentine, and dryers, and wish to paint my glasshouses inside and out.—ANXIOUS.

[96736.]—**Crystoleum Painting.**—Would a reader kindly tell me what the three mediums used in crystoleum painting are composed of, and exact proportions, so that I can make? One of them is adhesia, another is called a preservative, and the other is clearine.—F. E. A.

[96737.]—**Chemical Balances.**—Can any reader tell me how to make a pair of chemical balances? Or would any of your readers possessed of such give me a rough drawing, showing dimensions and details of knife-edges and other important parts? A drawing of one half only would be necessary, as the other is an exact duplicate.—G. E. O.

[96738.] — **Gas - Heating Soldering - Iron.**— Wanted, the best and simplest design of fitting up the above, connected by rubber tubing and portable?—BUNSON.

[96739.]—**Electrical Contrivance for Deaf Person.**—Will Mr. Bottone or some other reader kindly give me some hints about an electrical contrivance which will enable a partially deaf person to hear a minister preach from the pulpit?—IMPROVER.

[96740.]—**Efficiency of Small Gas-Engines.**—Can any reader tell me whether small gas-engines of 3in. bore and smaller have the efficiency of larger ones? Kindly give figures.—IMPROVER.

[96741.]—**Heating Room by Electricity.**—I should be glad to know how to heat a room by electricity. What is the most economical way? Whose method would you propose to adopt, supposing I have all the necessary arrangements for making electricity?—JOHN BOWDEN.

[96742.]—**Bore of Cylinder.**—Could you tell me what bore I should want for a double cylinder to give 2H.P., as I am making a motor-car? Also, how to find horse-power of a gas-engine, and whether the horse-power of an oil-engine is found in the same way?—F. MAUBY.

[96743.]—**Wimshurst.**—Will Mr. Bottone tell me if it would be of any advantage or otherwise in making a Wimshurst to have the sectors on both sides of the plates, and have them connected with a fine wire through a hole drilled through the plate?—NOVICE.

[96744.]—**Celluloid.**—I should be extremely obliged for information with regard to the repairing of celluloid articles, if it is possible to mend them, and how?—E. C.

[96745.]—**Flagstaff Problem.** — A person at a distance A from a tower which stands on a horizontal plane observes that the angle of elevation A of its highest point is the complement of that of a flagstaff on the top of it. Show that the length of the flagstaff is 2A . cot 2A? If the distance of the person from the tower is unknown, and if, when he recedes a distance c, the angle of elevation of the tower is half of what it was before, show that the length of the flagstaff is c cosec. a cos. 2 a?—PUZZLED.

[96746.]—**Grammaphone.**—As my grammaphone has not been as distinct as usual, I examined the diaphragm and found that part of the glue which attaches the point-holder to the diaphragm has fallen away. Please say if that is the cause of lack of precision. I would like to know what kind of glue is used. Is the diaphragm mica or celluloid, and is Berliner a German or American? How can an amateur take records? I have made records of my own voice in the graphophone, but find the high notes very bad and shrill, as if the trumpet of the receiver vibrated sympathetically with certain high notes; but the graphophone records are wax, while the grammaphone records are ebonite, and must have been taken when soft, and, therefore, warm, or could a soft surface be made by soaking in acetone of bisulphide of carbon for a short time?—IKOS.

[96747.]—**Retouching Negatives.**—Which is the best instrument for scraping negatives, so as to reduce the density of small portions. Some hints on the best manner of using it will also oblige.—MINYAM.

[96748.]—**Boilers for Motor-Cars.**—In connection with letter 42793, on p. 90, Sept. 8: (1) What H.P. will this boiler give? (2) Please give me dimensions of one big enough for a ¾H.P. engine at 45lb. steam pressure? (3) What ought the section of the boiler to be? I mean a ¾H.P. engine, not 3-4 cyl.—ALLEN ROBERT CRANE.

[96749.]—**Electro - Magnets in Series.**—I have two electro-magnets wound as nearly alike as possible in series. One draws its armature up with a bang, the other scarcely moves. Why is this, and what is the remedy? I use with them two largest size Leclanché cells.—SUBSCRIBER SINCE 1866.

[96750.]—**Spring Tides.** — The moon being full at x o'clock, how soon after will the highest tide take place? How much time will elapse from x to (1) commencement of the flow; (2) high water; (3) cessation of the ebb? What direction of wind would reinforce the tide the more? Position, lat. 53° 5′ N.; long. 4° 23′ W. Any information as to the *modus operandi* of arriving at the answer will greatly oblige.—DAFYDD JONES.

[96751.]—**Diving.**—Will any reader please inform me to what distance a diver is able to see clearly under the surface of the sea, and whether the use of a powerful electric light would increase the distance?—ENQUIRER.

[96752.]—**Motor-Carriage.**—I am making up two separate 1¾ cycle motors, instead of fitting these to two cycles. My intention is to fit both motors to one small four-wheeled carriage to carry two. Could any of our readers tell me if the two engines should be made up on one crankshaft, and should the cranks be set at right angles, or opposite, for self-starting? Shall I require two separate ignition batteries and two carburettors to supply the two cylinders, or could this be done with one? Shall I need an extra flywheel in addition to the four usual motor discs? What kind of gear should I adopt; tooth-wheels the same as in the cycle, or what arrangement would be best? The writer would be grateful for an illustration of the underneath of a two-cylinder motor-carriage, or any information as to construction thereof.—G. A. H.

[96753.]—**Acceleration.**—A train starting out of a station is made to move with a uniform acceleration of 25 kilomètres per hour. What is its velocity in kilometres per hour after it has gone a distance of 18 kilomètres?—H. H. W. P.

[96754.]—**Problem.**—A winner of a prize has a certain sum to spend on books. The unbound books are of equal value, and binding costs 6s. per volume. If he gets none of them bound, he will be able to purchase ten more volumes than if all were bound, but only four more if half of them be bound. What is the value of the prize, and how many books could he procure on each supposition?—H. H. W. P.

[96755.]—**Lamp for Firing Tube-Motor.**—To "MONTY."—Will you kindly further explain? Is the burner to be fixed vertically or horizontally? What is the use of the loose pan? How is the oil vaporised, as I do not see a coil of tube for it to pass through? Is the nipple screwed over the central pin?—INVESTIGATOR.

[96756.]—**Ornamental Blocks.**—I am preparing ornamental blocks by pasting together several pieces of tissue-paper covered with a piece of silk cloth, and by pressing the same under an engraved metal plate for embossing the design on the cloth. The silk cloth, becoming wet with the paste, loses its lustre. Will any reader please inform me of a suitable colour or composition, which, when applied to the embossed surface, will regain the lustre?—ENQUIRER.

[96757.]—**French Polishing.**—Will any reader kindly inform me of the maker of a powder used in the finishing-off in French polishing, to do away, as I understand, with the usual process of spiriting off? I have on several occasions heard of the fine finish and the lasting properties of this powder, and should like to test its merits. I should be glad of any information from an experienced polisher who has tried it.—RUBBER.

[96758.]—**Sharpening Files.**—I find the following method given to sharpen-up worn files; but I am told by an expert that the only economical process is to use the sand-blast. These are the directions, and they do seem rather funny:—"First clean the file thoroughly from all dirt that may be clinging to it, then dip it into a mixture of one part nitric acid, three parts sulphuric acid, and seven parts water. How long you are to keep it in this strong mixture must be regulated according to the extent the file has been worn and the finings (?) of the teeth; the time may vary from five seconds to five minutes. When you take it out wash it in water; next dip it in milk of lime, wash the lime away, and dry it; and, when dry, rub it over with a mixture of equal parts olive oil and turpentine, and, lastly, brush it over with powdered coke." I think the usual file-card and a few seconds under the sand-blast would prove more effectual. What do experienced readers say?—E. F. P.

[96759.]—**Bikes and Prams.**—I see by an account in the papers that some "judgment" has been given that bikes must not be wheeled on the footpath or sidewalks; but perambulators may. Can anyone tell me where to find the law on the subject?—ROTA.

[96760.]—**Model Loco.**—Will someone kindly give me the following dimensions below for a ⅛-scale model four-coupled bogie loco. (express)? Loco.: (1) Sizes of wheels, (2) sizes of cylinders, (3) sizes of boiler barrel and tubes, (4) size of outside firebox, (5) size of inside firebox, (6) lengths of side frames and thickness, (7) rail gauge. I have three companies' engines to choose from (1) 4-c. 73, Caledonian No. 721; (2) 4-c. 73, N.B.R. No. 729; (3) 4-c. 73, L. and S.W.R. No. 593. Which do you think would make the finest model for working?—J. BAIRD.

[96761.]—**Ginger-Beer Plant.**—Can any reader tell me what is really the scientific name of the "ginger-beer plant," or is it different from the vinegar plant? Does it make ginger-beer without putting ginger into the sugar? Is it anything more than Saccharomyces Mycoderma? The "books" seem to copy from one another, and in a well-known work I find it stated that "the ginger-beer plant is in reality a heterogeneous mixture of various Torulæ and bacteria, some of which appear to occur together constantly in nature." Where can I find definite information, or is it a Mrs. Harris?—ZINGIB.

[96762.]—**Dry Cell.**—Will some reader say if they have tried a dry cell named "Electrogene Dry Cell," stated to give 2·8 volts, to work in the greatest heat and under freezing point? This, if true, should be good news. Comes from Berlin, I think.—DRY CELL.

[96763.]—**Salicin.**—What is the chemical composition of salicin, and what changes does it undergo in passing through the body?—RANDAL.

[96764.]—**Charging Accumulators.**—I am using small electric lamps with my 5in. telescope, and should be much obliged if Mr. Avery would advise me how to re-charge the accumulators? Should not mind buying a dynamo if that would enable me to manage it.—E. WELDON, Tunbridge Wells.

[96765.]—**Bagatelle.**—(1) What is the limit (distance) from the bottom of the board where the balls may be placed for striking? (2) In finishing a game, if a player gets, say, three more than he requires, what is to be done?—BAGATELLE.

[96766.]—**New Lawson Biunial Saturator.**—Will someone who has used the new Lawson biunial saturator say if it is a success, and if one can dissolve quite easily with it, and if the lime that is supposed to be turned off goes quite dead, or at least red?—OPTICAL L.

[96767.]—**Wireless Telegraphy.**—To MR. BOTTONE.—I wish to connect up two houses a mile and a half apart with wireless telegraphy, and should be glad to know if it can be done with two Wimshurst machines with 18in. plates and Leyden jars, and also if the coherer and relay as recommended by you, the coherer consisting of 1½in. length of ⅛in. triblet tubing filled with nickel filings? The transmitter consists of three brass balls (2¼in. and 1·2in. in the centre). I should be glad to know what length of spark is necessary between each of the balls, and also how many dry batteries are needed for the relay circuit? I have a ⅛in. copper wire at one end, and a ³⁄₁₆in. at the other, 40ft. high. Are these sufficient?—A. L. M.

[96768.]—**Ironmould in Copper.**—Would anyone kindly tell me if anything can be done to my cast-iron washing copper? It ironmoulds the clothes when boiling them. Could it be coated with anything to make a permanent job of it?—A NEW SUBSCRIBER.

[96769.]—**Search-Light.**—Would some reader kindly give sketch, with dimensions, of an electric lamp for search-light to take about 20 or 25 amps. at 50 volts, or more if required? I have an 18in. concave reflector fitted into an 18in. by 24in. light steel tube. What I want is the simplest mechanism for lamp, as I will make it myself. I mean it to be hand-fed?—D. S. G.

[96770.]—**Flow of Water from Cistern.**—I would like the opinion of some fellow correspondent on the following subject:—A cistern of, say, 5ft. by 4ft., and 3ft. deep, full of water, is emptied through a hole in the bottom of the cistern; depth of discharge hole equals thickness of tank bottom. If a pipe, say, 10ft. long, of equal sectional area, be fixed to hole underneath, the tank would be emptied sooner. How does this come about?—NIMROD.

[96771.]—**Wall-Papering.**—I want to paper a wooden partition, and shall be thankful for any hints as to the best method of doing so. There are chinks in places between the boards, and I fear the paper will tear at those places. Will it improve matters if I paste strips of calico or canvas over the chinks?—PAPER.

[96772.]—**Probability.**—If I toss up a coin nine times in succession, the chances are 511 to 1 against their all being heads. Now, if I throw 512 groups of nine tosses each, what is the probability (1) that at least one group will be all heads, and (2) that only one group should be so? Of course, it is nearly certainty, but I should like to know the exact mathematical value of it. Concisely, if the probability of any event is $\frac{1}{n}$, what are the values of (1) and (2) in n trials, *mutatis mutandis*?—SCORPIO, Oystermouth.

[96773.]—**Saturn's Ninth Satellite.**—Would "F.R.A.S.," or some other astronomical authority, give me some information about this object? I recently saw it stated in a scientific magazine that the discoverer, Prof. W. H. Pickering, proposed the name of "Phœbe" for the new satellite. In conversation with a well-known observer a few days ago, however, I learnt that the discovery was regarded in certain quarters as a "mare's-nest." I have heard that some people "count their chickens before they are hatched," and that others name their babies before they are born. But surely astronomers cannot be charged with naming orbs which they have never discovered! At any rate, I would thank "F.R.A.S." if he could give me any news concerning the supposed new satellite, its period of revolution, and distance from Saturn, if the existence of the object is corroborated.—H. HINDAWSWEB.

[96774.]—**Isle of Man Steamers.**—Will any kind reader mention the speed, size, and description of engines, pressure, and passenger capacity of the *Mona's Queen*, *Tyndwald*, and *Peveril*, as I had trips in same little while back, and noticed such a comparison in style, &c.?—ALEXANDER.

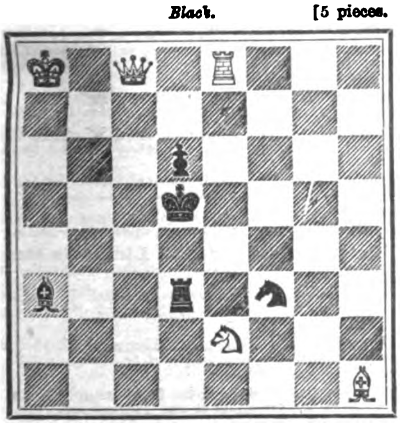
[96775.]—**Boiler for Marine Engine.**—Kindly recommend a suitable tubular boiler for model steamboat I have, which is 52in. by 6½in. by 7in. The engines are slide-valve, 1¼in. by ¾in. double. I want one that can be used other than charcoal fire. I have heard of lamp using benzoline or naphtha for fast generating steam at 40lb. If so, please give a sketch of one suitable that forms its own gas, and gives a very fierce heat.—ALEXANDER.

CHESS.

All communications for this column to be addressed to THE CHESS EDITOR, at the Office, 332, Strand.

PROBLEM No. 1694.—By F. M. TEED.

Black. [5 pieces.



White. [5 pieces.

White to play and mate in two moves.

(*Solutions should reach us not later than Oct. 9.*)

Solution of PROBLEM No. 1692.—By H. CUDMORE.

Key-move, B-R 3.

NOTICES TO CORRESPONDENTS.

PROBLEM No. 1692.—Correct solution has been received from Geo. Christie, F. B. L. (Devonport), E. C. Weatherley, Quizco, A. Tupman, Rev. Dr. Quilter, Whin Hurst, Richard Inwards, Hampstead Heathen, J. E. Gore, G. W. Underhill, T. Clarke, F. B. Oldham, E. Loebell, Jun.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries, put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Sept. 27, and unacknowledged elsewhere:—

L. B., E. M.—F. M.—E. L. Garbett.—B.Sc., Ipswich.—Loco.—H. O.—G. Barton.—A Fellow of the Royal Astronomical Society.—An Old Subscriber.—Wind-Gauge.

B. A., Oxon.—Your introduction of personalities, and of the correspondent's *name*, is quite unwarranted, and we cannot therefore insert. Any criticism of his arguments would be admissible.

ADVICE.—Better patent it, we suppose. The first stage—obtaining provisional protection—costs little. All information and forms can be had at the Government Patent Office.

INVISIBLE.—A very old device. The body is simply concealed, and the head is seen. The performer can, of course, speak. There are several devices of the kind, and similar illusions described in back volumes.

R. W. A.—An electric motor is generally used. There is an illustrated description of a speed governor for the phonograph in No. 1457, Feb. 24, 1893.

H. K.—Any good "black" ink will do, and the sketches should generally be twice the size they are intended to be when printed in the magazine or newspaper. That is, they should be so "scaled" as to enable the block to be one-half size, and suitable for the width of the column or page in which it is to appear.

LEE.—On p. 363, Dec. 9, 1892, you will find a list giving the "Pronunciation of Some Astronomical Terms," and in following numbers some comments. The best way to learn is to join the British Astronomical Association, and take notes on the pronunciation generally adopted by the readers of papers. See the index to Vol. LVI.

H. G. COOMB.—We quite agree with you; but with the terrible flood of letters in upon us about the Deluge, pardon us if we shrink from another about the Tower of Babel. The dull season is drawing to a close, and so are the innings of "E. L. G." and his friends!

MAJOR BADEN POWELL.—Sorry, but we cannot depart from the usual rule. See "Hints to Correspondents" No. 6 above.

JAMES BROXUP.—We do not know the address.

H. C.—Simply a matter of will. Learn to control your "feelings," and you will not blush.

J. MUIRHEAD.—There are plenty of notes on the construction of hydraulic rams in back volumes, but apparently you want working drawings. You can see the volumes in any of the free libraries in your city, and with the aid of the illustrations therein given can work out the necessary drawings.

A. MORGAN.—See many notes in back volumes. A fair consumption for a decent gas-burner is five cubic feet per hour; but they are of various sizes, and something depends on the quality of the gas. The mantle, so to speak, conserves the lighting power, and becoming incandescent, increases the illumination. The given burner passes the same amount of gas.

M. L. ROUSE.—You would take us too far. This is not the paper in which to discuss the advisability of new translations, &c. When we discuss the Deluge, or any other event recorded in sacred or profane history, we desire to do so—in these columns—purely as ordinary natural phenomena, and without any reference to religious opinion. Mr. Garbett nearly always get us out of our depth at once, and we fear we are much to blame very often for allowing him to do it; but we have our weaknesses, like other people. Just now we have enough of the Deluge, and so we think have most of our readers.

VER-VIR.—Of any wholesale homœopathic chemist. We cannot give addresses. See Post-Office Directory.

FREETHINKER.—In preparation; the author has been ill, but promises the article soon. 2. Very likely! Between your "surprise" at our encouraging what you call "religious nonsense" and the remonstrances of readers on the other side who insist we are "encouraging infidelity," we get a lively time of it! At the present moment we feel rather sorry that Noah's Ark *did* escape the Flood!

IN connection with the export of anthracite coal from Philadelphia, it is stated that a representative of this industry is visiting European countries, including Britain, with a view to opening up the trade.

IN countries where sand is plentiful it is used instead of hay or straw as beds for cows. It keeps the animals perfectly clean.

NOTICE TO SUBSCRIBERS.

Home Subscribers receiving their copies direct from the Office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary if it is desired to continue their subscription.

Foreign Subscribers will have the Pink Wrapper sent ONE MONTH before expiration, in order to give them time to forward fresh remittance before subscription expires.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, post free to any part of the United Kingdom. For the United States, 13s., or 3dol. 25c. gold; to France or Belgium, 13s. or 16f. 50c.; to India, New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-Office Order. Back numbers can also be sent out by the ordinary newspaper post at the rate of 3d. each.

Vols. XXIV., XXX., XXXII., XXXVI., XXXIX., XL., XLII., XLIII., XLIV., XLV., XLVI., XLVIII., L., LI., LII., LIII., LIV., LV., LVI., LVII., LVIII., LIX., LX., LXI., LXII., LXIII., LXIV., LXV., LXVI., LXVII., and LXVIII., bound in cloth, 7s. each. Post free, 7s. 7d.

Indexes to Vol. LI., and to subsequent Vols., except Vols. LIII., LV., LVI., LVII., LIX., LXI., 3d. each, or post free 3½d. Cases for binding 1s. 6d. each.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each post free from the office (except index numbers, which are 3d. each, or post free 3½d.)

ADVERTISEMENT CHARGES.

The Charge for Advertisements in the Columns headed:—

For Exchange.
For Sale.
Wanted.
Addresses.
Situations.

is Sixpence for the first Sixteen Words, and Sixpence for every succeeding Eight or part of Eight, which must be prepaid. *No* reduction on repeated insertions. Advertisers should state under which heading they wish their announcements to appear.

The address is included as part of the Advertisement and charged for. No displayed Advertisements can appear in above columns. Rates for Displayed Advertisements are as follows:—

For advertisements on inside pages, except page facing leader, for less than a quarter-page; per inch single column—

1	6	13	26	52 insertions.
7s. 0d.	6s. 6d.	6s. 0d.	5s. 6d.	5s. 0d. each.

Per Column.—

1	6	13	26	52 insertions.
£3 0s.	£2 15s.	£2 10s.	£2 5s.	£2 0s. each.

	1	6	13	26	52 insertions.
	£ s.	£ s.	£ s.	£ s.	£ s.
Per Page	8 8	7 0	6 0	5 5	5 0 each.
Half-page	4 10	3 15	3 10	3 0	2 10 "
Quarter-page	2 10	2 5	2 0	1 15	1 10 "

Back Page, £10 10s. A few dates open during 1899.

ORDINARY ADVERTISEMENTS.

	£ s.
Thirty Words	2 6
Every Additional Eight Words	0 6

Front Page, Five Shillings for the first 40 words, afterwards 9d. per line. Displayed Advertisements, 10s. 6d. per inch. Paragraph Advertisements, One Shilling per line. No Front Page or Paragraph Advertisement inserted for less than Five Shillings.

All Advertisements must be prepaid, and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.'s.

Advertisements *must* reach the Office by 1 p.m. on Wednesday to insure insertion in the following Friday's number.

For the convenience of advertisers, replies to advertisements (except those in the Exchange and Sale Columns) may be addressed to "———," care of the ENGLISH MECHANIC Office, and will be forwarded by post to the advertiser, for an extra fee of Sixpence per insertion over and above the cost of the advertisement.

All Cheques and Post-Office Orders to be made payable to THE STRAND NEWSPAPER COMPANY, LIMITED, and all communications respecting Advertisements should be distinctly addressed to:—

THE PUBLISHER,
THE "ENGLISH MECHANIC,"
332, STRAND, LONDON, W.C.

This is necessary, as there are several papers published at the same address, and unless letters are fully directed, it is impossible to tell for which paper they are intended.

For Exchange.

The charge for Advertisements in this column is 6d. for the first 16 words, and 6d. every succeeding Eight, which must be prepaid.

SPECIAL NOTICE. — *Correspondents are strongly recommended not to send money or goods to strangers. The safest way when dealing with unknown advertisers is to send a Post Office Order made payable —— days after date, when in case of non-arrival of goods, or dissatisfaction, payment can be stopped.*

Exchange 3H.P. **Engine**, with boiler, belt, two saws, and spindle for Motor or Motor Cycle.—MILLINER, Tatsfield, Surrey.

Exchange and Cash. **Hand Camera**, Rapid Rectilinear lens, stops, magnifier, for 12½ plates, for ½ or ¼-horse Boiler.—USMAR, St. Rhadagunds, East Sheen, S.W.

Astronomical Telescope, Newtonian, 8¾ glass speculum, equatorial mount, divided, slow motion, copper tube, brass mountings.—Below.

Telescope, with 2in. star finder, weight about 6 cwt., price £25, half exchange.—STEPHENS, "Dunedin," Penmartin road, Brockley.

For Sale.

The charge for Advertisements in this column is 6d. for the first 16 words, and 6d. every succeeding Eight, which must be prepaid.

New Illustrated Price List of **Screws, Bolts**, and **Nuts** for model work, drawn to actual size, sent on receipt of stamp.—MORRIS COHEN, 132, Kirkgate, Leeds.

Watch and Clock Tools and Materials. Catalogue, over 1,000 Illustrations, post free, 6d.—MORRIS COHEN, 132, Kirkgate, Leeds.

Wheel-cutting and Dividing in Brass or Iron to 12in. diameter.—CLEGG, Belinda-street, Hunslet, Leeds.

Lathes and Machined Parts, Wheels, Chucks, Fans, Angle-plates. Illustrated list, 2d.—JARRATT, Queen-street, Leicester.

Carving. — Brass, Iron, Burnt Wood, Bamboo, Leather, Fretwork, and Picture Framing. Catalogue free.—HARGERS, Settle, Yorks.

Inventions Protected, £2 inclusive. Designs registered, 30s.—BROMHEAD and Co., Registered Patent Agents, 33, Cannon-street, London. Established 26 years. Send for list.

Sidereal Time Indicator, invaluable to all users of equatorials, with complete directions, 21s. post free.—Below.

Astro-Photographic Apparatus, does really good work, 15s. post free.—HORNE and THORNTHWAITE, 416, Strand, London.

Books.—All out-of-print books speedily procured, any subject. State wants.—BAKER'S GREAT BOOKSHOP, Birmingham.

50,000 Choicest Microscopical Objects.—Bargains. Catalogues free. Microscopes, cabinets. Collections purchased.—SUTER, 10, Highweek-road, Tottenham.

Rubber Outer Covers, 3s. 6d. Prepared Canvas, 90 by 9, 1s. 3d.; rubber solution, best quality, 1lb. tins, 1s. 6d.—PEMBERTON.

Air Tubes, all sizes, best quality, 2s. 9d. each. Air tubes with Dunlop valves fixed, 3s. 9d.—PEMBERTON.

Cushion Tires, 3s., 4s., 5s. Solid Tires, 3s. All sizes stocked.—PEMBERTON.

Detachable Outer Covers (Licensed), 12s. 6d. each; all cycle accessories and cycle rubber goods stocked.—PEMBERTON and Co., 1, Cardwell-place, Blackburn.

Acetylene. — Send for particulars of the patent "Incanto" Generators, Purifiers, Burners, Carbide, &c.—THORN and HODDLE, 1, Tothill-street, Westminster. Works, Harris-street, Camberwell.

Inventions Protected and Sold. Inventors assisted. Advice free.—ELY and Co., 43 Southampton-buildings, Holborn, London.

Nuts and Bolts for Model Work. Illustrated List, 2,600 varieties, 3d.—BUTLER BROS., Haggerston, London.

Screws, Screw-plates, Taps, round and hexagon special steel brass and iron rods. See list.—BUTLER.

Have You Sent Yet

For Our "Twenty-five Best Books"?

They are Good Value for the Money.

They are Now Ready, and we shall Not REPRINT.

Fifty Shillingsworth of Books and a Half-guinea Bookcase for 30s.

For Full Particulars see Illustrated Advertisement on another page.

Best Assortment of High-class Popular Literature ever obtained at the price.

A Splendid Present to a Friend, or a Village Club, or Working Men's Institute.

Guaranteed to give Satisfaction. Well printed, well selected, well bound. Price, all complete, only 30s.

Send Cheque or P.O.O. for 30s. at once to the Publisher of the ENGLISH MECHANIC, 332, Strand, W.C.

Delivered in London Free. Country orders sent carefully packed, by rail, carriage forward. Please write address plainly.

Send at Once to Save Disappointment. Price for the set complete, in oak bookcase, 30s. Obtainable only at the Office of the ENGLISH MECHANIC, 332, Strand, W.C.

Simplex Typewriter, 14s. 6d., delivered. Thousands in use. Illustrated particulars free.—ATKINSON and Co., Harehills-avenue, Leeds.

Automatic Machines of every kind, including Musical Polyphons, new game machines, and novelties for public bars and restaurants. Also money-making machines for seaside resorts. Illustrated catalogue free.—Address INTERCHANGEABLE AUTOMATIC MACHINE Co., Ltd., 327, Upper-street, London, N.

Stereoscopic Views, 1s. doz., list 4,000. Sample 1d. stamp.—PUMPHREY, Stanhope-street, Birmingham.

Brass and Gunmetal Castings of finest quality. Prices on application.—DANIEL YOUNG, Witney, Oxfordshire.

Foreign Hardwoods for Amateur Turning and Fretwork.—DANIEL, 242, Bethnal Green-road, London. List one stamp.

Wheel-Cutting.—Spur, bevel, mitre, or spiral gear, in all metals, to any pitch.—MOTOGRAR, below.

Differential and Spur Gearing as illustrated in "E. M." Motor tricycles. Special prices.—MOTOGRAR, below.

Accurate Screwcutting and Fine Turning a speciality.—THE MOTOGRAR ENGINEERING Co., 78, Queen Victoria street, E.C.

"Gem" Gas-Engines.—Still simplest and best for small powers.—MOTOGRAR Co., below.

"Gem" Gas-Engine Castings. — Easiest to make up.—MOTOGRAR ENGINEERING Co., 78, Queen Victoria-street, London.

"Gem" Oil-Engines.—New designs for launches and vehicles, &c.—MOTOGRAR Co., above.

Booker Brothers' Engines and Motors, oil or gas, ½H.P. upwards, also castings.—Tyrrell-road, East Dulwich.

Bargain.—Magnificent **Model Vertical Engine**, tubular boiler, glass gauge, whistle, double action, slide-valve cylinder, bronzed stand, exhibition model, silver-plated, high-speed, and perfect. Worth 42s., accept 12s. 6d. free. Photograph 1d.—MANAGER, Marshgate Chemical Works, Stratford.

Bench Lathe, 12s. 6d. Photo. and List 6d. Lathe Catalogue, 6d.—STIFFIN, South Hackney, London.

Foot Lathe, 25s. Photo. and List, 6d. Lathe Catalogue, 6d.—STIFFIN, South Hackney, London.

F. C. Allsop, Manufacturing Electrician, 126, Queen Victoria-street, London. The leading house for all electrical goods.

F. C. Allsop's Electric Bell Catalogue (Section B), post free 6d. Electric bells, indicators, pushes, batteries.

F. C. Allsop's Electric Light Catalogue (Section L), post free 6d. Cables, switches, accumulators, dynamos, motors, &c.

F. C. Allsop's Telephone Catalogue (Section T), post free 6d. Hunnings microphones, receivers, magneto switch bells, &c.

F. C. Allsop's Induction Coil Catalogue (Section M), post free 6d. Spark coils, medical coils, X-ray apparatus.

F. C. Allsop's Electrical Handbooks, over 80,000 copies sold. "Practical Electric Bell Fitting" (7th edition), post free 3s. 6d.

F. C. Allsop's Electrical Handbooks. "Practical Electric Light Fitting," 5s. "Telephones: Construction and Fitting," 3s. 6d. "Induction Coils," 3s. 6d.

Motor Tricycle Fittings. — Axles, Brackets, Heads. Latest French-pattern Axles. Castings or finished. Illustrated list free.—H. F. HARDING, 303, Brixton-road, London.

"Simplex" Gas and Oil-Engines, new series, "Otto" principle, ¼B.H.P. to 2B.H.P., from £9. Guaranteed.—Below.

"Demon" Gas-Engines, awarded prize medal, ⅛B.H.P. to 12B.H.P., low price, high efficiency, economical. Guaranteed.—Below.

"Demon" Gas and Oil-Engines are thoroughly reliable. First-class workmanship.—PASLEY and Co., Sherborne, Dorset.

Model Boiler, 13in tubular, nearly new, tested 50lb., brass mountings, 17s.—51, Winchester-road, Romsey.

Acetylene Cycle Lamps, exceptional value, from 5s. 6d. Illustrated list, 1d.—WRIGHT, 318, Upper-street, London, N.

Sparking Plugs, 5s.; Insulated Wire, 7s. per set; coils, dry batteries, switch handles, carburettors, pinions.—Below.

Motor Tricycle, 1¾H.P., £50. 3H.P. Coventry Motette, £50; all in good order.—Below.

Illustrated Catalogue sent on receipt of stamped (1d.) wrapper.—SOUTHERN MOTOR Co., 59, Brixton-road, S.W.

Watches, Clocks, Jewelry, Musical Boxes, Novelties. Dealers supplied at rockbottom trade prices for cash. Cheapest house in England. Lists on application. Gentleman's crystal face keyless nickel silver, 2s. 9d.; not less than three will be sent.—WOOLARDOE and Co., 90, 91, Queen-street, London, E.C. Agents wanted. Mention paper.

Royal Lifeboat Procession, Hammersmith. Electric lighting en route by "Seal" Oil-Engine.

"How I First Saw Saturn" (telescope making, paper mounts), illustrated, 7d.—WALTER BELL, Architect, Cambridge.

A MOST WORTHY EXAMPLE.

Although I attended church regularly I had not heard a word the Pastor said for many years, was totally deaf in the right ear for 30 years—the result of typhoid fever—and the left was so bad I could not hear my husband's voice if he shouted in my ears. It is simply wonderful the good Aerial Medication has done for me, can now hear ordinary conversation and a sermon nicely, the constant cough, expectoration and shortness of breath have left me entirely, am quite cured of hoarseness and sore throat, my chest is a treat now, can breathe freely, and my general health is greatly improved.—Mrs. BOULTER, School House, Whalton, Newcastle-on-Tyne.

FREE.

To prove beyond doubt that Aerial Medication is a positive cure for deafness, catarrh, throat and lung diseases, I will, for a short time, send medicines for three months' treatment, free. For symptom form and particulars, address J. H. MOORE, M.D. (U.S.A.), Dept. T 5, Bloomsbury, London, W.C.

New Engine Castings, ¼-horse, 5s. 6d.; half-horse, 11s. per set. Catalogue two stamps.—TOMLIN, Ironfounder, Oldham.

Economical Manufacture! This cannot be attained with common low-priced tools.—BRITANNIA Co.

We are Bona-fide Makers of over 300 varieties of Lathes, Planers, Shapers, Slotters, Drilling Machines.

Special Tools and Machinery Designed or made to drawing. Makers to the British Government.

Call 100, Houndsditch, London. All letters—BRITANNIA Co., Colchester, England.

Heavy Tools up to 20 tons are now made by our heavy tool department.

Machinery Dealers throughout the world should apply for present terms.—BRITANNIA Co.

5in. Back-gear **Screw-cutting Amateur Lathe**, not used, by Mitchell. Offers.—45, Mander-street, Wolverhampton.

Loco. Slide Valve, ¾ by 1¼, 15in. long, 30s. Also Horizontal Engine, 1 by 2in. stroke, with boiler, nickel-plated, 25s.—USMAR, St. Rhadagunds, East Sheen, S.W.

Cinematograph Films. Second-hand, good condition, best pictures, List free.—8, Liverpool-street, King's Cross, London.

Rubber Outer Covers, average 16oz., Para rubber 6s. each.—FRANKLANDS.

Rubber Outer Covers, 3s. 6d. each, 36s. per dozen.—FRANKLANDS.

Cushion Tires, 3s., 4s., 5s. Solid Tires, 2s. 6d., 3s. All sizes stocked.—FRANKLANDS.

Air Tubes, best quality rubber, 2s. 9d. each. Fitted with Dunlop valve, 3s. 9d.—FRANKLANDS.

Air Tube, Para rubber. Marvellous value. Large stock to clear. Perfectly air-tight., 2s. each.; 21s. per dozen.—FRANKLANDS.

Cycle Capes, 3s. 6d., 4s. 6d., 5s. 6d. Also a few cycle Capes, guaranteed waterproof, 2s. 6d. each.—FRANKLANDS.

Detachable Outer Covers, licensed, 12s. 6d. each.—FRANKLANDS.

Saddles.—A clearing line in ladies' and gents' saddles, 3s. 6d. each, 24s. per dozen.—FRANKLANDS.

Inflators, 18in., 1s. 6d. each, 15s. dozen.—FRANKLANDS.

Bells.—Special line, double gong, usual price, 12s. dozen, will clear 5s. per dozen.—FRANKLANDS.

Prepared Canvas, 90 by 9, 1s. 3d. each, 12s. per dozen.—FRANKLANDS.

Pedal Rubbers, 6d. per set of four, 4s. 6d. per dozen sets; no rubbish.—FRANKLANDS.

Spanners, nickel, usual price, 13s. per dozen. Will clear a few dozen at 7s. 6d. per dozen.—FRANKLANDS.

Cycle Accessories and Cycle Rubber Goods. We hold the largest stock in the North.—FRANKLANDS, Astley Gate, Blackburn.

Gramaphones, Cycles, and Typewriters by Monthly payments, from 10s. monthly. — Depot, 70, Manningham-lane, Bradford.

Material for Clothbinding "English MECHANIC," 9d. Other material equally cheap. Practical advice given.—ALFRED BEAN, Hartlepool.

W. Probert and Son, Brassfounders, Whateley-road, Handsworth, Birmingham,

Manufacture Brass Fittings in quantity to sample or drawing.

Brass Tubes, Sheet, Rods, Wire or Strip.

Brass Castings to Pattern.

W. Probert and Son, Whateley-road, Handsworth, Birmingham. Works: Tower-road, Aston.

Cycle-Motors.—Castings and Forgings, rough or machined to instructions in the ENGLISH MECHANIC.—BORLAND Leeds.

Motor-Cycles. — Carburettors, Castings, rough or machined. Component parts ready shortly.—BORLAND, Benson-street, Leeds.

Fretwork, Carving. Lists free. Catalogues, 3,300 illustrations, 9d.—ZILLES and Co., 19, 21, Wilton-street, Finsbury, London.

Calcium Carbide. 14lb., 4s. 6d. Acetylene Generators, universally best, from £2 2s. Burners, 1s. 6d. dozen.—HOULDERSHAW, Liversedge.

"The Tool and Machinery Register," published monthly, contains details of over 2,000 lots of Engines, Boilers, Lifts, Hydraulic Jacks, and every sort of machinery. Specimen copy, 2d.—BRITANNIA Co., Colchester.

Model Boiler, 13in. tubular, nearly new, tested 50lb., brass mountings, 15s.—BATE, 2, King Edward-road, Hackney

Inventions Worked Out and Models Made. —HENRY GORE, Engineer, 7, Wenlock-street, New North-road London.

Wanted, Cycle Manufacturers to Send for Our Price List.—KING'S CROSS PLATING AND ENAMELLING Co.—Below.

Nickel Plating on scientific lines for scientific purposes, best work, no premature rust, never strips.—Below.

Stove Enamelling and Lining in black and colour, no better work obtainable.—174, Pentonville-road, Clerkenwell.

Microscopical.—Diatoms mounted in highly refracting media, including realgar, styrax, &c. Prices reasonable. Approval.—GATRELL, Barnes.

Armstrong's Accumulators, highest quality, greatest durability, 6-volt 9-hour, curred, 9s.; rectangular, 7s. 10d.—ARMSTRONGS', Twickenham.

Armstrongs' Scarfoin Set, complete, 7s. 9d.; vastly superior to other makes at 15s. Unprecedented value.—ARMSTRONGS', Twickenham.

Armstrongs' 12-hour Cycle Set, accumulator, leather case, powerful searchlight lamp, complete, 16s. Order at once.

Armstrongs' are makers of over 500 sizes in Portable and Pocket Accumulators. Lists 4d.—ARMSTRONGS', Twickenham.

Cycle-Motor Castings, described in "E. M." Price List 1d.—F. HOMER, 93, Hurst, B'ham.

Cycle-Motor Castings, as described in "E. M.," most complete set, rough or finished.—EVERETT and Co., 22, Charterhouse-square, E.C.

Gear-cutting.—Spur, Bevel, Mitre, or Spiral, in all metals, milling, turning, boring, and screw-cutting. — JAMES, Engineer, Borough-road, Birkenhead.

Cinematograph Films, large variety, new and second-hand, popular subjects, for sale cheap.—Apply 1, Houndsditch, E.C.

AND WORLD OF SCIENCE AND ART.

FRIDAY, OCTOBER 6, 1899.

MOTOR CYCLES.—XX.

[CONCLUSION.]

FIG. 115 shows the axles of the front hubs and steering pivots. These are forged in good mild steel, and too much care cannot be taken to insure the forgings being sound. I advise the forgings being made in one piece,

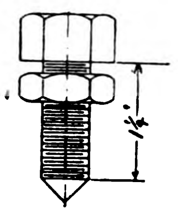

FIG. 116.

and no welding used at all. It will be noticed that the short levers, A, are not at right angles with the hub spindles; this is to allow the wheels turning to different angles. Were these levers square with the spindles, the wheels would always be parallel, and one wheel would skid in turning corners. The countersinks at top and bottom of the steering-pivot require to be well case-hardened. I have also shown a 1/16in. hole carried through from the top to the bottom.

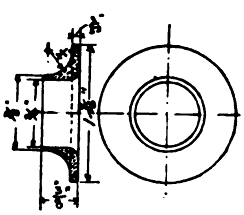

FIG. 117.

This is to facilitate the lubrication of the bottom pivot. The weight is all taken on the top pivot, the lower one merely steadying the forging. Observe that the spindle-ends are screwed, one right and one left-hand. The spindle with the left-hand thread goes on the right-hand side of the machine. The centres on which the steering-pivots work are seen in Fig. 116. They are made of tool-steel carefully fitted to the screwed holes in the forks on the ends of the front axle.

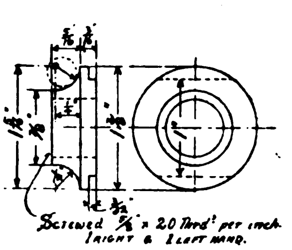

FIG. 118.

When made, they must be hardened and tempered to a dark-brown. The points must be made a good fit to the countersinks in the steering pivots. The lower screw is adjustable; the upper being screwed hard home, and prevented from slacking back by a ¼in. set-screw being put through the boss of the fork, with its point just entering the centre-screws. Fig. 117 gives the dimensions for the fast cones for the ball-bearings of the front hubs, and Fig. 118 the loose or adjusting cones. The fast cones, Fig. 117, are bored a good fit for

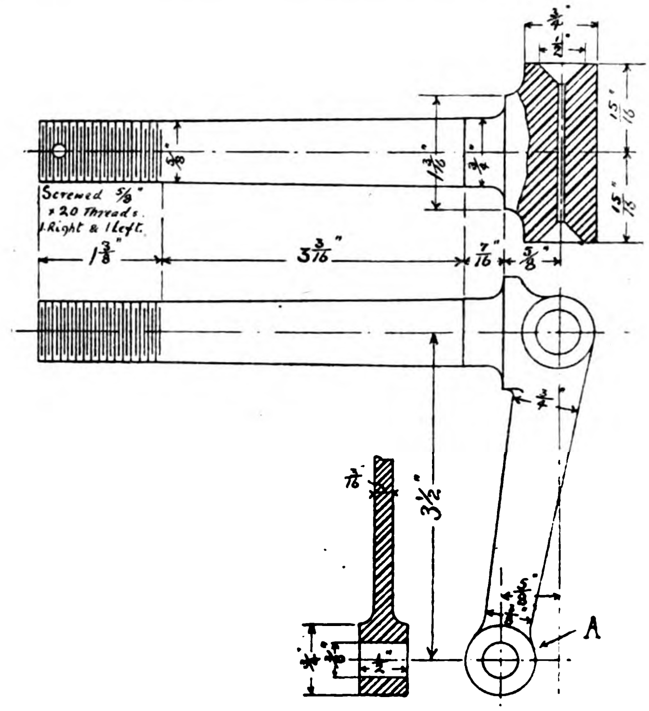

FIG. 115.

the part of the front axles figured ⅝in. diam., this part being left parallel for 7/16in. long. The loose cones are threaded to fit the screwed

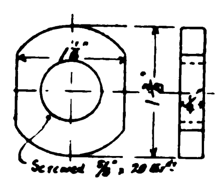

FIG. 119.

ends of the axles. All four cones are to be hardened, the loose cones being tempered a medium straw colour. The fast cones have

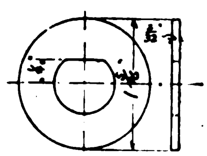

FIG. 120.

to be sweated on to the spindles, and the heat employed for this will be sufficient to temper them. The loose cones are locked in position after the bearings have been adjusted by the nuts, Fig. 119. The washers, with D-shaped hole, Fig. 120, are placed between the cones and lock-nuts, a flat being filed on the spindles to fit the holes in the washers. Then when the lock-nuts are screwed up, the washers will prevent the adjustment of the cones from being altered. As an additional precaution, a ⅛in. split pin is put through the axle ends.

The hubs themselves are turned from mild steel to the shape and dimensions given in Fig. 121, the flanges being drilled with

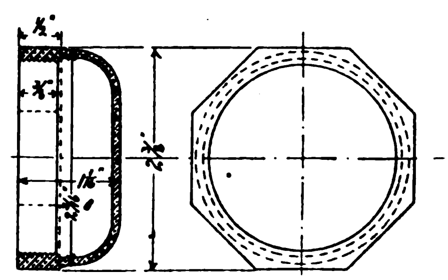

FIG. 122.

twenty holes for No. 10 B.W.G. spokes. The holes are countersunk alternately inside and outside as described when dealing with the back wheel hubs. At the outer ends the hubs are screwed to receive the gunmetal dust-caps, Fig. 122. The ends are counter-bored to take the hardened steel bearing cups, Fig. 123. Make the cups of such a size on the exterior that they will just fail to enter the counterbore in the hubs. Then when they have been hardened and tempered to a pale straw colour, the hubs are to be heated until they expand sufficiently to allow the cups to be drawn into place by means of a

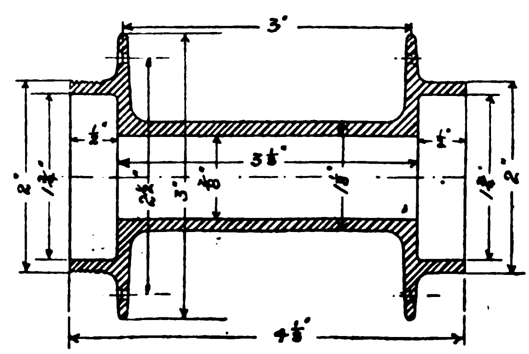

FIG. 121.

long bolt with washers each end and a nut. This will be safer than driving the cups in by hammering, which is liable to split them. As soon as the cups are home, cool the hubs off in water, otherwise they may be softened. To make a first-class job the cups should now be ground out with lead laps and emery and oil till they are perfectly circular and dead to size. It goes without saying that the cups must be perfectly square with

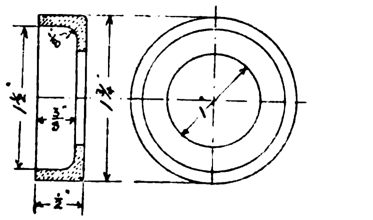

FIG. 123.

each other to allow the bearings to be free, but not loose. The dust-caps, Fig. 122, are of cast gunmetal, and are to be made a good fit on the thread on hub ends. Their exteriors are turned bright all over, and should be nickel-plated to match the hubs. From a piece of ¼in. or 5/16in. iron a key or spanner to fit the octagon of dust-caps is made so that they can be tightly screwed up without damaging the plating.

To connect the two short levers A, Fig. 115, a length of ⅜in. by 16 gauge steel tube, with a mild-steel fork brazed into each end, as seen in Fig. 124, is used. The forks are

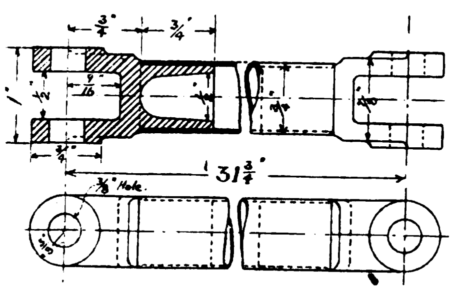

FIG. 124.

forged from mild steel, and should be nicely filed up to shape, and the jaws and ⅜in. holes case-hardened. The bosses on the ends of the steering pivot levers are also to be case-hardened. The exact length of the tube will be 30¼in., and from centre to centre of the ⅜in. holes in the forks 31¾in. This must be rigidly adhered to; otherwise the steering will not be correct. The part of each fork which is brazed into the tube should be bored

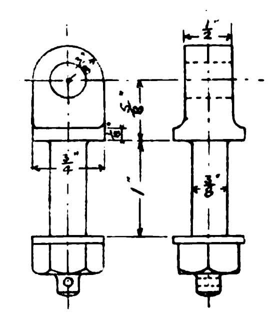

FIG. 125.

out, as much for the sake of increased strength as for lightness. Take care to drill a small hole in the tube to allow the air expanded by the heat, and the steam from the borax used in brazing, to escape; other- a serious accident may result. The pin for the fork at the left-hand side of the machine is shown in Fig. 125. The head of this pin is made flat, with a ⅜in. hole through it to take the fork on the end of the rod which couples the steering levers to the front forks. The pin for the fork at the other extremity will be the same size with the exception of the head, which will be flat, ¾in. diameter by 5/16in. thick. A malleable iron casting or mild steel forging, of the shape and sizes given in Fig. 126, will next be required. The exact length of this part will depend on the width between the extremities of the tricycle front forks. It should be the same as the length over the shoulders of the cones on the front-wheel hub. A 5/16in. bolt is passed through forks and casting and screwed up tightly. Through the boss A, Fig. 126, a pin, similar in all respects to Fig. 125, is passed. The position of the boss A is to the right of the centre line of the machine, as seen in the plan view of the quadricycle,

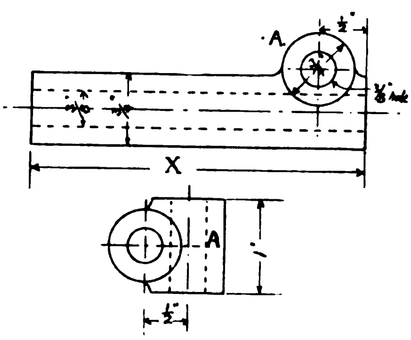

FIG. 126.

Fig. 107. The exact length of the rod connecting the forks to the left-hand steering-pivot had best be found after the other parts are all in position. It will be made exactly the same as the tubular rod, Fig. 124, the exception being the distance between the centres. It may be found necessary to crank this tube in order to get a good clearance between it and the front axle.

The front seat and tool-box, Fig. 107, is made of good dry mahogany, ⅜in. thick. The footboard will not need to be of such expensive material—good dry pine will be quite good enough. The seat is to be stuffed and sprung. Its width is 18in., length from front to back 19in., height from footboard 16in. The footboard is the same width as the seat, but 22in. from front to back. The rails at the back and sides of the seat are made of ⅞in. weldless steel tube, and should be nickel plated. The shape of the sides of the footboard are best left for each to make to individual taste. The tool-box below the seat should not be less than 6in. deep inside to be of any practical utility. Leather is as good as any material to cover the seat and back-rest with, as it does not hold the dust as cloth would. A mat of rubber or coir fibre is to be placed on the footboard. Mud guards can easily be arranged over both back and front wheels, and add to the appearance and finish of "Motor Cycles."

[The thousands of readers who have been interested in this series will be glad to know that in a few weeks the author will commence another on "How to Build a Small Motor-Car." The car to be described will be one embracing the very latest improvements, of a very solid and reliable type, and capable of being built and sold for about £60. We are sure that the coming series will do as much to popularise the motor-car as the ENGLISH MECHANIC did thirty years ago for the bicycle.—ED.]

ORNAMENTAL TURNING.—XXVIII.

By J. H. EVANS.

AS intimated in my last, I now take in hand the details of the spherical slide-rest. This, it will be remembered by many of our old subscribers, I have done once before. At that time I was called upon to give working drawings of this important instrument; but, for some reason, due probably to the occupation of valuable space otherwise required, they did not appear. Since that period, now nearly seven years ago, I have, I hope, found fresh information to impart.

Without endeavouring to touch upon the subject of such slide-rests of this character as were made in the very early period, I think a few words relative to the more simple ones, as used to some extent for trade purposes at the present time, will be of service, and show more distinctly the vast difference to that which may now be termed the most perfect instrument of its kind in existence.

There is little doubt that the difficulties arising in the production of the perfect sphere by plain hand turning, gave rise, on the part of many whose trade more or less depended upon such productions, to the institution of some mechanical means of overcoming the difficulty, and these appear, according to an earlier writer, to consist merely in the construction of a rest that would carry the tool in a circular path round the work while revolving in the lathe. This, with the means of placing the axis of the circular movement identical with that of the work, appears to be all that was considered. This particular type of rest I do not propose to further describe or illustrate. Should, however, any reader be desirous of further introduction to it, it will be found in Bergeron's work on the subject, which was published about 100 years ago.

As far as I know, it is only within the last 30 to 40 years that any attempt to improve this particular instrument has been made. This, indeed, is my experience, and by the various suggestions of scientific amateurs, coupled with a serious study of its capabilities, the spherical slide-rest has become at the present time a most effective, not to say complicated, piece of machinery, capable of many more movements with reference to concave as well as convex formations of solid forms, which when decorated by aid of the various instruments that can be made available for use in conjunction with it, it is one of the additions to an ornamental turner's outfit that should not be omitted. There is, of course, the one drawback, which is the costliness of its production; but when I have fully explained by the various diagrams the large amount of work and minutiæ it contains, it may be regarded as not the most expensive item when comparisons are indulged in.

I have now said sufficient, I hope, to create a desire on the part of many, not only to know more about it, but to undertake the interesting part of making one. I have had a considerable experience, and I find that amateurs take a much greater delight in using a tool of their own make than one that has to be purchased. When, by practical use of the instrument when finished, it is clearly shown what it is capable of, I feel every confidence in saying that the happy possessor of such a tool will rejoice that he was bold enough to make the attempt, for it will require an amount of serious thought to see distinctly what has to be overcome.

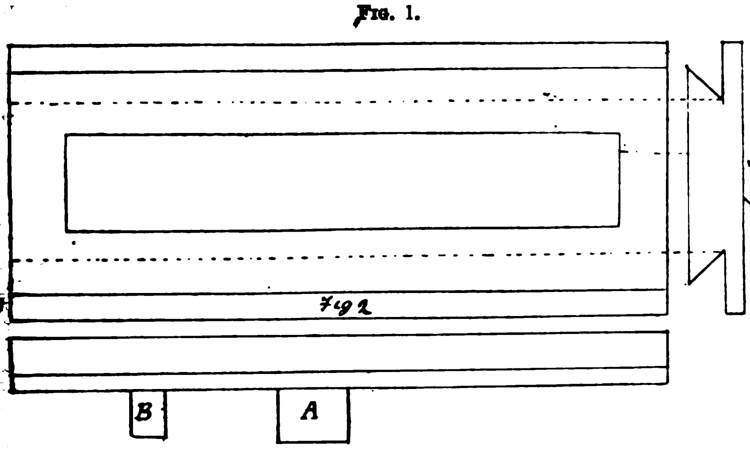
But I hope that the details following will offer every assistance, and I should like it understood that I am at the disposal of any gentleman for further information should it be required.

As in the case of all such tools, the commencement should be at the foundation, and this will be found in Fig. 1, which is the lower or first slide. In this particular part a considerable improvement has been made by extending the length of the slide beyond the lathe-bed, away from the operator. One of the principal advantages in this is found when the rest is used for the turning and decoration of large concave curves, which will be more fully explained as we proceed.

The material used for the slide should be compressed steel or malleable iron—the former is much preferable. Ordinary cast iron is no use; in the first place it is very difficult to get it free from blow-holes, and, secondly, the plates being of very light construction, it is not so suitable. So I will assume the compressed steel is decided upon, and as it may assist my readers, I may as well at once say that the best and only place I know where to obtain such forgings is Sir Joseph Whitworth and Co., Manchester. In order to obtain the forgings as nearly as possible to the required shape, it will be necessary to send well-made wooden patterns of each piece. The cost must not be considered in an expensive tool of this kind. I mention this simply because the material selected is the most expensive.

Fig. 1, then, shows the base or lower slide, which should be about 15in. from end to end, and the tenon, A, Fig. 2, placed 5½in. from the end

Fig. 1.



overhanging the lathe-bed. The width of A must, of course, be made in accordance with the corresponding interval in the lathe-bed. A projection, B, is forged in the solid, and so placed that it will allow the tenon and itself to pass freely over the bed. This so far arranged, and the forgings obtained, the slide is placed on a planing machine by the top face, and bolted securely to it. The under surfaces are then accurately planed to the required measurements.

The tenon must be planed perfectly true to a right angle to the slide. No approximation will do; it must be absolutely true, as a very great deal ultimately depends upon this point. When the under-part has been thus trued up, it must be reversed and re-chucked on the machine, that part already surfaced forming the means of setting it all out truly. In consequence of the two projections at the base, a pair of parallel slips must be employed, upon which the slide is placed, in order that the surfaces may be adjusted to be both flat and true. The top surface and angles will form the next proceeding. Fig. 3 illustrates the end view of the slide. It will require great care in bolting the slide to the machine, in order to avoid springing it, which, if it occurs, will cause no end of bother in getting up the slide, as it will become tight and loose from end to end without any apparent cause, provided the angles are planed quite parallel, which is a point also that requires equal care and attention.

When planing up the tenon it is not necessary that it should accurately fit the interval of lathe-bed. It is preferable to have it quite free. A screw is fitted through B, at the centre of the depth of flange of bed, and when this screw is tightened against it, it draws the tenon into close contact with the inside of bed, and thus certifies its permanent accuracy.

Although scarcely necessary, I will again revert to the extreme caution that is required with reference to the accuracy of the tenon in relation to the slide. When planed at a right angle it will be readily understood that a very minute error will be greatly multiplied by the length of the slide.

We will now proceed with the plate which forms the slide that works on the lower part we have just so far finished. This is made as illustrated by Fig. 3*, and has one side forged in the solid. This must be first surfaced on the upper side, and then carefully chuck by that surface, while the inside and angle are planed. Here again considerable care is required to prevent the plate from buckling or twisting, which any foreign substance under one end would cause it to do. When this slide is correctly scraped and surfaced, both on the flat and angle, they must be ground together with a little very fine oil-stone powder. It is better to avoid emery of any kind. If carefully surfaced they will not require very much grinding at all.

We may now get to work upon the side strip, Fig. 4, for the opposite side. By referring to this it will be seen that it is precisely of the same form as that in the solid; it may be composed of either steel or gunmetal, the former for preference. A hole is countersunk at each end, to receive the head and plain part of the screw that fix it to the plate. These holes must be slightly elongated to allow the two set-screws to move it forward when set up, for the purpose of adjusting the slide with this strip, or the slide may be finished straight off. The screws that hold the side bar to plate are made with countersunk heads, because the space is so limited that there is insufficient room for projecting or button heads, when it is remembered that within the space of less than 5in. we have to provide for four slides and a circular movement, it will be equally clear that we have no room for superfluous material, therefore all the screw-heads are sunk to the level of the strips.

Fig. 3*.

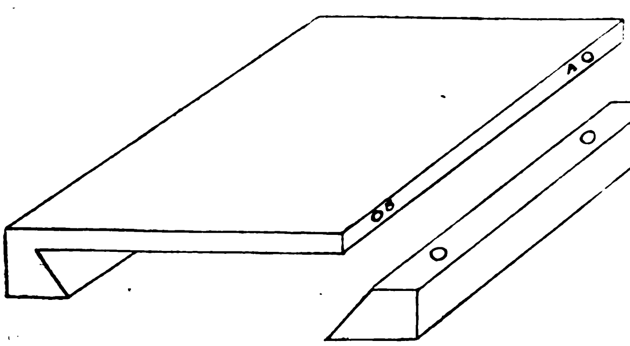


Fig. 4.

So far, then, and I may say after a good deal of talking, or rather writing, we have one slide, and one only, completed; but as the process for those remaining to be done is precisely similar, so much explanation will not be required.

The set-screws must be tapped into the slide (Fig. 3*), as shown by A and B. It is usual to place the hole as near as possible to the lower face of the slide; but the plate being necessarily narrow, in this case it is better to place them in the centre, as there is ample projection of the screw-head to operate against the loose strip when it is set up.

It is quite a matter of indifference whether the lower slide be now drilled and countersunk to receive the main screw, and the nut fixed; but, as a matter of preference, I should advise that it be left till all the slides are got up, and the fitting of screws and nuts all be done at the same time, while the drills and cutters are about.

I have now given sufficient details for the commencement of this important addition to the ornamental lathe, which I feel sure will render the undertaking in every way more easily carried through.

SOME METEOROLOGICAL INSTRUMENTS AND THEIR USES.—V.

THE annual cost of preparing weather forecasts in the British Islands works out at one-third of a farthing per head of population. Per square mile meteorology costs 2s. 6d. in the British Isles, as compared with 1s. in the United States of America, the amount spent by the latter Government being more than that disbursed by all the other meteorological services of the world put together. Seeing, therefore, that each member of the British community is called upon to pay so little for his forecasts of weather, it is not altogether surprising that he is not stimulated to take much interest in the subject of meteorology, apart from criticising the unfortunate weather prophets when they make a mistake. In many other countries, however, methods are adopted to create a public interest in the subject, and means are devised for keeping the members of the community well informed as to the changes taking place in the weather, and there is a generosity displayed as regards the distribution of weather charts and bulletins, and other meteorological publications which far exceeds anything our own Weather Office is able to do. The United States Weather Bureau, whose methods of procedure continually serve as models to all the sister weather services, not only provides general forecasts, but special warnings are prepared by local officers concerning such matters, for instance, as floods and "cold wave" warnings, which have proved of immense service to growers of fruit, cotton, and similar agricultural products. It would be impossible just now to give a detailed account of the many methods adopted to place the latest weather information in the hands of the people, and, indeed, there is no necessity to emphasise the fact that, compared with other communities, we, in this country, have not yet thoroughly realised the importance of making it possible for the authorities to disseminate promptly the weather information which is daily received at a central office from all parts of the country.

Now, supposing an isolated observer, is thus cut off from all supplies of meteorological information, he will experience great difficulty in interpreting the changes which takes place in his barometer. In the preceding articles many different kinds of barometer have been described; but even the best of them will tell little about coming changes in the weather unless its readings are supplemented by other information concerning the movements of the clouds and thewind, and the changes occurring in the humidity and temperature of the air. The two great divisions to which all forms of distribution of atmospheric pressure may be referred are cyclonic and anticyclonic, and since the winds circulate in opposite directions in the two systems, the characteristics of the accompanying weather being also no less different, it becomes of primary importance for an isolated observer to discover which sort of system is passing overhead at any given time. Moreover, if he desires to gain clearer notions as to the uses to which his barometer may be put, he should commence his investigations by briefly considering the movements of the atmosphere as a whole. Commonly it is considered a sufficient explanation of these larger atmospheric movements to say that there are heated currents of air which rise at the Equator and flow towards the Poles, and complete the circulation by returning at a lower level to the Equator again. But these currents of air, when they reach polar regions, become greatly reduced in temperature, and grow more dense, and it might at first thoughts be supposed that all around this region the atmospheric pressure would be very great, and only high barometer readings recorded. In reality, however, observations show that there is a low pressure at the Poles, and, without going farther with a subject which is only referred to as a means of clearing the way to other matters, it need only be noted that this lessening of the atmospheric pressure is owing to the fact that the currents of air are distorted by the rotation of the earth. The researches of Ferrel have given meteorologists clearer conceptions as to how these low barometer readings are produced, and, very roughly stated, they are produced by the centrifugal force of the earth's rotation, so that much in the same way that

the earth itself is flattened at the Poles, so is the atmosphere, the result being to produce a gigantic atmospheric whirl around the Polar regions.

Ferrel also pointed out that, supposing there was an absence of friction at the Poles, the immense centrifugal force of this unrestrained polar vortex would result in there being no air there at all; but it is probably owing to the friction of the land that this whirl is broken up and the Polar outflow allowed to creep back to the Equator. At the South Pole where the masses of land, so far as is at present known, are smaller than at the North, the lessened friction would, according to this theory, result in lower barometer readings—a forecast, it is of interest to observe, verified by each new set of observations obtained in these areas. Not the least interesting of the many facts which forthcoming Antarctic expeditions may be expected to provide will be those which throw additional light on the theories which meteorology owes to the genius of Ferrel. The search for the causes which produce the cyclones and anticyclones may, therefore, well be begun by making some attempt to realise the manner in which the atmosphere circulates as a whole, and although only a few of the factors which form part of this problem are as yet known, it is desirable to understand something of the early stages of the greater aërial currents which are primarily responsible for the pulsations to be noticed in the barometer. In these initial researches the understanding is possibly only embarrassed if it is required to contemplate the various effects exerted upon the great aërial currents by masses of land and areas of water and by the rotating earth, and all therefore that needs be done at this stage, from the standpoint of the isolated observer, is that he recollect that cyclones and anticyclones have probably had their individual characteristics impressed upon them by the movements of the atmosphere in far-distant localities.

To continue a little further, there are reasons for supposing that as the great currents of air flow along in the upper regions of the air, certain portions of them reach the surface of the earth in spots or areas, which help to build up the anticyclones or regions of high pressure. Under certain conditions this descending air would have its temperature raised by compression, but owing to the action of radiation this heating is overcome, and an anticyclone, wherein the pressure is high and the air cold and dry, is the result. It has further been suggested that the cold air which flows outwards from these anticyclonic areas underflows the moist warm currents at the surface of the earth, and in this way the lighter air between the anticyclones is lifted up and set in cyclonic rotation, the rotatory motion being largely due to the fact that the currents of air flow in towards one another from various directions. Now, the energy in an ordinary cyclonic storm has been described as being equal to 500,000,000H.P., or more than that of all the mechanical, human, and animal labour in the world at the same time. Such tremendous activity requires equally great force to keep it going, and among the interesting matters connected with this part of the subject is that which concerns itself with discovering the hidden sourses of this energy. When, therefore, a cyclone is swirling overhead, and the wind blowing, say, at 70 miles an hour during the great part of a day, it is a question worth asking "How is this vortex maintained?" Now, it may at once be said that this subject, similarly to those connected with the greater air currents, has not yet emerged from the region of theory, and were one to propound a series of questions it would be found that to any one of them a dozen different answers could be given. If, therefore, it be asked, "How is a cyclone produced?" and "How is its energy maintained?" it will be found that meteorologists are not yet agreed as to the final answers to be given to these queries. But in all investigations some sort of working hypothesis is desirable, and there are few students of the weather who do not find themselves drawn towards some particular theory among the many offered for their consideration, and it is advisable thus to determine upon some point of view with which one's observations and conclusions may be compared.

Few phenomena provide so many interesting points for consideration and investigation as the moisture in the air, and it appears to be more than probable that the energy of a storm is kept going by the latent heat which is set free during the condensations of moisture which occur during most cyclonic disturbances. According to this widely accepted theory, a cyclone commences as an ascending current of warm moist air, the place of this rising air being taken by currents which flow inwards from surrounding areas. This rising current of air presently reaches a level where clouds commence to form and rain to fall, the air being carried still higher by the heat which is thus set free during the processes of condensation. Now, in this statement there is something with which an observer may compare his weather observations, and if he once commences to try and trace the inflow of these cyclonic winds, the changes which occur in the temperature and humidity of the air, and seeks also to trace the alterations in the movements, shape, and distribution of the clouds, he will find that the subject of the weather will become an attractive one. Similarly, however, to all other meteorologists, his researches will mainly refer to the lower strata of the atmosphere, and unless he be an adept at observing the movements of the upper clouds, the changes taking place at high levels will remain as a sealed book to him. A pause has indeed occurred in meteorological progress for want of knowledge as to the conditions prevailing in the upper regions of the air at any given time, and although much useful work has been done by means of mountain observatories, balloons, and kites, the exploration of these upper regions is as yet only in its infancy. It is, therefore, to the upper clouds, and more especially to the cirrus, cirro-stratus, and cirro-cumulus, that an isolated observer must look for early knowledge of approaching storms, and by combining such observations with those obtained from a well-exposed wind-vane and a good barometer, considerable success may be achieved in preparing local forecasts of the weather.

Supposing, then, that a solitary observer, who has no information concerning the distribution of atmospheric pressure other than that which his own local observation supplies him, has gained some idea of the general circulation of the atmosphere, and has become able to distinguish cyclonic from anticyclonic conditions, he is in a position to make further advances. Now, probably the first consideration which obtrudes itself in connection with cyclones and anticyclones is that different kinds of weather and different winds are associated with each different quadrant of the system. These differences are most readily illustrated by the varying kinds of weather which occur at the front and rear of a cyclone, or depression as it advances from the westward. Thus the haloes and cirro-stratus clouds develop at the front of the system with a falling barometer, while at the rear the barometer rises and the sky becomes covered with cumulus clouds. A rise in temperature and winds drawing in from the south-east herald the approach of a storm, and a wind from the north-west and a drop in the thermometer commonly announce that the disturbance is passing away.

Similar changes are to be observed in the different quadrants of an anticyclone; but since these high-pressure systems drift through the air more slowly than the cyclones, the changes from one kind of weather to the other are less rapid. A cyclone, for instance, may traverse England in half a day, and during this period the weather will run through a whole gamut of changes, and rain, thunderstorms, gales, and blue sky will be experienced in a few hours. An anticyclone, however, will often take two or three days to accomplish the same journey, and under these latter conditions the weather is more permanent, and the changes more gradual and less violent. As a general rule, therefore, it is easier to forecast the weather under anticyclonic conditions than under cyclonic, and, in these autumn days, local weather prophets may be recommended to turn their attention to the anticyclones; for it is at this season of the year that anticyclonic weather is most easily recognised. The early morning frost and mist which gives place to midday sunshine are very typical, and it has long been noticed that animals and birds respond to these exhilarating conditions. It is, indeed, from these signs, together with the local weather saws and proverbs, that an isolated observer must glean his information concerning the distribution of atmospheric pressure and coming weather. His barometer will tell him the amplitude of the diurnal range in pressure, and this knowledge, coupled with his own local observation, will assist him to interpret the meaning of those atmospheric variations which are, indeed, but offshoots from greater and more complicated aërial currents.

MILLWRIGHT'S WORK.—XI.

If a swivel bearing is more economical of power than a rigid bearing, a roller-bearing should effect a still further economy. Actually, there is a saving of about 25 per cent. of the roller over

FIG 68

FIG 69

the rigid type. A considerable number of experiments have been made with a view to ascertain the relative values of the friction of sliding and that of rolling as applied to the bearings of vehicles. Thus, a loaded waggon weighing 5½ tons, when fitted with ordinary bearings, requires 110lb. to start it on a level; one fitted with roller-bearings, 15lb. only. A tramway car fitted with ordinary bearings and weighing 2 tons 15cwt. was let loose from a point 56ft. up an incline with 1ft. 6½in. rise. It ran down this incline, and 57ft. along the level—a distance of 113ft. A similar car with roller-bearings ran

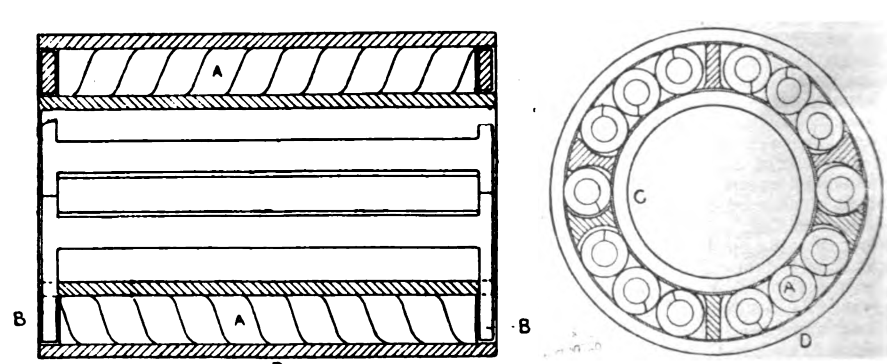

Fig. 70.

376ft. It has been proved experimentally that the power required to drive two Blackpool cars precisely alike as regards weight, dimensions, &c., was 30 per cent. less with roller-bearings than that with common bearings.

The difference between sliding and roller friction is illustrated in a rough way by rubbing the palms of the hands together and then rubbing them with a pencil interposed. Another illustration is that a roller will run quickly down a slope of 1 in 100 (Fig. 68), while a poli-hed

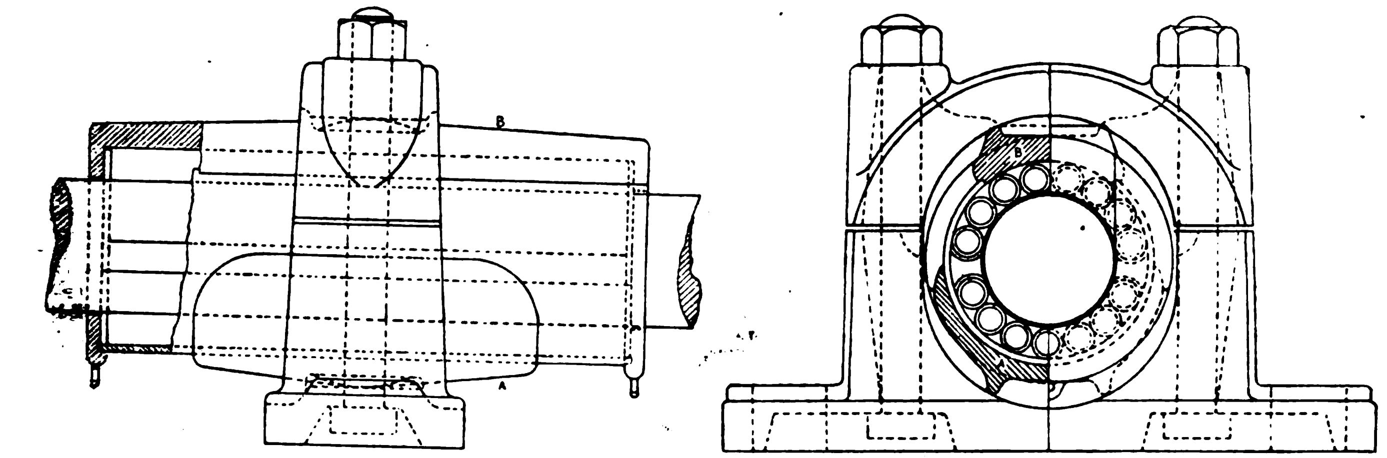

Fig. 71.

metal block will barely slide down a well-oiled slope of 1 in 14 (Fig. 69). Another is, the difference between a sledge and a wheel, between the old wheelless cars which one may still see in Devonshire, and the wheeled vehicles. It is, in a lesser degree the difference between a very small wheel and one of large size.

These obvious facts are being applied to the bearings for shafting. There is nothing new in the idea, but the practical difficulties in the way of its application have been immense.

Whatever lessens friction in the shaft bearings lessens other expenses, besides that of engine power. It diminishes the wear of the bearings and of the shaft journal. It lessens cost of belting by diminution of strain thereon, and less lubricant is required. The rivalry now lies between ball-bearings, solid roller-bearings, and flexible roller-bearings.

The ball-bearings are hardly suitable for shafting, though they are employed very satisfactorily

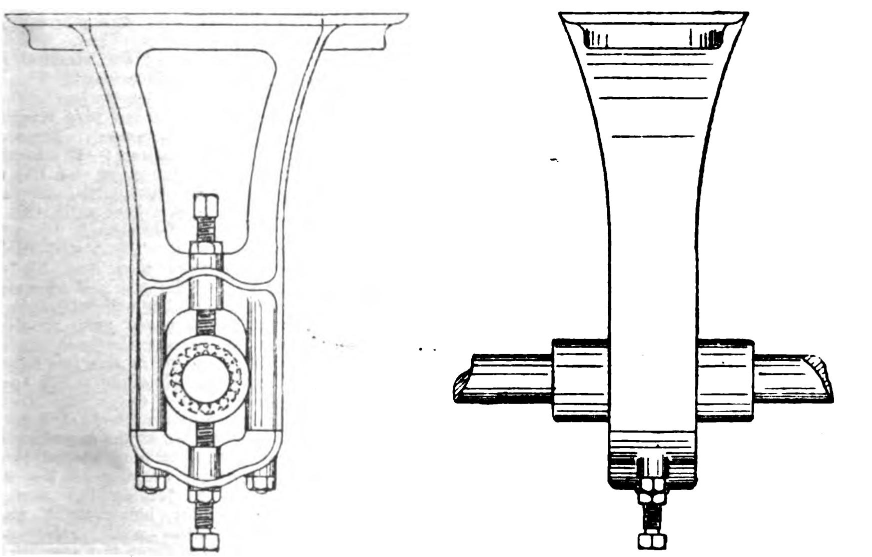

Fig. 72.

for the end-thrusts of various machine-spindles, and worms; for tramcar journals, and light-running spindles generally. The general objection to these for shafts is that contact occurs only at a point, by which pressure is concentrated to an undesirable extent, and that, if the points of contact are increased by increasing the number of the balls, the friction is increased. The fitting of such balls, too, is costly, because they and their races have to be hardened and ground very exactly in order to insure that they all take their share of the work. Practically, therefore, for ordinary shafting ball-bearings would appear to be ill adapted.

In roller-bearings, the rollers, like balls, revolve about the shaft; but they are arranged in various ways. They are loosely in contact or they are retained in cages, which may consist of washers having holes drilled to receive pins, turned on the roller ends or in other ways. In one the rollers revolve on pins. The difference between the two types is this: that in the first, the rollers in their revolutions come into frictional contact with each other; in the second, these are kept apart.

Solid roller-bearings have the advantage that they take their bearing along a line, so distributing the pressure better than in balls. But the cost of hardening and grinding accurately applies here as in ball-bearings. Though used largely for tramcars, they have as yet had comparatively little application to shaft bearings.

Illustrations are here given of the applications of the third class, the Hyatt roller-bearing to shafting. These are termed "flexible," to distinguish them from solid rollers, because each roller is formed by winding two strips of steel of rectangular section into a helix, which is afterwards ground truly in special machines. These are of American manufacture. Detail drawings have been kindly furnished me by R. W. Blackwell and Co., of Westminster, the English agents of the Hyatt Company.

There are two main types of roller arrangements. In one, a yoke guide made of gunmetal maintains the rollers in alignment, dividing them into groups. In the other, the rollers are maintained in position by means of rods passing through the centre. The rods are retained in end rings, through which they are riveted. These are made as solid rings, forming a bush type of bearings, or as half-rings for divided bearings. Steel sleeves or inner bushes are sometimes inserted to protect the shafts from wear, and outer bushes or linings nearly invariably for cast-iron boxes in cases where high pressures have to be sustained.

Fig. 70 shows the standard type of bearing in section, A being the rollers, B the yokes, C the inner bushing, and D the outer lining. Roller bearings of this type have been made from $\frac{3}{4}$in. to 20in. in diameter, from 1in. to 28in. in length, and with rolls from $\frac{1}{4}$in. to $1\frac{5}{8}$in. in diameter.

These bearings are applied to rigid and to swivelling plummer-blocks, to hangers and wall brackets alike. They are fitted to the swivel boxes by riveting guides or saddles to the outside of the steel shell. These guides are made to suit purchaser's requirements. In the case of hangers, floor stands, and wall brackets, the guide-pieces also receive the screws by which the bearings are adjusted, and upon which they pivot.

Fig. 71 illustrates a Hyatt bearing fitted to a swivelling plummer-block. A B are the fittings riveted to the outer lining. The upper one, B, is continued out, and brought over the ends of the rollers to confine them endwise, and a corresponding collar is fitted over the lower portions of the outer sleeve to fulfil the same purpose. The rollers are confined sideways between yoke-guides. These bearings are four diameters long. The boxes are of steel, securing the minimum of weight, a matter of importance in overhead shafting.

Fig. 72 shows a Hyatt bearing fitted to a hanger. The same inverted becomes a floor bearing. The steel box or cage fits wall brackets by

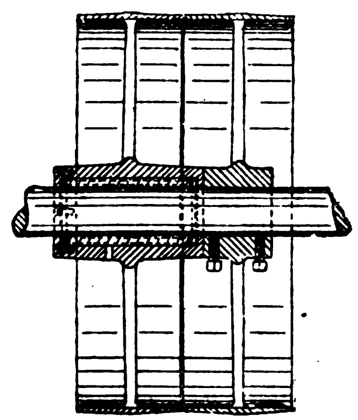

Fig. 73.

the guide or saddle. The construction of the bearing is similar to that shown in Figs. 70 and 71.

The Hyatt bearings are fitted to loose pulleys, Fig. 73. The pulley is bored up to a shoulder, the cage of rollers inserted, and inclosed by a loose flange screwed over the end.

The increasing use of roller bearings during the last half-dozen years has come rather as a surprise to many. The writer has known attempts made to produce large roller-bearings, among the work of a general shop, but always with unsatisfactory results. The difficulty has usually been got over by abandoning hardened surfaces, and using a tough quality of cast or mild steel. The fact is, however, that the successful manufacture of rollers, as of ball-bearings, is not work for general engineers. Inaccurate bearings are worse than plain friction bearings, and that is probably the reason why these have only found much favour of late years since a few firms have laid themselves out specially for their reproduction.

J. H.

Only one marble statue of the human figure with eyelashes is known. It is the sleeping Ariadne, one of the gems of the Vatican, and was found in 1503.

SCIENTIFIC RESEARCH IN ENGLAND AND GERMANY.

In view of the progress made with the scheme for the enlargement of the Government Physical Laboratory at Kew, where researches in theoretical and applied science are to be carried out, it may be of interest to present some details of the foundation and work of the two similar laboratories—the Reichs-Anstalt and the Technischen Anstalt—in Berlin, the prototypes of all such institutions.

The facts and information given below are derived from an article by the late Prof. von Helmholtz, which appears in Volume I. of the "Abhandlungen der Physikalischen-Technischen Reichs-Anstalt": Springer, Berlin, 1894.

The first proposal to found such an institution was made in 1872, and was due to the interest of the late Emperor Frederick (then Crown Prince) in technical science. Commissioners were appointed to investigate and report upon the training of mechanics in the higher branches of optics and trigonometry. They sat in 1875-76, and again in 1882-83. The direct outcome of their labour was the foundation of the Physikalisch-Technisches Institut at Charlottenburg as a branch of the Technical School. The need for the addition of a second department to this new institute was emphasised by von Helmholtz and by Dr. Werner von Siemens, both of whom had been on the commission. On account of the hindrances caused by lack of funds, Dr. Werner von Siemens presented a plot of ground next to the Technical School in Charlottenburg, and later £25,000 (500,000M.) for the erection and fitting of such an addition.

In the letter accompanying this gift, dated March 20, 1884, Dr. Siemens stated that the usual State assistance to the progress of science was limited to care for instruction in physical science. The progress of scientific knowledge was thus left to private effort. Russia was the only country where university funds were spent directly in supporting original workers whose duties did not include teaching.

The increased cost of apparatus and chemicals and greater energy and knowledge now demanded for original investigation had also rendered it more difficult for those engaged in teaching work, and drawing only the usual stipends, to engage in original research. As an example of this difficulty, Dr. Siemens mentioned the determination of the exact value of the units of electrical measurement, a work that was performed in England in private laboratories. It was the work of rich independent scientists that gave to England an important place in the present progress of scientific knowledge. Without these *dilettanten* she would be nowhere.

These considerations led Dr. Werner von Siemens to decide to leave a legacy for founding a laboratory where investigations of fundamental principles could be carried out. One hectare of ground in Marchstrasse, Charlottenburg, was bequeathed. The necessity for recognising the national character of the new step in scientific progress was now forced upon Dr. Siemens's attention. "In the present vigorous competition between different nations, that nation which first steps out along new paths, and applies the newly-studied scientific laws and principles to industrial purposes, has a decided advantage in the struggle. . . . Investigation of difficult theoretical problems in abstract science often lead to most valuable industrial processes; and therefore the promotion of abstract science is of highest value for the material progress of any country."

In consequence of Dr. Siemens's gift, the original plan of the Institute was much enlarged in scope. (See Reichstag proceedings, Budget, 1887-1888.) Theoretical work commenced in the new building in 1890-1891, but had proceeded in temporary premises since 1887. The technical branch was carried on at first in rooms lent by the technical school at Charlottenburg; but as the work of this branch rapidly increased, new buildings were erected in 1894 on ground rented to the Reichs-Anstalt.

The superintendence is intrusted to a council appointed every five years by the Emperor, the selection being made from scientists in every part of the Empire. The president of this council is head of the Reichs-Anstalt, while a special director is charged with the superintendence of the technical department.

The *Ersten* or *Physikalischen Abtheilung* devotes itself to physical investigation and measurements, which, on account of expense or time, cannot well be carried out in private laboratories. The *Zweiten* or *Technischen Abtheilung* is devoted to scientific problems directly connected with industry and to the technical application of the results obtained in the first department of the institute. The results of the first *Abtheilung* are only published at long intervals, since the investigations carried out in it usually demand much time to complete. Those of the second *Abtheilung* are published as rapidly as possible in order that the industries concerned may have the benefit of the researches made. The results of the investigations carried out in the latter department are also published in the *Zeits. für Instrumentenkunde.*

The first inquiry undertaken by the *Physikalischen Abtheilung* was the investigation of all the units and laws connected with the mechanical theory of heat.

It is interesting to note that, while Government aid has been necessary to bring about the initiation of the English scheme, private effort was sufficient in the case of Germany; and only at a later stage did the German Government take the financial responsibility for the laboratory. This is a reversal of the usual procedure in the two countries. The remarks made by Dr. Werner von Siemens upon the relative position of scientific research in England and Germany are of considerable interest, and are no less true to-day than at the time they were written.

The researches carried out in the two institutions in Charlottenburg—whose humble beginnings are described above—have grown in number and importance year by year, and four quarto and 16 octavo volumes, published by Springer, of Berlin, bear witness to the activity of the scientists attached to the two *Anstalten*. It is to be regretted that those engaged in certain English manufactures and industries do not make greater use of this valuable reference library of scientific research. With the exception of the researches of the Charlottenburg experts on the durability of writing and printing paper (abstracts of which were published by the Society of Arts in 1898), these investigations have been much neglected by English chemists and manufacturers.

In time, no doubt, the research laboratory in Albemarle-street, presented to the nation in 1897 by Dr. Ludwig Mond, and the new research laboratory at Kew will yield equally valuable results; and the reproach of Dr. Werner von Siemens that without her rich *Dilettanten* England would be nowhere in the field of scientific research will cease to be justified by the actual facts.—By "A Correspondent" in the *Times.*

NOVEL HYDRAULIC PRESS.

The accompanying engraving shows a hydraulic jack press which was designed by General Foreman R. B. Gibbons, of the Santa Fé-road at

Las Vegas. We are using it for rod and driving-box work, and it has given good service for over a year. Most of the old screw press now decorates the scrap pile, and we wonder how we got along without this as long as we did. The columns are made of cast-iron extension piston-rod casings. The arch is the top of the old screw press. A 30-ton jack is hung from the top by a swivel-plate bolted to arch, the barrel of the jack being held by the two rods shown and a weight which is connected to rods by rope. One man now does the work which took six or seven with the old screw press. Hope this will be of interest, as it is easily made in any shop.—L. D. Webb, in *Locomotive Engineering*, N.Y.

TARSIA WORK, OR WOOD MOSAIC.*

This interesting handicraft was the forerunner of the better-known work, marquetry. It was introduced into Italy in the fifteenth century from Persia and India, and was a kind of mosaic in woods, representing houses in perspective view by inlaying pieces of various-coloured woods into panels of walnut wood, which were used to decorate the backs of seats and chairs in churches. It was also used for the decoration of furniture. The woods of our ancient craftsmen were lime, holly, box, beech, and poplar for those parts to represent white; for a brown colour, pine, laburnum, palm, lignum-vitæ, walnut, teak, and partridge wood; for red, logwood, mahogany, and cam-wood; satinwood for yellow; tulip for purple and rose-wood. These woods are cut into thin sheets.

To-day the professional inlay-workers use dyes, such as aniline and chemical compounds, to enhance their work. For the beginner the following stains will be found sufficient. With these stains we will select three woods to work with: Walnut as the ground, with holly, maple, or lime as the white woods, which can be used either natural or stained any colour by using different coloured dry pigments dissolved in spirits of turpentine to about the consistency of milk. The veneers, which are about ⅛in. to ⅜in. thick, are allowed to soak in the liquid for one hour or more, according to the thickness of the wood used. When taken out of the dye, the veneers are wiped with a rag to remove the surplus liquid, then placed between two boards, which should have a weight upon them until they are dry. When thoroughly dry, several colours are selected for the design in hand. These are gummed together, with a piece of newspaper in between, thus forming one solid piece. The grain of the woods should be all one way, not crossing each other. The design, which is generally of a geometrical pattern, is traced upon thin paper and gummed upon the board. As the inlaid surface is generally a repeat, there are several duplicates of the same pattern, but in different colours. For instance, take walnut as the ground, with yellow and green as the ornament. One set would have a yellow ground with walnut and green ornaments, and the other a green ground with walnut and yellow ornaments. Of course, this could not very well be done if the design was flowers and birds, therefore the repeats would be wasted. The bench for piercing, providing the machine is not used, is a piece of board 18in. long, 12in. wide, and about 1in. thick. Clear maple is preferred; 12in. of this overlaps the table. The other 6in. is either fastened to the table by clamps or screws. Up the centre is cut a V-shaped slot, about 1¼in. wide at the outer edge, tapering for about 4in. down the board. This slot is the clearance for the saw. The seat should be very low, so that the chin of the worker does not come more than 5in. above the work.

The sawing out of the design is the next operation. This is done with the ordinary fret-saw bow, or with the fret cutting machine. A small hole is made with a fine gimlet upon one of the lines of the design, through which a very fine piercing marquetry saw is put, which has been previously secured in the upper jaw of the piercing frame with the teeth of the saw downward. The other end is now fastened in the lower jaw. This requires great skill, as the saws are very fragile and break with the least side movement. The method of securing the saw is as follows:—The handle of the bow is placed against the chest and the upper jaw against the slot in the saw bench. The saw is now fastened in the upper jaw with the teeth towards you. This is determined by passing the thumb along the edge. The teeth, being so very fine, they cannot be seen, but by feeling you will find one way of the saw will be comparatively smooth, while the other will be rough. The saw being secured to the upper jaw, it is passed with the right hand through the hole previously referred to. Hold the work in the left hand, the design away from you. Now press the bow together, and secure the other end. The saw when fastened should be taut like a banjo string. Now turn the saw bow, and work at the same time on to the table, and start the piercing, keeping the saw in a horizontal position, working all the while, and at the same time feeding the saw with the left hand—the cut being made on the downward movement—the work being moved with the left hand to follow the saw, not the saw to follow the work. This must be done with the utmost care, following the outline of the pattern. The course of the saw should cause no greater waste than the width of the pen line laid down for its guidance. The suppleness and narrowness of the steel permits the saw to turn in and out of the smallest curves, making every angle with distinctness and indicating with accuracy the abruptness of a corner. After being cut, the different layers are separated by using a long, thin knife-blade inserted between them. When all are separated, each layer presents a groundwork and set of ornaments. The pieces from the green and yellow layers can be immediately set in the walnut layer, and *vice-versâ*. When properly pierced out, it will be found that an exact fit in every line is secured. These pieces are now glued down upon a board of a certain thickness, according to what the work is intended for. This should be of the same material as the ground which forms a backing. A little glue and sawdust from the woods used join the edges and fill up all the fine openings made by the saw.

When all is completed the panel is placed between boards bearing heavy weights, or compressed with a vice or clamps. This will serve to straighten out the thin wood, which will naturally curl up from

* Extracted from an article by Richard Wells, in the *Art Amateur*, N.Y.

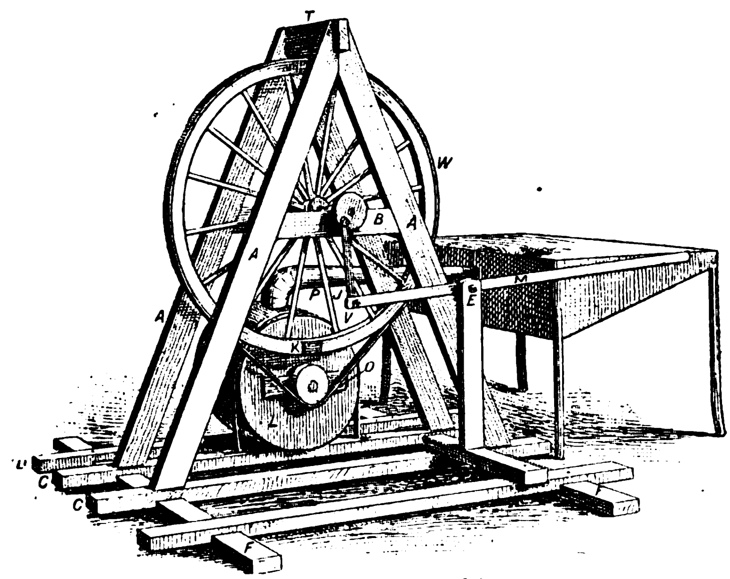

FIG. 1.—The Forge complete.

the moist glue being put upon it, and at the same time drive the small pieces together, producing an even surface. When thoroughly dry, the surface is scraped down smooth and even and sandpapered with several grades of paper until all blemishes and scratches are removed. Should there be any gaps in the joints, these should be filled in with coloured sawdust and glue. It is now ready to be "French" polished.

HOME-MADE FORGE.

THE following directions for making a forge are given by Mr. A. D. Marootte, Church Point, Louisana, in the *Blacksmith and Wheelwright.* I herewith inclose plan and illustration for building a home-made forge. Referring to the sketch, we will

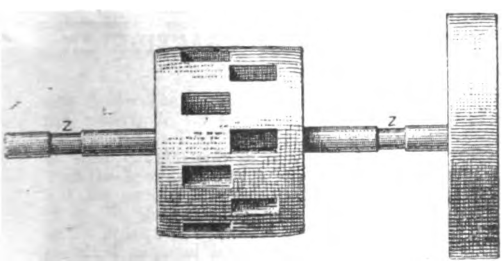

FIG. 2.—The Flywheel Hub.

start at the foundation, F F, which is two pieces 2ft. by 4ft. by 4ft.; C C, two pieces 2ft by 4ft. by 6ft., notched and bolted to F F. A A represents main stock, four pieces 2ft. by 4ft. by 5ft. 11in.,

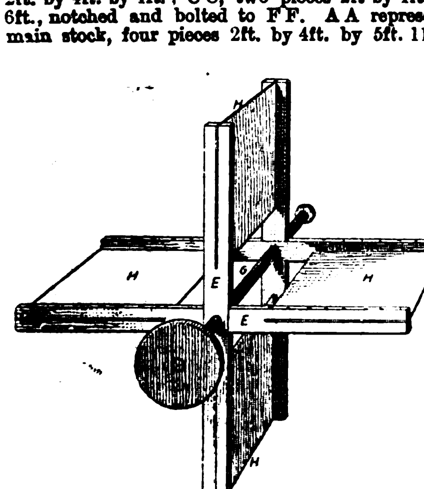

FIG. 3.—The Fan.

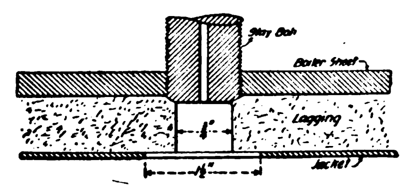
4ft. open at bottom, bolted to C C. B B, cross-bars that support flywheel bolted to A A. T, top bar to hold stock A A. W, wheel, which is made as follows:—Take an old buggy with hub parts dodged, Fig. 2, cut off each end up to the iron band, and fill with spokes to fit, turning the dish inside—i.e., fill every other mortise near the edge with dish inside rim with 1½ by 2 rim; drive in peter, which can be obtained from an old reaper and binder. Cut the rod 28 at 18in. from shoulder; file end down to fit box at Z and Z, 73, put in place and bolt to B B, cross bars, and the wheel is complete. The fan is made thus:—Take an oil barrel; cut ends off so as to leave centre of barrel the proper width for fan, as per Fig. 3. E E are two pieces of oak, 1½ by 1, the length of your barrel—i.e., the diameter. Rip the ends with a fine saw, so as to insert the fan blades H, which are of tin; screw on firmly, insert axle G, and your blast-wheel is ready to go in fan case L. Head neatly, leaving a 4in. hole for air at each end. Bolt a cross-piece, O, to support fan axle G. Put on wheel 5in. in diam. P is pipe made cone shape, the proper length. The elbow is an ordinary stove elbow. Lever B is supported by a piece 15ft. 2in. by 4ft., height to suit, hinged at E. Connecting rod J is attached to fetter and lever M at V, which runs flywheel W. Put a weight on wheel at K to make the wheel start in the proper direction. Wheel W should be 3½ft. in diameter. Place tuyere iron in hearth, insert blowpipe at back of chimney in tuyere iron, and your forge is ready for use.

HEAT-ABSORPTION POWER OF WATER.

THE subject of the heat-absorption of water has been recently before the Institute of Marine Engineers, and notes have been received from members which are of special interest. The paper which was the cause of the discussion and the notes was read some time ago by Mr. G. Halliday, and that gentleman, in the course of a reply, said that a number of the theories brought forward by Mr. Northcote were very similar to the theories brought forward by Mr. McFarlane Gray at a previous meeting. Mr. McFarlane Gray and Mr. Northcote were both wide-world authorities on the subject of this transmission of heat and its application to modern industries; but they had not got rid of some of the old ideas, and he (Mr. Halliday) thought they were not standing still—that it was not necessary to simply believe in old ideas when new experiments had proved that they did not give sufficient reasons for what happened. Mr. McFarlane Gray tried to prove that he was wrong in his experimental results when those results showed that there was a drop in transmission after a certain point in the velocity. His reason was that Rankine held that the rate of transmission varied approximately as the square of the difference of temperature between the fire side of the plate and the water side of the plate. That was quite right if they left everything out of account but the simple transmission due to difference of temperature. The rate of transmission did vary, but a great number of other things came in. There was the condition of the water in the tube, and there was the condition of the water on the other side of the plate. If they allowed the water to remain quite stationary on the side of the plate, a film of steam came between the water and the plate; if they rushed the water quickly over the plate, that film of steam was rubbed away, and therefore there was better contact between the water and the plate and better transmission. Rankine was quite right in his theory, but he did not bring in the condition of the water on the side of the plate; that was a later theory, which was brought forward by Lord Kelvin, and gives absolutely new ideas with regard to transmission, and, looking at the question of transmission from Lord Kelvin's views, they found that the law put forward by Rankine was almost insignificant in comparison to that put forward by Lord Kelvin. Both Mr. Northcote and Mr. McFarlane Gray had forgotten or insufficiently read the new ideas by Lord Kelvin. Mr. Northcote put forward the old idea that they could not expect to gain anything by robbing Peter to pay Paul. Paul stood for the water and Peter for the steam. There was no attempt on the part of Paul to try and steal anything from Peter; they were a joint stock company, and Paul goes up to Peter and says: "Peter, if you will give a little of the heat of your steam away to heat up the feed-water before it comes in to me I will have higher efficiency, I will produce more steam, I will gain by it more than you lose." There was the arrangement between the water and the steam. The water says to the steam, "You give a little, I will gain more." Paul, as the water, tries to get as much heat out of the heating surface as he can by travelling as quickly as possible across it, but as soon as he did this cold water was thrown on his exertions through the cold-water feed, and he was prevented from taking heat as he would under other conditions. He could only get up his speed by keeping the temperature of the water in the boiler always the same, always at boiling-point; and, although there was a loss of efficiency by using live steam to heat up the feed water, the loss of efficiency was not so great as the gain received by keeping the temperature of the water in the boiler always the same.

FIREBOX LAGGING FOR LOCOMOTIVES.

THE results of the elaborate tests of the efficiency of different locomotive boiler coverings made last winter on the Chicago and Northwestern Railway, made such a favourable showing for the general practice of covering about 61 per cent. of the exposed surface with lagging, as to lead to an extension of the covering to the sides and throats of boilers having narrow fire-boxes. The advantages of this were obvious; but the difficulty was to provide for



the necessary inspection of the stay-bolts. All of the stay-bolts are drilled with tell-tale holes, and wire nails of suitable length are inserted in these holes, after which the sides and throat of the fire-box, below the running-board, are covered with a plastic covering about ½in. or ⅝in. thick, taking care to have it fit the sheets closely. When this has dried sufficiently, the ends of the stay-bolts are exposed by cutting out the lagging opposite each bolt by means of a circular punch about ⅞in. in diameter. The nails inserted in the holes serve to locate the bolts.

The jacket is of sheet steel, about $\frac{1}{16}$in. thick, and it is perforated with holes opposite the stay-bolts, as shown in the sketch. The holes in the lagging are made as small as practicable, in order to cover as much surface as possible, and those in the jacket are made larger, in order to facilitate the removal of broken bolts. The jacket is put on in three pieces, one on each side and one at the throat. The throat and side sheets are lapped over each other at the front corners of the fire-box. The jacket is held in position by a number of ½in. bolts placed about 16in. apart. Care is taken to make the jacket fit the lagging as closely as possible.

In this way probably about 80 per cent. of the entire surface of the boiler is protected against radiation, and, according to the tests referred to, this should effect a respectable saving in coal. It was found that when the lagging was extended to the back heads of the boilers the men found the cabs too cold in severe weather, and parts of it were removed. It should be possible to cover the back heads for warm weather, and remove enough of the lagging to properly heat the cabs in winter.—*American Engineer.*

SANITATION AND TROPICAL MEDICINE.

ADDRESSING the students of the London School of Tropical Medicine, Dr. Manson, lecturer on tropical diseases at St. George's Hospital and Charing-cross Hospital Medical Schools, said that the first lesson, and a most important one it is, that the student of tropical medicine should learn is that the distribution of the

germs of the more important tropical diseases is not in any way dependent on the influence of temperature on the human body, which is proved by the fact that once established in the human body the germ will flourish therein, in the coldest as well as in the warmest climate. Thus, for example, a malaria parasite acquired in tropical Africa may remain alive for months, perhaps for years, after its human host has come to live in England. The same may be said of the filariæ, of the ankylostomum, and of many other parasites, proving that temperature regulates the distribution of disease by directly or indirectly acting on the germ during its passage from human host to human host, and not by any direct influence it may have on that host. Our sanitarians and the public do not fully recognise all that the community of interest as regards disease germs of man and beast means in the spread of disease. At all events, if they do understand it they certainly do not act as if they appreciated it. To turn for an illustration to a subject which, at the moment, is of pressing importance—the extension of plague. This disease, no longer, as it had been for some 200 years, of academic interest, merely, in one of those recrudescences, the explanation of which is still obscure, is again threatening to spread over the world. It is even now knocking at the door of Europe. What have sanitarians done with the mass of facts about this disease which has been accumulated for them by etiologists and pathologists during recent years, and, more especially, what have they done with the demonstrated fact that the *Bacillus pestis* is a parasite of rats? Judging from the recent history of the disease in Hong-kong, Bombay, Poona, Mauritius, and other places, plague goes on as if there were no such thing as sanitary science. The reason for this lies in the fact that the sanitarian, like other mortals, is slow to depart from traditions and customs, slow to adopt new ideas, slow to adapt himself to novel circumstances. He has been active and willing enough, but not active in the right direction. Like some physicians he has only one remedy for every disease. In his efforts at preventing and stamping out plague, he has simply followed old and stereotyped lines applicable to certain other diseases, but not applicable to plague, and has disregarded, practically ignored, the well-attested fact that the ubiquitous rat contracts plague before and more readily than man. From the fact that the rat is attacked by plague before the disease appears in epidemic form in a human community, the inference is indicated that the rats are a principal agency in preparing any given place for the epidemic outburst of disease in man; and it also suggests that if the rats in any given place were destroyed, although plague might be introduced, the disease would not spread as an epidemic among the people, at all events that its chances of spreading would be enormously reduced. As regards communicability plague cannot be said to be a very infectious disease, certainly not nearly so infectious as smallpox, scarlet fever, or even typhus. The attendants on plague cases, provided they exercise a reasonable and by no means irksome care, do not contract the disease. Man to man infection, therefore, cannot be the only, or even the principal, means by which this disease is conveyed; were it so, plague would not have spread as it has done in the recent and current epidemics in China, India, and elsewhere. Did its prevalence depend on man to man infection, considering the sanitary measures that have been put in operation, sanitary measures which have proved so effective in typhus—a much more communicable disease than plague—it would have died out long ago. There is certainly some way, other than man to man infection, by which plague epidemics are kept going. In my opinion that way is the rat. This animal is not included in and is not affected by ordinary disinfection operations, it cannot be isolated or segregated like the human being, it runs about from house to house unrestrained, infecting other rats and spreading the disease. It is completely indifferent to Orders in Council, to sanitary authorities, to Acts of Parliament, and even to men in uniform. We know all this, but is the knowledge acted on in that energetic and efficient manner which a lively belief would imply and insure? Certainly not. Attention in plague epidemics is principally directed against man to man infection, hardly at all against the most important rat to rat and rat to man infection. I believe were rats exterminated in any place, plague could not become established in that place.

The Baldwin Locomotive Works have secured an order for the construction and supply of twenty compound locomotives to the Saxon State Railway Administration. The engines will cost 54,760 marks each, and will be delivered free at Chemnitz railway-station, the price including the payment of customs duty and the cost of erecting the locomotives complete at that station. The lowest German tender was 54,540 marks, but the time required for completion of the engines was much longer.

PRESS WORK WITHOUT THE PRESS.*

At one time it was my province to act as a sort of commissioner of ways and means in a small machine shop. The size of the shop was not, however, comparable to the ambition of the proprietor, and, despite the paucity of tools, we undertook to repair almost anything, from a steam-engine to a musical box. A good deal of the business, early in the history of the shop, depended upon the working out of the ideas of several inventors, so far as these could be embodied into actual models and machines. As a general thing, inventors labour under a double disadvantage: Limited means and an inability to fully appreciate the value of the labour required to give their ideas mechanical form. Under stress of these forces, acting in and out of the shop, some peculiar jobs were handled in an equally peculiar way. For instance, take Fig. 1. Here the shoe bears a snugly-fitting metal cap A, which comes

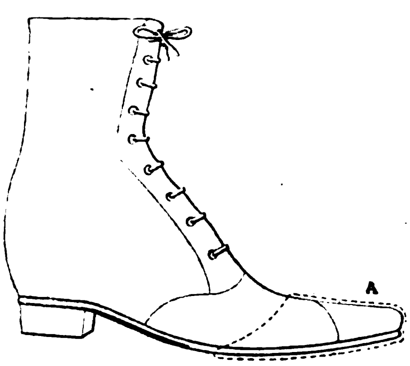


Fig. 1

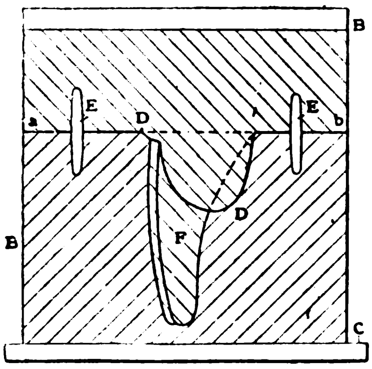

Fig. 2

Fig. 3

well up over the toe and back under the sole, as shown by the dotted lines. The cap was roughened underneath and a sheet steel clamp was applied, somewhat similar to the arrangement on an "Acme" skate, to hold the whole thing in place. The inventor's hopes and fears centred about the clamp, while the machinist was mainly concerned with the means to produce the cap.

Several plans might have been adopted. A last equal to the exterior of the shoe might have been procured, and some sheet brass or copper carefully hammered to fit the upper part, and then another piece could have been bent up for the sole, and the two pieces soldered together at the edges. Or a cast-iron die might have been made from the shoe to strike up the two halves, which could then have been joined to form the cap as before.

It may be mentioned here that a veteran moulder who took some interest in the article on "Cast-Iron Dies," in issue of May 11, tells me that the secret of making cast-iron dies is in the use of oil-tempered sand.

To get back to the shoe cap, which may be cast as in Fig. 2. The shoe is covered with clay to the thickness of metal required. The cylindrical shell B and flat plate C retain the plaster in place when poured in up to *a b*. The dowels E E are put in and the parts D D are cut away while the stuff is soft. The surface is oiled after hardening, and the cylinder B filled to the top with plaster. When the two halves of the mould are taken apart the portion F is gone over with a steel point or graver—the point projecting out of the handle the requisite depth—and then the surface is cut away to the lines thus made, and holes are made for the passage of the molten metal and for vent.

The above method could be varied by first making a plaster-cast of the shoe, then increasing the size of it by the addition of clay, and then making the other half of the mould, afterwards removing the clay and leaving a space, when the two halves were put together, for the desired thickness of shell. One of these methods, and I dare say both, have been used in the making of ornamental metal work.

I give these methods because they were suggested to me as the way in which the job was actually done. As a matter of fact, the groove around the sole was partially filled, and over the surface to be covered by the cap was applied a good coat of blacklead, and it was then electro-plated with copper to the proper thickness, after which the copper surface was buffed and nickel-plated. We were then handling, in the shop, platers' repairs and supplies, and the consequent trade made a very cheap, good job.

If the plating was put on slowly, as in the days of the old Smee battery, the cap would be about as smooth on the outside as on the inside. Life is too short for that process; and with such a task as that I have described, where the outside can be easily polished, the dynamo does very well. Should, however, the circumstances be reversed, and it was necessary that the metal article be smoothest on the outside, a guttapercha case or mould could be made, by coating the pattern and then plating inside the mould. Where articles of this sort are to be made in quantities, of course it is a different story; but when only one or two are needed, the kink is useful.

Fig. 3 is similar to a sketch that came my way along with a few strips of sheet copper and the instructions: "There's nothing particular about this; probably you can find something about the press to feed them along and force them up into shape." The strips were about ½in. wide and 3ft. long, and No. 26 B. and S. gauge. The dimensions on the sketch came very near a 6-P gear tooth, and the draw-bench gears, being that pitch, were put in motion to act both as feed and press.

Both of these, the shoe cap and the corrugated strips, may be not improperly considered press work; and there is some satisfaction in avoiding the use of expensive tools on an occasional task of this sort, even if the one for whom it is done has little or no interest in the means by which it is accomplished.

COMPRESSED-AIR TRACTION IN NEW YORK.*

The extensive compressed-air plant which has recently been erected by the American Air Power Company, at the corner of Twelfth-avenue and Twenty-fourth-street in this city, is now in active operation, and the new compressed-air cars which it supplies are in regular service on the Twenty-eighth and Twenty-ninth-street lines of the Metropolitan Street Railway Company. The compressing-engine is of special interest, both on account of its abnormal size and power and the high working pressure which is obtained. The single compressing-engine is of 1,000H.P., and the compressed air, after the fourth stage of cooling, is stored in the flasks at the high pressure of 2,400lb. to the square inch. The engine, which is of the vertical cross-compound type, built by the Allis Company, of Milwaukee, is an extremely handsome specimen of the engine-builders' art, and together with its massive brick foundations, it towers 60ft. above the ground-floor of the building. The diagram of the whole plant shows the compressors and the four inter-coolers situated on the ground floor of the building. The compressing-engine has cylinders 32in. and 68in. in diameter by 60in. stroke. Steam is furnished at a pressure of 150lb. to the square inch, and working with the most economical point of cut-off the horse-power is just 1 000. Our illustration shows the massive character of the construction, and as an instance of the size of its parts, we may mention that the crank-shaft is 22in. in diameter, with bearings 20in. in diameter by 36in. in length, while the flywheel, which is placed centrally on the shaft between the cranks, is 22ft. in diameter, and weighs 60 tons. The air compressor, which is carried directly beneath, is of the four-cylinder type, the compressing-cylinders being securely anchored between the masses of brickwork which form the two legs of the piers. The low-pressure cylinder is 46in., the intermediates are 24in. and 14in., and the high-pressure cylinder 6in. in diameter, the common stroke, of course, being 60in., or the same as that of the engine. The initial and first intermediate air cylinders are placed directly below the low-pressure steam cylinder, and the second intermediate and high-pressure air cylinders are below the high-pressure steam cylinders. Each crosshead of the steam-engine has four transverse arms, from which four distance-rods lead down to connect with the corresponding crosshead to which the air-pressure piston-rod is attached.

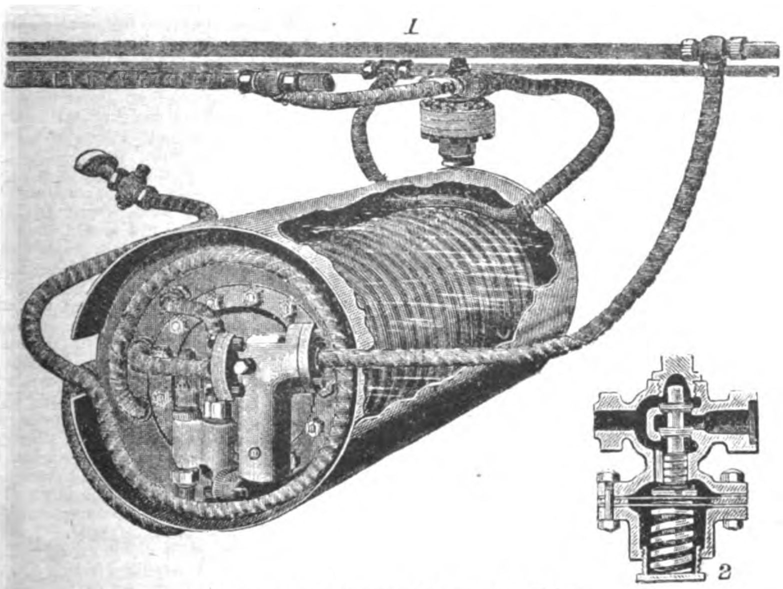
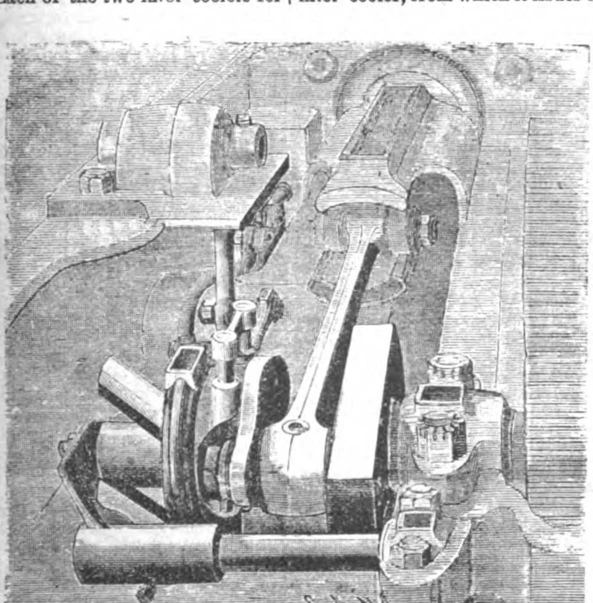
Arrangement of Storage-Flasks, Motors, and Heater on Compressed Air-Cars of Metropolitan Street Railway Company.



Details of the Heater and Reducing-Valve.

There are four sets of intermediate coolers for reducing the temperature of the air at each stage of compression, placed conveniently on either side of the foundations. Each of the two inter-coolers for



Half-View of one Motor, showing Reversing Gear.

the lower pressures consists of a cylindrical shell containing a set of vertical cooling-pipes, while in the coolers for the higher pressures a single-coil pipe is used, the air in each case passing through the pipes, which are surrounded with circulating water at atmospheric temperature. The action of the system is as follows:—The air after compression in the low-pressure cylinder is led through the first inter-cooler, from which it issues carrying a pressure of 40lb. to the square inch. It then passes to the first intermediate cylinder, where, after further compression, it is led to the second inter-cooler, which it leaves at a pressure of 180lb. to the square inch. It is next compressed in the second intermediate cylinder, then cooled to atmospheric temperature at a pressure of 850lb., and finally it is compressed in the 6in. cylinder and cooled to atmospheric temperature under a pressure of 2,400lb. to the square inch, at which pressure it is led to a nest of storage cylinders in the charging-room. The water used for cooling the air in the inter-coolers is taken from the North River, which is only a couple of hundred yards distant, through a 16in. water-main, and after passing through the inter-coolers the water is returned to the river through a discharge-main of the same size. Adjoining the engine-house is a charging-plant and a car-house. The cars on their return from a trip are run in on the tracks adjoining the storage-cylinders, where suitable connections are made, and a fresh supply of compressed air at the working pressure is fed to the storage-cylinders, which are carried beneath the seats of the cars.

The cars which are being used in this service are practically the same in construction as the four-wheel cars which are used on the underground trolley lines. The car body weighs 6,000lb., the trucks 4,500lb., the air-reservoirs 4,200lb., two motors weigh each 1,400lb., and the other parts and fittings of the car bring up the total weight to about 9½ tons. The air motors are carried one upon each axle, in two dustproof cast-iron casings. Each axle is driven independently, one of them by the two high-pressure motors, and the other two by the two low-pressure motors. It will be thus seen that the cars are made to conform in respect of distribution of the driving power to the standard practice on electrically-equipped lines. The high-pressure motor has now two high-pressure cylinders, each 4in. diameter with a 6in. stroke, and similarly the low-pressure motor has two cylinders 8in. in diameter by 6in. stroke. In each case a 9¼in. pinion is geared upon the crankshaft, and meshes with a 21in. gear-wheel keyed on the middle of the car-axle. The cylinders are bolted to the casing, and lie outside of the same, while within the casing are the piston-rods, crossheads, cranks, gears, and, in fact, all of the moving mechanism, and the whole is closed in with a cast-iron cover, which on being lifted exposes all the moving parts for inspection or repairs. One of our engravings, showing one cylinder and its connections, is introduced to illustrate the construction of the reversing mechanism. The eccentric disc is not mounted directly upon the shaft, but upon a pair of parallel guides, which are pitched at an angle to the shaft, one above and one below it, and have a motion parallel to its axis. When the guides are thrust in towards the crank the eccentric disc is thrown up, and when they are drawn out the disc is thrown down, thereby giving a forward or reverse motion to the engine. The idea is not new; but it has been ingeniously applied in the present instance, and lends itself admirably to the peculiar construction of these motors. It does away with one eccentric and the usual link motion. The bottom of the casing is filled with oil, so that the motors are self-lubricating, after the fashion of the Westinghouse and other fast-running engines. The construction is very compact, and the whole design well worked out.

The compressed air is carried in seamless steel flasks, which are placed beneath the seats of the car, three on each side, as shown in the accompanying engraving. The flasks are 2¼ft. in length by 2ft. 5in. in external circumference, and they are tested, before being placed in service, to a pressure three times as great as the working pressure. From the ends of flasks the air is led through the heater, a wrought-iron cylindrical reservoir which is supported between the two motors, as shown in the detail drawings of the car and the heater. The latter is charged with 60c.ft. of hot water under a pressure of 210lb. at a temperature of 400°. After the pipe has passed through the heater, where the air takes up sufficient heat to prevent the sub-

sequent freezing of any moisture which it may contain, the air enters another reducing-valve, of which we show a sectional view, where its pressure is lowered from 2,400lb. to 320lb. to the square inch. It then passes to the throttle-valves at each end of the car, and thence to the injector, where a proper amount of moisture is sprayed into the air from the heater, the temperature of the spray being, of course, 400°. The air with the moisture which it has taken up now passes through a spiral coil in the heater (see detail view), where its temperature is raised to that of the heater, or 400°, at which temperature and corresponding pressure it enters the high-pressure cylinders. From the high-pressure cylinders it is carried direct to the low-pressure cylinders, and then exhausts to the atmosphere on the under side of these cylinders through a muffler. The exhaust, except at starting, is scarcely audible.

Under the present conditions of working, the cars have a capacity of 15 miles with a charge of air occupying all space intermediate the seats, or the capacity could be increased up to as high as 40 miles by placing on the cars as large a number of flasks as could possibly be crowded in, or it could be increased by raising the working pressure, a change which the company is now about to make. The motion of the cars is very agreeable; there is an absence of jar such as is noticeable on the cable and electric roads, and we understand that, as far as they have been tested, they are giving great satisfaction. We are indebted for our particulars to the courtesy of Mr. W. Hoadley Knight, the engineer of the American Air Power Company.

JAPANESE AND CHINESE PAPER.

THE results of the inquiries of the commission of industrial experts, which was appointed by the German Government to visit and report upon the markets of East Asia, show, according to a German trade review, that the various markets present excellent prospects for the paper trade, and the paper industry generally. The Corean hand-made papers, thus far very little known in foreign countries, are of much interest. They are of yellowish colour, silk-like gloss, and extraordinary strength. In purity they are behind the better grades of Chinese papers. These papers are made in sheets about 29½in. by 51in. Oiled papers of this kind are used in place of window glass, and very impure, but extremely strong, board is also made of the same raw material, as well as blotting and wrapping papers. The Japanese hand-made papers are divided into two classes. The so-called "hanshi" (half paper) is loaded with about 20 per cent. of rice starch; the "minogami" consists entirely of fibre. The Hanshi papers are the stronger and coarser, and are made in smaller sizes (about 9¾in. by 13in.), while the Minogami papers are thinner and better, and of larger size (11in. by 16in.) A quire of paper is called "jo" in Japanese, and has from 20 to 48 sheets; a ream is called "shine," and has from 480 to 2,400 sheets. The prices of hand-made paper have recently risen about 15 per cent., because the growers of bast demand and obtain higher prices for their product. Printing paper is used in Japan not only for printing purposes, but also for writing. The most popular sizes of printing paper are 25in. by 27in., and 31in. by 43in., flat. The consumption of paper has increased extraordinarily in Japan, and, although the home production is large, there is a good market for imported paper. Rice straw is an important factor in the manufacture of Japanese machine-made paper; only when there is a poor rice crop is wood fibre imported to any appreciable extent. Several Japanese paper-mills, as well as the Fuji paper-mill (the largest in Japan), produce their own wood pulp and wood fibre; the Ixono mill is said to be the only fibre-mill which sells its products. Wood fibre is imported for the most part from Sweden, and fetches, according to quality, from £16 to £24 per ton. In Skiroishi and in Atami, families make a paper textile in which the warp threads consists of silk or cotton yarn, while the woof threads are twisted from narrow strips of hand-made paper. How much the production of hand-made paper increases is demonstrated by the fact that in 1887 the total value of the production amounted to £940,000, while in 1895 it had risen to £1,820,000. The production of machine-made paper in Japan was in 1896 approximately as follows:—Fuji, 12,000,000lb.; Oji, 12,000,000; Kobe, 7,000,000; Senji, 6,000,000; Yakaichi, 3,000,000; Abe, 2,000,000; Yukosha, 800,000; Shimozato, 800,000; Ixono, 200,000; or a total of 43,800,000lb. The Muramatsu paper-mills, near Shizuoka, produce excellent hand-made paper, and especially noteworthy are the napkin tissue-papers, unrivalled in silky gloss and beauty, which are also painted or printed with pictures, as well as the unsurpassed Japanese crape tissue-paper. Among the most curious things to be seen in Japan are the jackets and trousers of strong hand-made paper with which the Japanese Japanese soldiers were supplied during the war between Japan and China. The seams and button-holes were sewn with cotton-thread. Chinese hand-made papers are made mostly of rice straw, and are coloured or stained on one side by hand; for instance, crimson for visiting cards (which are thin large octavo sheets), pale red for bills, yellow sprinkled with gold or green for wrapping goods, orange for wedding finery, &c. Large quantities are consumed in the principal place of its manufacture for decorating various places of worship, which are visited by Chinese from all over the country, and considerable quantities are also sent to the adjoining provinces. There is no doubt that cheap imported machine-made printing papers, stained or unstained, could successfully compete with these home-made and hand-made papers, and the East Asiatic countries would certainly appear to present an attractive and lucrative field for the European exporter of paper.

"THE QUEST OF THE IDEAL."

SIR JAMES CRICHTON BROWNE on Monday delivered the address introductory to the session in the Department of Medicine at Owens College. In the course of it he said: One of Manchester's most gifted sons, who has embellished our literature by his stately rhetoric and so used our language as to add to its polish and beauty—Thomas de Quincey,—born near this spot in 1785, has described his native town as "gloomy and of repulsive exterior, mud below and smoke above"; but he has added that it contained a population with strong hearts, of noble moral qualities, and infinite perseverance, and "as yet not much alloyed with Celtic adulteration." At the time of which De Quincey wrote—a hundred years ago—the torch of improvement had not been lit in Manchester or carried through its slums and alleys, and could he revisit the glimpses of it to-day, he would have to withdraw his "repulsive" adjective, admit that the gloom has been pierced if not scattered, as perhaps it never can be altogether where a teeming and steam-drudging population closely congregates—and he would have to redouble even his fervid approbation of the enterprise and resolution of its inhabitants with or without Celtic admixture! On all hands he would discover growth and evolution, unmistakable and marvellous signs of progress, enrichment, refinement, philanthropy, and, in this institution, under the auspices of which we are assembled here, he would recognise not the least admirable of the many great public works to which the spirit of Manchester of the 19th-century has given birth.

Manchester and Collegiate Education.

The primary impression on the Outlander surveying your College and school is one of wonder at their early maturity and youthful lustihood. They are of yesterday, and yet the vigour of centuries is in their veins. At the period to which I have already alluded, 100 years ago, when De Quincey was learning Greek, to some purpose, in your Grammar School, then 330 years old, there was no serious thought of a college in Manchester. No doubt some vague schemes for providing training for those entering the learned professions and commerce had been put forth, but these had been speedily snuffed out by the practical men, who argued that higher education spoilt boys for commerce, and that to be successful in business men must be kept intellectually lean and hungry, and it was not until 1825 that the first successful effort was made to establish an institution for systematic teaching in any of the higher branches of knowledge. Before that there had been isolated courses of lectures on anatomy and chemistry, so that the claims of science were beginning to be felt, and in 1814 Mr. Jordan had essayed to organise a medical school; but it was not until 1825 that a properly-equipped and co-ordinated school of science was commenced. I think we must be gratified to remember that that school was the work of the medical profession. It was Mr. Turner who founded it, and that action of his seems to me to have been the germinal vesicle of the magnificent organism Owens College, in which we now rejoice. This school, which was provided with lecturers on anatomy, chemistry, materia medica, surgery, midwifery, and botany, was the first provincial medical school in England, and in consideration of that fact and of its public usefulness it was permitted in 1836 to add the prefix "Royal" to its name. It is only three-quarters of a century—a man's life—since Mr. Turner's first step was taken; but in that brief span of time there has been incessant movement and steady advance in educational affairs in Manchester, advance marked here and there by momentous and memorable events, such as the foundation of Owens College in 1846 and the incorporation of your medical school with it in 1871. Your school buildings have cost the college authorities upwards of £70,000 since the school and college joined hands—that is to say, during the last 25 years—and this, I see, is frequently referred to as a munificent expenditure. So it may be, if measured by the standard of what has been done elsewhere, but so it is not if measured by the requirements of science in these days or by the duties and resources of this great city. I have no wish to startle, but use the words of soberness, when I say that the £70,000, although inadequate so far, does not exhaust the pecuniary claims of the medical school on the community, and that, if in the future it asks twice that sum to meet the educational calls made upon it, and to keep pace with science, which is now so mobile and so expensive, Manchester should cheerfully put its hand in its well-lined pocket and produce the money, knowing that, after all, it is only a judicious investment in life assurance.

A Medical School and its Work.

The lecturer contrasted the £70,000 spent on the school buildings with the enormous expenditure, drawn from the rates, on lunatic asylum. Mental and nervous diseases, he went on to say, are the diseases of the future, and we have as yet no protective serum to employ against them. All the more important is it therefore that they should be diligently studied and scientifically investigated. In the early days of your school the lunatic hospital of Manchester formed part of the General Infirmary, and then, for good reasons and with excellent results, it was moved out to Cheadle, where it now is, and where my friend Mr. Mould successfully presides over it and utilises it for clinical teaching. The Cheadle Hospital admirably supplies a clamant public want, but, I confess, I hope the day will come when another lunatic hospital will spring up in Manchester—an asylum organised in all respects like an ordinary hospital, and near to your school, so that you may have daily access to it. In the lunatic hospital of my imagination the medical staff, consisting of consulting, visiting, and assistant physicians, aided by specialists of several kinds, would be exempt from all the administrative and clerical work which now weigh so heavily on asylum medical officers, and would thus be free to devote themselves to their purely professional duties, to research, and to teaching. Resident house physicians and clinical clerks would maintain constant observation and keep the medical records, while psycho-physical and pathological laboratories would afford facilities for experiment and demonstration. Courses of lectures on psychology, neurology, comparative psychology, and mental and cerebral pathology would enable students to benefit fully by the work in the wards (which their critical presence would always maintain at a high pitch of thoroughness), and prepare them to deal in their own practice with a prevalent and obscure group of diseases, while an out-patient department would bring under skilled treatment cases of mental derangement in their incipient and most curable stage. I am *not* inappreciative of what is being already done in the way of science in our asylums in this country, and especially in the department of pathology, often under disheartening and difficult circumstances; but I say deliberately that until we obtain in London, Manchester, or elsewhere a lunatic hospital organised somewhat on the lines I have indicated, the great problems, social and medical, in connection with insanity, which press for solution, cannot be adequately dealt with. Perhaps some still hiddenly purposed benefactor of your school and lover of his species, perhaps the county council, tired of building costly receptacles for decayed and damaged mind-stuff, may bestow such a genuine lunatic hospital upon you, and thus vastly extend your usefulness and heighten your prestige. I am, I admit, heavily requisitioning the future on behalf of the Manchester Medical School, and it may be that in doing so I have not sufficiently acknowledged what Manchester has already done for it. No doubt the Medical School has owed much to Manchester; but, on the other hand, Manchester has owed much to the Medical School. In the central coil and in every purlieu of the city its influence has thrilled; there is not a sumptuous mansion or a miserable tenement in which some emanation of its virtues has not been felt, for a brisk and efficient medical school not only trains medical students, but raises the whole tone of medical practice in its vicinity, especially when, as in your case, it affords opportunities to medical men engaged in practice to renew their studies from time to time, and so to keep abreast of all advances made in our knowledge of disease, its nature, causes, and effects. I do not know any surer blessing which a populous district can enjoy than to have a medical school in its midst. This radient influence of a medical school, if I may so call it, cannot be weighed or measured, but it is real and substantial enough, and, of course, it will be most potent just where the conditions of life are most insanitary and provocative of disease. And so in Manchester in the past it has had free scope and sway. When the Queen visited the city in 1851 her keen and sympathetic eyes noticed, as she has set down in her diary, that the crowds in the streets, both of Salford and Manchester, were made up of "a very intelligent but painfully unhealthy population." And about the same time Mrs. Gaskell, whose writings did much to create kindly feeling and break down the barriers separating employers and employed, pictured the mill-hand in lugubrious

colours. The men, she said, in "Mary Barton," were of stunted growth and fragile build, and had wan, ashen faces, telling of scanty living and grinding toil; and the women, lacking in beauty and symmetry, showed pinched and sallow countenances, in which acuteness and intelligence contended with care and debility. All that has been changed. Manchester crowds to-day present no such saddening spectacle. Your proletariat is as winsome and robust as that of any other large manufacturing town. Your death-rate has dropped. Yet much—infinitely much—remains to be done before you can be said to have reached a level of public health that can be pronounced even tolerably satisfactory. In some of the slum districts of Salford—now happily to be cleared away—the death-rate has in recent years reached 100 and even 104 per 1,000; in one district it has never fallen below 60 per 1,000 for the last six years. In some parts of Manchester—for instance, in Hulme—shocking overcrowding prevails. At a recent meeting of the City Council it was stated that in one case there a father, mother, and six children all slept in one room 8ft. by 6ft., without a fireplace and with windows that would not open. In another case a father and mother, short of work, and so of food and fuel, occupied, with their two children, a small room the fireplace and windows of which were papered up to keep out the cold. Little wonder that one night the youngest child was asphyxiated. It is clear that still cheek by jowl with your opulence and refinement are pinching poverty and squalid debasement; and that those indefatigable promoters of disease and degradation, over-crowding, over pressure, over-drinking, under-feeding, under-breeding, under-thinking, are still busy at their deadly work amongst you. Strenuous efforts are still required of Manchester to raise its submerged masses into decent habits and health, and in these efforts it will, I am sure, draw inspiration, guidance, and support from this centre of medical science. In what has been already done to raise the masses your medical school has had some share, for whatever ameliorations have been secured have been due, not solely to economical changes, but also to the sound doctrine of sanitary reform which has here been preached. Your school has diffused around it just methods of thinking on medical and sanitary matters, and I question whether, but for the atmosphere it has created, those wise measures for the prevention of tuberculosis which Dr. Niven and Dr. Delapine have advocated would have been adopted by your civic authorities. I have already referred to what is no doubt a just source of pride to all connected with this school, and that is the steady arithmetical progression in the number of entries of students from year to year, a progression all the more gratifying because it has been, as the registers of the General Medical Council show, proportionately greater than that in the other medical schools of Great Britain. It is thus evident that the advantages you offer are attracting students from beyond your own proper fief or territory, and that you may in time become no longer a county palatine but a cosmopolitan institution. It is not, however, by its entries, but by its exits, that a medical school is to be judged—not by the raw material but by the finished article—and in that respect you have, I think, no reason to be ashamed, for having looked over the list of your associates and of your graduates in the Victoria and London Universities I observe that for so comparatively young a school you have sent forth quite a remarkable number of men who have already made their mark in their profession. They have won a good name for your school; and it is for the men I see before me to live up to the standard they have set, and, with ampler opportunities than they enjoyed—for your school is always improving its machinery—to better their example.

"The Materialistic Virus."

I should consider myself fortunate if I could say any word this afternoon that might stir one or two present to more vigorous endeavour in the work before them, that might heighten in a few their conception of their errand in life, that might bring home to the many an enhanced sense of the responsibilities they are undertaking. In considering how I might best in some small measure achieve this, it has occurred to me to improve the occasion by warning you against certain dangers which will assuredly beset your path, dangers not generally recognised, but to my thinking real enough. I allude to those tendencies to materialism, which regards mind as a mode of motion, or to its congeners, naturalism, which subordinates spirit to mechanism and sets unchangeable law as supreme, and agnosticism, which ignores both mind and matter and confines its attention to phenomena—tendencies the influence of which you are all certain to feel, and to which some of you are not unlikely to succumb. If your local teachers supply you with no antidote to the materialistic virus, the great catholic teachers to whom all who are interested in medical and biological science are obliged sooner or later to turn will inject it into your veins with tenfold virulence. Herbert Spencer is certainly responsible for a widespread diffusion of materialism. The splendid cogency of his argument that the whole procession of phenomena in the universe, the vast array of nebula and star, of sun and planet, of planet and moon, of rock and crystal, of plant and animal, is deducible as a physical and mathematical corollary from the simple fact that the quantity of force in the universe is fixed and unchanging, and that it exists under the antagonistic forms of attraction and repulsion, dazzles the intellect and disposes to the purblind acceptance of his deliverances on all other subjects. And thus it is perhaps that his theories as to the evolution of mind, which notwithstanding his admission of an Unknowable as a necessary datum of consciousness are pure and undiluted materialism, have obtained such ready currency. He insists that mind arises out of the molecular vibrations of matter, just as do light, heat, and electricity, and that the only difference between the commonest sensation and the most transcendent emotion lies in the number and complexity of the molecular vibrations of nerve substance. He does this with a subtlety and ingenuity that almost inevitably command for his propositions the assent of those whose daily experiences impress them with the constant and intimate connection between brain states and mental manifestations, and so his philosophy has dashed to pieces the ideals of many medical postulants. But if Herbert Spencer has done much to scatter broadcast materialistic ideas in medical circles, Huxley has done more, for, in spite of his repudiation of the title materialist as a reflection on his agnostic allegiance, there are few recent writers who have better deserved the designation. He invariably leans towards the primacy of the physical side in phenomena. He has said that the history of science has "in all ages meant, and now means more than ever, the extension of the province of what we call matter and causation, and the concomitant gradual banishment from the region of thought of what we call spirit and spontaneity." He has taught that molecular changes in the brain are the causes of all states of consciousness. Volitions, he affirms, do not enter into the chain of causation at all, voluntary acts being as purely mechanical as reflex action. High thinking, in his alembic, turns out to be merely increased resistance and friction in certain nerve circuits. He has reduced our species to conscious automata. Consciousness, according to him, is a collateral product of the working of the organism, and cannot under any circumstances, in man or brutes, be the cause of any change in the motion of the matter of the organism. With a matchless power of lucid exposition, with relentless logic, he has pressed home these views, and the weight of his authority as a scientific investigator, added to the charm of their simplicity and completeness, have given them potency and popularity, and helped them to swell that great tide of materialistic thought which surges through our medical schools to-day, and sweeps away many precious and ennobling ideals. As I have already hinted, the materialistic tendencies of the hour, dispersed everywhere, but focussed in our medical schools, have not even in them by any means undisputed dominion. They are resisted by those who are, by constitution or training, fortified against them, or who, by wrestling with them, have overcome them. The loss of the ideal is a personal calamity. "That way madness lies," as those engaged in my special department of practice are not seldom made aware; and the loss of the ideal is inevitable if no solution of the world-problem can be arrived at, or if that solution be materialism. For materialism reduces all things to the pull of opposing atoms. Under its interpretation intellect is the activity of nerve cells; immortality is a delusion; virtue, honour, duty are forms of selfishness, and heroism becomes a kind of disease. To drift into materialism from indolent acquiescence, or callous sensuousness, or out of deference to scientific authority; to adopt it in defiance or bravado; to rest in it without testing its credentials again and again in the new lights that the changing years bring to us, is the height of folly. To let the ideal slip from us by clutching it loosely, or by neglecting to supply it with the necessaries of its life, is to sacrifice our most precious birthright. I cannot help thinking that in our medical tribunals we are too apt to allow judgment to go in favour of materialism by default, and to let blatant assertion pass for proof. The battle is not ended; it is scarcely begun; and if I discern the signs of the times aright, there are hard knocks in store for materialism, naturalism, and agnosticism. What I have to say is simply an exhortation to hold fast, as your sure refuge, by idealism, which, in one shape or another and however smothered up, still dwells in each of you, and with that exhortation I would associate a suggestion that the assumptions of science which exclude an idealistic view of the world, as well as the prepossessions against anything but solid facts and their material explanations which your studies may have engendered in your minds, are still open to doubt and refutation.

The Limitations of Science.

Vast as the sphere of science is, it is still limited in all directions. Physical science can never prove to us the existence of mind in our fellow-men, and yet that is one of our most rooted convictions. And physical science is equally incapable of substantiating that the quantity of force in the universe is fixed—the first principle without which science is impossible, and which we have to take on trust. In these and in other instances which might be adduced it is seen that our whole mental fabric is built up on beliefs, lying deeper than science, in regions into which, with all its modern acuteness and instrumental aids, it cannot penetrate. These regions are called metempirical, but it is not on their shadowy immensities I wish for the moment to touch, but on certain unfathomable chasms that are well within the bounds recognised science, and the existence of which is inconsistent with the material hypothesis. First there is the chasm between the organic and the inorganic. Astronomical physics bring us down gently, as has been said, from the incandescent gas of a nebula to this round earth; but when we begin to examine the earth's surface, we are pulled up with a jolt at the cleft between the lifeless and the living. There is no physical theory of the origin of life, which in our experience never arises except through the mediation of life already existing. Abiogenesis is an exploded myth. Virchow's phrase, "Omnis cellula e cellula," is an axiom in biology. The volumes of Herbert Spencer's philosophy, which should have traced out the connection between inorganic and organic evolution, are, strange to say, still wanting. Darwin never entertained the notion of a mechanical derivation of life, but wrote: "It is mere rubbish thinking at present of the origin of life; one might as well think of the origin of matter"; and Lord Kelvin, notwithstanding what has been called his "forlorn hypothesis" of the meteorite, a skin-graft from another world, has declared that "the only contribution of dynamics to theoretical biology is absolute negation of the automatic origin of life." Secondly there is the chasm between the physical and the vital, for if the origin of life is wrapped in obscurity, so is its maintenance. Physiology has, in its materialistic fervour, vaunted itself on having banished vitalism and established the identity of all vegetable and animal functions with physical forces. In 1889 Sir John Burdon Sanderson, in his address to the British Association, declared that "the word 'vital,' as distinctive of physiological processes, must now be abandoned altogether"; but in view of recent researches I question whether he would to-day repeat that statement. Thirdly there is a chasm, the widest of all and the most fatal to materialism, between mind and matter. And it is just this chasm which, as young medical scientists, you are most likely to overlook, for the absolute dependence of the mind upon the brain is a presupposition of much of your work, and is obtruded on your attention in your clinical, physiological, and pathological studies. Even those of you only entering on their curriculum will be prepared to affirm that thought is a function of cerebral cortex, for the accredited proofs of that proposition are patent to all. The intelligence of animals is on the whole proportionate to the size and differentiation of their nerve centres. In the different races of mankind a correspondence is observed between mental power and brain bulk and elaboration. Sir James Crichton Browne proceeded at some length to elaborate this thesis. How, he asked in conclusion, is the ideal, whether it is in the mind innately or has been won by sore travail, to be fostered and nourished and kept alive? By all those observances and ordinances that the wisdom of ages has consecrated, and that in these hurried and indifferent days we are too apt to neglect. By the assumption of an attitude of reverence and sympathy, which will incline our ear to the whisperings of the infinite and afford us glimpses of the inner impulses by which other men shape their lives. By the practice of that self-renunciation for which our profession affords the finest scope, for in ministering to the wants of others, even at the sacrifice of our own, we mount to blessedness. Scepticism, unbelief, and deadness to the ideal are sometimes the outcome of an overweening egotism of isolation and an exaggerated notion of one's own importance, and are to be corrected by a broad survey of humanity, of the poor and toiling multitudes to whom faith in some shape still make their meagre existence good and palatable and full of meaning. And for this broad survey your profession, in its practical aspects, will afford you abundant opportunities, thus in some degree making amends for the epicurean leaven of its purely scientific study. You will witness much of tragedy and pathos in humble homes. You will contract an affectionate esteem for lowly toil, and for the patient endurance and devotion of the poor, without sacrificing your respect for the many noble qualities that mingle with the frivolities and follies of the well-born and affluent classes.

A CHURCH in Chicago has a steeple on which are lights are placed. The lamps are 225ft. above the level of the street, and produce an excellent effect.

MEDICINE, OLD AND NEW.

In his address to the students at St. George's Hospital, Dr. W. Howship Dickinson, after comparing medicine with the other learned professions, said that the medicine of the past was largely empirical, and justified in its results the sarcasms which were directed against it. But empirical as was the system, it was in operation from time immemorial, and provided many drugs which were among our most important agents. By "empirical" was meant, as the dictionary has it, "practised only by rote without rational ground." The advance of modern medicine he considered under three heads: learning that many diseases which our forefathers supposed to be under the control of medicine were not so; enlisting in our service the influences of the external world; tracing many diseases to minute organisms which formerly were unknown. The old treatment of pneumonia and typhoid was contrasted with that of to-day, and other instances were referred to in which our fathers played an active part where we were content to be passive. Much of our progress was negative, in the abandonment of what was injurious; but positive gains were to be recognised. Foremost among these was the trust we had learned to repose in external nature as exemplified by the employment of climate in the treatment of disease. The bacilli of anthrax, relapsing fever, tubercle, diphtheria, tetanus, cholera, glanders, typhoid, plague, and leprosy were exposed to view, not to mention the important discovery of the organic causes of suppuration. While these intruders from the vegetable kingdom were successively coming into view, the animal kingdom was delivering up secrets of scarcely less importance in the shape of the Filaria, the source of some of the gravest and hitherto most incomprehensible of the diseases of the Tropics, and the organic generators of malaria and dysentery. With regard to bacilli and the diseases ascertained or presumed to be caused by them, there were three ways of prevention or cure, killing or excluding the microbes; establishing immunity in the individual exposed to them; employing antidotes in the shape of the antitoxins. Looking at what had been done, and in how short a time, in tracing diseases to foreign organisms, and at the possibilities of prevention and cure which were implied, we could not but wonder and hope.

SWINE FEVER, RABIES, TUBERCULOSIS.

In his introductory lecture at the Royal Veterinary College, Prof. Sims Woodhead, M.D., said that, although we are an essentially practical people, we did not learn as much as we might from the practices of others. For example,

Swine Fever

had been a scourge for years. We had had an elaborate system of inspection, of central examination, and of compensation. He believed that we were going the wrong way to work to get rid of the disease. Into the question of compensation he scarcely felt competent to enter; but he could not help thinking that this permanent system of compensation had something to do with the continuance of the disease among us. At present, if the disease broke out in an area, the farmers were sure that their loss would not be borne entirely by themselves; and even the best of men had not the same stimulus to exert themselves to adopt preventive measures, when they felt assured of certain compensation, as they would have were they to feel that they would inevitably be involved in considerable loss if the disease should break out among their swine. Some temporary system of compensation might no doubt be just, but it should be for a period only sufficiently long to enable effective measures to be taken against the spread of the disease. In the matter of inspection, however, he held that at present, when such enormous capital was at stake, we were making a grand mistake. He did not wish for a moment to hint, even, that the men who were at present doing the work were not capable of carrying out the orders that were given to them. They were no doubt an intelligent set of men, honourable, active, energetic; but the work that they were called upon to do was not that for which they were fitted. For administrative and secretarial work let them be kept in their present position; but for the actual inspection of buildings, of animals—whether dead or alive—he maintained that no one but a thoroughly qualified veterinary surgeon should be employed, and this for many reasons. Only a veterinary surgeon could understand the disease thoroughly in its many-sided aspects. The symptoms, the lesions, and the like were not always the same, and it might be years before an inspector saw every lesion and appearance that might be present in such animals; and during the time that he was gathering his experience, the latent and irregular forms of the disease were centres from which infection might be spread broadcast. An inspector who had been brought up as a soldier, or in some civil occupation not associated with scientific work, could have little knowledge of the principles of infection and disinfection, of hygiene and the like, by means of which only could the disease be prevented. He could not keep himself *au courant* with most of the recent discoveries as to the pathogenesis of the disease; he must always be behind the veterinary surgeon, and never so completely equipped. More than this, what inducement had the ordinary inspector to get rid of swine fever? He had been taken from his previous occupation to stamp out a disease by the disappearance of which his present occupation would be gone. He did not mean to say that this could weigh with the bulk of men; but there were always a few men in whatever sphere of life one moved with whom an inducement of such a kind had a certain amount of weight, even though in some instances they might be unconscious of it. In the case of the veterinary surgeon, when swine fever disappeared, he had still some other branch of his profession to fall back upon.

Rabies.

Another matter to which he would like to refer was the so far successful effort there had been made to get rid of rabies from our midst. It was not long ago that anyone advising systematic muzzling to be adopted for the purpose of stamping out rabies would have been laughed at as an enthusiast and hooted down as cruel, and no Government would have dared to carry out the behests of such an individual. Some might say that it was the practical man who had brought this about. He did not agree with this. He held that, curious as it may appear, Pasteur's researches on hydrophobia had been the means of rendering such a course as that recently adopted by the Board of Agriculture at all possible. Should there ever be another outbreak of hydrophobia, as there might be when the lessons of the last few years had been forgotten, he was convinced that no half-hearted, localised measures would be adopted—every dog in the kingdom would be muzzed at once, and the result would be that, instead of its taking two or three years to get rid of rabies, as had now practically been the case, there would not be a rabid animal left in the kingdom in six months. The Pasteur system for hydrophobia must remain in force and be of great value so long as there were rabid dogs in existence, and so long as the disease could be transmitted by the wilder animals; but in civilised countries and in those where wolves did not exist universal muzzling would do away with any necessity for the Pasteur treatment.

Tuberculosis.

Referring to the question of tuberculosis, he said that extremists of all kinds had had their say, and we were gradually coming to see that the spread of tuberculosis was not necessarily according to any one method, but that there were many forms of distribution. We had now got over what might be termed the time of panic. With the growth of our knowledge of the means of the spread of the disease had come light on the methods of prevention, and we were now even far more hopeful as regarded treatment; but withal we had come to see that it was only by the co-operation of medical men, of veterinary surgeons, of public administrators, and of those who were interested in the raising of cattle and the supplying of milk that we could eliminate tuberculosis. It was for that reason that they were so thoroughly instructed in the use of tuberculin, by means of which, as was now recognised, the most latent forms of tuberculosis might be made out. They were to show the farmers that it was to their interest to have nothing but healthy stock, they had to prove to them that some of their stock was unhealthy, and that quite apart from the danger that a tuberculous animal might be to the community, and quite apart from the fact that it was possible now and again to feed a tuberculous animal so that it might be disposed of at a fair market price, that he was dealing with the disease which might render it impossible, or, at any rate, uneconomical, to feed cattle for the market. The more serious aspect of the question—the danger to the public health—could not be demonstrated to the farmer in the same way as the less serious aspect could, and, therefore, he was not so ready to receive it; but once let him be convinced on either point and he was satisfied that there would be little difficulty in prevailing on him, first of all, to submit his animals to the tuberculin test; and, secondly, to place them under such conditions that the danger of the spread of tuberculosis might be considerably minimised.

The quantity of iron ore exported from Sweden during the first half of the present year is returned at 467,246 tons, as compared with only 363,275 tons in the first six months of 1898.

Taking as unity the intrinsic brightness of a sheet of Bristol cardboard illuminated by a standard candle at one mètre distance, that of a candle-flame itself is from 12,000 to 22,000; a kerosene lamp flame 97,000; and platinum at its melting-point, 1,008,000.

SCIENTIFIC NEWS.

The small planet which was observed by M. Jean Mascart, of the Paris Observatory, on August 26, as mentioned on p. 113, has been proved to be the same as the discovery of M. Goldschmidt, of Paris, on Oct. 26, 1854, which is known as Pomona, No. 32.

Holmes's comet (III. 1892) was rediscovered by Mr. Perrine, of the Lick Observatory, on June 11; but it appears that no one else has seen it, although it is still approaching the earth. It is considered probable that its detection in 1892 was due to some temporary increase in brightness. The period is calculated to be about 6·9 years, and another return is calculated for 1906. It is a remarkable body, because its orbit is more nearly circular than that of any other comet, and is included between the orbits of Mars and Jupiter. When Mr. Perrine picked it up on June 11 last, it was under exceptionally good conditions, very faint and difficult to observe.

Mr. J. E. Gore, F.R.A.S., has another article on suspected variable stars in this month's *Knowledge*, and says that the stars mentioned "look very suspicious, and seem deserving of further examination."

It is stated that the plans for the University of California, submitted by M. Bernard, of Paris, have been awarded the first prize. The buildings will cost more than fifteen million dollars, and will be erected at the expense of Mrs. Phebe A. Hearst.

In the course of the meeting of the International Geographical Conference at Berlin a discussion took place on the approaching German and English Antarctic expeditions. Sir Clements Markham said that these parallel enterprises would form the greatest geographical undertaking that the world had ever seen, and he confidently anticipated that the domain of human knowledge would be vastly extended by them. They would also promote good fellowship between the two nations. The hearts of all geographers rejoiced to see the countrymen of Humboldt, Ritter, and Kiepert united in this work with those of Banks, Rennel, and Murchison. Prof. Drygalski, who will be the leader of the German Antarctic expedition, gave details of its scientific and other equipment. Dr. Nansen also spoke, and expressed strong doubts as to the existence of a great continent in the Antarctic regions. He congratulated the German nation on its co-operation with the English, and expressed the opinion that it would inaugurate a new era of exploration.

The Gresham lectures on Geometry will be delivered by Mr. W. H. Wagstaff, M.A., on Oct. 10, 11, 12, and 13; on Law, by Mr. G. H. Blakesley, M.A., Oct. 17, 18, 19, and 20; on Rhetoric, by Mr. J. E. Nixon, M.A., Oct. 31, Nov. 1, 2, and 3; on Divinity, by Rev. H. E. J. Bevan, M.A., Nov. 6, 7, 8, and 10; and on Astronomy, by Rev. E. Ledger, M.A., Nov. 14, 15, 16, and 17. The Music lectures will be delivered by Sir Fredrick Bridge, Mus.Doc., Oxon., on Oct. 24, 25, 26, and 27, the first at Gresham College, and the other three at the City of London School.

The death is announced of Dr. Theodore Puschman, professor of medical history at the Vienna University in his 56th year. Prof. Puschman, an authority in his department, was known in England through the translation into English of his "History of Medicine in Vienna during the Last Hundred Years." He was a frequent contributor to the medical annual published by Profs. Virchow and Hirsch.

Dr. Alexander Wallace, who had distinguished himself in the study of botany and entomology, died on Sunday at his residence in St. John's-terrace, Colchester, at the age of 70. He received his professional training at St. Bartholomew's Hospital and at Oxford, where he took the M.B. and A.M. degree in 1858, having been elected a member of the Royal College of Physicians, London, the preceding year, and in 1861 proceeded to the M.D. degree. He was for a time Physician to the Metropolitan Free Hospital, and the St. Pancras and Northern Dispensary, and he was a member of the Entomological Society of London, Acting Physician to the Essex and Colchester Hospital, and a member of some of the learned societies. He was well known and deservedly popular in sporting circles, taking

special interest in cricket, for which he gained his "blue" when at Oxford. In later years he attained no less distinction in tennis.

The medical schools opened on Monday, and some notable addresses were delivered, the more important of which will be found in another part of the paper. In her address to the students of the London School of Medicine for Women (Royal Free Hospital, Gray's Inn-road), Mrs. Garrett Anderson, M.D., referring to a much-debated subject, said:—There can be no doubt that the experimental method of teaching is the true one, whether much or little of any subject is wanted as a foundation for the scientific study of medicine. This method in physiology does not necessarily include vivisection. At this school there never has been any vivisection. The tissues of many animals retain their vital properties for some little time after death, and also after all power of receiving sensation has been destroyed. The study of pathology, or the causes and effects of departures from health, ought, if possible, to precede work in the hospital wards. The student should know what disease is before she attempts to recognise it in individuals. All honest quackery is based upon complete ignorance of pathology—dishonest quackery on the conviction and the hope that the patient is completely ignorant of it also. In studying how to investigate the meaning of symptoms in a patient the best rule is to look at everything and to guess at nothing. In the words of Sir William Gull, "We make many more mistakes by not looking than by not knowing."

It is asserted that the "open-air" treatment for consumption has been attended with much success at the North London Hospital for Consumption, Hampstead Heath, as, out of 183 cases since January last, 43·7 per cent. have left the institution to return to work. It is not stated whether they were "cured."

A fatal result attended the trial on Saturday last of a new "flying machine" in a field at Stanford Hall, the seat of Lord Braye, near Market Harborough. The contrivance is the invention of Mr. Percy S. Pilcher, who has for a considerable time been making experiments with the object of devising such a machine. It appears that Mr. Pilcher had given several years to the study of flying machines, and had from personal acquaintance with Mr. Hiram Maxim so realised the difficulties to be overcome that he manufactured a machine on the lines of that designed by Herr Lilienthal as being, in his opinion, the nearest to perfection. The machine, with which he had previously made several successful ascents, resembled a great eagle. The two wings were covered by about 170ft. of cloth, and the tail, or rudder, with its sails, was fixed about 2ft. from the main body of the machine. The frame itself consisted of bamboo, with wires like the ribs of an umbrella. The weather on Saturday was most unfavourable for such a trial. Rain fell heavily up to 2 p.m., and gusty winds followed. After several ineffectual attempts to start, a signal was given about twenty minutes past four, and Mr. Pilcher rose slowly in the machine until he had travelled about 150 yards and had risen to a height of about 50ft. or 60ft. Then a sharp gust of wind came, and the tail of the apparatus snapped. Instantly the machine turned completely over and fell to the earth, Mr. Pilcher being underneath the wreckage. As will have been seen in the newspapers, Mr. Pilcher, unfortunately, succumbed to his injuries.

The veteran aëronaut Mr. Henry Coxwell, writing to *The Times*, says that balloons have their tender and vulnerable parts, and that they may be destroyed by marksmen who know how and where to strike with precision. He says:—"If the officers who have been sent out to South Africa with the aëronautical section should rely with undue confidence upon the safety of their balloons against 'rifle fire and field artillery,' I beg to remind them that one war balloon at Santiago was brought down by the splinters from shrapnel, and that holes made by bullets may, under certain conditions, cause a hasty descent, though I freely admit that it depends entirely upon where the envelope is perforated. To my mind, after an aëronautical experience of nearly 60 years, the risks to be encountered over the heads of sharpshooters who may be provided with suitable weapons, having ample swing, exact elevation indicators, and perhaps a ripping long-range messenger to send forth for destructive objects, should not be lightly pooh-poohed because dynamite shells in mock battle on a trial drop should have reached the ground with terrible effect."

The buoy which was found recently, and was believed to be the "North Pole buoy" to be dropped by Andrée as he passed over or near the North Pole, was examined at Stockholm, but nothing definite was learned. According to a Reuter telegram, "At the examination of the buoy Capt. Svedenborg, who was present at the ascent of the balloon, stated that the ring of the buoy did not seem to be made fast. The buoy, therefore, could not have been let down by means of a cord. The buoy was then opened. First of all the copper cover fixed to the rim underneath the buoy was sawn off, and some sea sand fell out. A copper head, with a tube of the same material attached, was then taken out. Inside this was some water. The copper tube was then sawn off. In the lower part of the tube was an indiarubber plug, and on it a little sand. Inside the tube was a coating which seemed to resemble paper, but which a microscopical examination showed to be growth of algæ. Prof. Nathorst declared that the buoy could not have been carried from the Pole to King Charles Island. Capt. Svedenborg expressed the opinion that the buoy had been thrown out empty. Prof. Montelius said it had not been shown that the buoy had been thrown out empty. Prof. Nordenskjold said that a search would be made next year at King Charles Island." It appears from further telegrams that the substance "resembling paper" proved to be algæ.

Another wonderful discovery is reported from Vienna—this time in connection with rapid telegraphy. It is asserted that the new apparatus—the invention of two Hungarian engineers—will send over twenty words a second, and it is further asserted that in the presence of the representatives of the German Ministry of Commerce and others, a number of telegrams were exchanged between Budapest and Berlin, and it was found that the average rate of wiring with the new apparatus was 22 words per second, giving 1,320 per minute, and over 79,000 per hour. The new apparatus is a marvel of ingenuity. The messages are first perforated on a slip of paper by a kind of typewriting machine. These signs are then transmitted at lightning speed over the wires and received as a photogram at the other end, where they can be read and prepared for delivery with the utmost ease and celerity. The inventors, Messrs. Pollak and Virag, have, it is asserted, made a discovery which will produce many changes in telegraphy. Instead of forests of telegraph lines now seen stretching in all directions, one single wire between each station will amply suffice for the most pressing emergency. Blocking of lines will cease, while the cost of telegraphic service will be considerably reduced. It will be advisable to take this item of news with an "open mind." Further experiments are to be made soon between Budapest and Vienna.

A rather important memoir has been presented to the Paris Academy of Sciences by M. Considère. It is important to engineers, architects, and builders, and refers to experiments on the variations in volume of Portland cement resulting during the setting. The expansion of prisms of cement were studied by M. Considère for two months, comparisons being made between loaded and unloaded prisms whilst under water. It was found that the expansion increased regularly, but were much less with mixtures of cement and sand than with pure cement.

Electric signalling on railways seems to have been developed in America if the following statement is true. It is stated that the signalling on the whole of the Pennsylvania railroad system is now operated electrically. When a train passes a signal bridge it closes an electric circuit which moves a signal semaphore to the "danger" position. When the train passes beyond the next bridge a circuit is opened and the signal indicates that the block from which the train has just passed is clear. Finally, when the train passes beyond the third bridge, another signal arm on the same post drops, showing the driver of an approaching train that there is nothing on the next two blocks ahead. It is not stated, however, whether signalmen are dispensed with altogether. The idea is comparatively old, but the details have not been explained.

The new International Code of Signals for use by the mercantile marine will come into use shortly—that is, if owners and masters of vessels will adopt it and use it. An official of the Board of Trade is reported as saying that a "code on the Morse system, for the use of ship-masters who may desire to signal at night, is embodied in the new book of 'International Signals,' which will presently come into use. The adoption of the system will be purely optional, and it will rest with owners to say whether their ships shall be fitted with the necessary appliances or not. A special knowledge of the Morse principle will, of course, be necessary, and it does not follow that those who control the signalling stations of the coast will adopt the suggestion. With a general use of such a code at night the advantage would, I am sure, be very great, especially as a means of warning vessels against impending danger."

It is announced that the Bristol Docks Committee intend to recommend a dock extension scheme to the City Council which, if carried out, will enable the largest steamers to enter Portishead.

The French Minister of Marine has signed an order for the immediate construction of four new submarine boats at Rochefort on a new plan which is not that of the *Narval*. There will be no effort to multiply vessels of the *Narval* type until entirely conclusive results have been obtained from the trial of that boat. The plans of the vessels, which will be named *Farfadet*, *Gnome*, *Korrigan*, and *Lutin*, have been prepared by M. Maugras, first-class naval engineer. The *Journal's* Toulon correspondent telegraphs that M. Goubet hopes to make preliminary trials shortly in deep water with a submarine boat propelled by oars alone without the use of electric power. By this primitive means he expects to obtain a speed of four knots.

USEFUL AND SCIENTIFIC NOTES.

It is stated that the use of steel ties for experimental purposes on the New York Central Railroad has not given satisfactory results. They are durable, but are hard to line; the ballast shakes away from them, and they give a rattling sound from the stone ballast and from the bolts. Some are said to have proved so unsatisfactory that they are now being removed and replaced with oak ties.

The yield of rubber trees has been estimated by experts to be as high as 3lb. yearly from the sixth year. A leading authority does not consider that trees should be tapped before their ninth year, and says that 1lb. of rubber, say 2½lb. to 3lb. of milk, is a good annual yield. The milk may be extracted twice each year, during the rainy season, about two months after its commencement, and again towards its close, the best time being when the tree has dropped its leaves, and when the sap is most abundant and active.

Prize for Life-Saving Apparatus.—The Board of Trade have been informed by the Foreign Office that a prize of 100,000fr. has been founded by the heirs of the late Mr. Anthony Pollok, of Washington, to be awarded during the Universal Exhibition, Paris, 1900, to the inventor of the best apparatus for the saving of life in cases of maritime disaster. The prize is open to universal competition. This sum is now in deposit with the American Security and Trust Company of Washington, D.C., and will be paid over to the successful competitor when a decision shall have been rendered by an appointed jury and formally communicated to the Secretary of State of the United States through the Commissioner-General of the United States to the International Exhibition of 1900. The juror selected on behalf of the Government of the United States is Lieut. William S. Sims, U.S.N., Naval Attaché of the Embassy of the United States at Paris. In considering the award the jury will be governed by the following conditions:—(1) The total amount of the prize may be awarded to a single individual on condition that the invention is of sufficient practical value and importance to justify the proposed award; (2) should several persons enter inventions of equal value, the jury, as it shall consider right and just, may award a portion of the prize to each; (3) should none of the inventions entered be of sufficient value to entitle it to the prize, the jury may reject any and all of them, but at the same time shall be empowered to indemnify competing inventors in such amounts as may be deemed advisable. The instructions to competitors will be issued in due course by the jury, with the sanction and approval of the authorities of the French Exhibition. These will be distributed upon application. Correspondence, however, may be addressed to the members of the jury at Paris, or to Mr. Charles J. Bell, president of the American Security and Trust Company, No. 1,405, G-street, Washington, District of Columbia, U.S.A.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, *332, Strand, W.C.*

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE REPORT OF THE SAVILIAN PROFESSOR FOR 1898—THE GREAT GLOBE AT SWANAGE—THE AGE OF THE EARTH—LUNAR CRATER NEAR TIMOCHARIS—STAR MAGNITUDES—THE TELESCOPE—THE DIPLEIDOSCOPE—POETRY OR PHYSICAL FACT?—THE DELUGE—THE MOSAICAL DAY—LIGHT (AND DARKNESS?) IN A NEBULA—THE "AUTHORITY" OF THE ROYAL ASTRONOMICAL SOCIETY—BICYCLES AND PERAMBULATORS—THE NINTH SATELLITE (?) OF SATURN.

[42896.]—The annual report of the Savilian Professor to the Visitors of the University Observatory at Oxford follows on somewhat familiar lines, the measurement and reduction of the plates for the Astrographic Catalogue constituting its most prominent feature—586 plates out of the 1,180 required have been measured, and 525 of them completely reduced. Incidentally I may remark that Prof. Turner has found that he sometimes gets between 300 and 400 stars on a plate 2° × 2° with only 20 seconds exposure, and that with three minutes exposure in the region of this area, whose centre was in R.A. 19h. 43m. and 29° North Declination, no less than 2,440 stars were measured. To avoid having an unnecessary number of stars on the plate, it has been found necessary to reduce the time of exposure. As the result of the laborious investigations carried out by Prof. E. C. Pickering, of Harvard, it has been found that with a photographic doublet lens large fields are obtainable sensibly free from optical distortion. This being so, the Savilian Professor regards the scheme of the Astrographic Chart with its hours' exposure of plates embracing regions only 2° by 2°, is more or less a waste of time and labour, and has indefinitely postponed the taking of these long-exposure plates. The rest of the report may be summarised by saying that the great dome is so leaky that it is to be replaced by a new one costing £440, and that Prof. Turner continues to insist on the urgent necessity for a residence at the Observatory. One reason given for this is its unprotected state; in illustration of which it is mentioned that several windows have been broken by bullets from catapults. Whether undergraduates are suspected of this gross misuse of an ancient weapon, or whether it is supposed to be the work of the ubiquitous British boy, is not mentioned. In conclusion, I must not omit to mention the valuable addition to the Observatory Library, in the shape of the books of the late Mr. George Knott, F.R.A.S., which have been aquired from his executors.

Can any brother-correspondent furnish me with information concerning the great globe at Swanage? A friend of mine has sent me a photograph of it, unaccompanied, however, by any details or explanation. From certain data cut on a slab on a wall in front of it, it would seem to have been erected for some astronomical purpose, and hence I am curious to know its history, and the specific object for which it was constructed.

As I can scarcely be accused of any disposition to depreciate or undervalue mathematics, I have no hesitation in expressing my gratification at the direct way in which Sir Archibald Geikie has joined issue with Lord Kelvin in his admirable address on Geology delivered at the meeting of the British Association at Dover. As I have had occasion to remark before in these columns, too many people are apt to imagine that because the equations of a great mathematician are irrefragable, that hence the conclusions which they were framed to establish must be equally indisputable, wholly ignoring the fact that *everything depends upon the soundness of the data on which they are founded.* Viewed in this light, and considering our curious ignorance of the solar temperature and of the rate and method of the sun's cooling, Lord Kelvin's calculations, however elaborate and ingenious, seem very little better than worthless as furnishing a categorical determination of, or even probable guess at, the real age of the earth.

As I am far away from my own home and observatory, I am in no position at present to reply to "R. P." (letter 42839, p. 134) on the question as to the existence of his small crater near Timocharis. I will look for it on my return.

As by "the greatest magnitude star" I presume that "Silverplume" (letter 42840, p. 134) means the smallest star visible in his 2·85in. achromatic. I may say that he ought to be able, with a power of 120 or upwards, to glimpse, by fits, on a moonless night, a star of the 11·5 magnitude. For the reason given in my previous paragraph, I cannot furnish him with such a list of stars as he asks for, but can only supply one of a few of the brighter ones. Of the first magnitude Aldebaran and Altair, β Geminorum, 1·1; Regulus, 1·4; α Persei, γ Orionis, and β Tauri, all 1·9; α Arietis, 2; ζ Orionis, γ Geminorum, and α Hydræ, 2; Polaris, γ^1 Andromedæ, and κ Orionis, 2·2; β Cassiopeiæ, and η Canis Majoris, 2·4; α Ceti and α Leporis, 2·7; γ Pegasi, γ^2 Ceti, η Tauri, and ϵ Persei, 3·0; β Trianguli, γ Persei, and ζ Persei, 3·1; δ Andromedæ and ξ Geminorum, 3·4; ι Ceti and ϵ Cassiopeiæ, 3·6; μ Andromedæ and γ Tauri, 3·9; ν Geminorum, 4·0; o Piscium and ξ^1 Ceti, 4·4; ϵ Piscium, 4·5; δ Piscium, 4·6; 20 Ceti, γ^2 Andromedæ, and 6 Cancri, 5·0; 51 Geminorum, 5·4; 67 Ceti, σ Arietis, and η Cancri, 5·5; ω^1 Tauri, 5·8; 99 Tauri, 3 Cancri, 19 Sextantis, and 55 Leonis, 6·0; 28 Tauri, d^2 Cancri, and p^2 Leonis, 6·2; 3 Arietis, 16 Tauri, A^2 Tauri, 3 Geminorum, 8 Geminorum, and 36 Sextantis, 6·5; 83 Cancri, 6·6; 11 Tauri, 35 Virginis, and 94 Virginis, 6·7; γ^1 Ceti, 6·8; 34 Sextantis, 7·7. This is as far as I can carry the matter in the absence of the "Harvard Photometry," which, of course, I have not with me here. As I have spoken of Aldebaran and Altair as being of the *first* magnitude, I may just add that stars brighter than the two mentioned have fractional magnitudes assigned to them. Thus Arcturus is said to be of the 0·0 magnitude, Capella and Vega both 0·2, Rigel 0·3, and Sirius (the brightest star in the heavens) − 1·4.

I cannot answer query 96684 (on p. 144) for the simple but sufficient reason that I have only the number of the English Mechanic for the current week at the place whence I am writing, and have not the slightest idea what Mr. Clarke's letter (42784) was about.

Certainly "Tempus" (query 96695, p. 144) can obtain the time within two or three seconds with the dipleidoscope—but only at apparent noon on a sunny day.

I scarcely remember a more disingenuous disputant than Mr. Garbett (vide letter 42875, p. 158). My reference was to Psalm cxiv. 3 and 4; in the latter of which we read: "The mountains skipped like rams, and the little hills like lambs." Now, either this is a statement of physical fact or it is not. "The earthquakes that accompanied the exit of the Israelites from Egypt" have their existence in the imagination of your correspondent only, for assuredly the Bible says not one syllable about them. The evil fashion of making blatant assertions in the hope that their readers will not trouble to check or verify them, is one which cannot be too strongly condemned. Any one must be childishly ignorant of the very rudiments of geology and palæontology, who can believe that bone caves (such for example as Kent's Hole at Torquay) were filled with the remains we find *stratified* in them in a few weeks, months—or, for the matter of that, thousands of years either.

Mr. Rouse, who follows him, in letter 42876, apparently errs through crass ignorance alone. Whom does he expect to believe that the shells found at an altitude of 15,000ft. on the Pamir Mountains were deposited by the legendary Noachian Deluge? And how does he correlate the alleged salvation of one man and his wife, that of the seven men and seven women, the re-creation of both men and brutes by Nanabusha, &c., with the tradition preserved in Genesis? But I must do him the credit of admitting that he simply errs apparently from knowing nothing whatever of science, natural or physical.

Mr. Hardy (letter 42877, p. 159) may rest assured that the compiler of the story from the account or accounts of the Elohistic and Jehovistic narratives of the Creation which have come down to us in Genesis, believed that the visible universe was created in seven literal days of 24 hours each, and that that narrative was not left to deceive mankind until Mr. H. was raised up at the end of the 19th century to reveal its nature and true significance to mankind. Why, I thought that we were commanded to rest on the seventh day, specifically because "in six days the Lord made heaven and earth, and rested on the seventh day." If this was Mr. Hardy's "cosmic" one, I can only complain that I, for one, have failed to enjoy so long a period of rest, and alas! how many poor creatures there are who would have been only too thankful for it!

It would be a mere waste of time to notice letter 42878, p. 159, further than to say, in connection with its concluding paragraph, that if, as is practically certain, the new star which appeared in the Great Nebula in Andromeda in 1884 was immersed in the nebula, it would enjoy a perpetual light of vastly inferior brilliance to that of its own self-luminosity, and not have any evenings at all.

In Mr. Wood's letter (42895) on "The Mistakes of Authorities," on p. 163, he refers to "An example. . . . . furnished in the *Monthly Notices* of the Royal Astronomical Society, Vol. LVII. p. 73." But as he does not give the slightest hint as to the nature and character of this example, and I have no means of access to the R.A.S. publications at the place whence I am writing, this conveys little or nothing to my mind. When, however, your correspondent talks of "errors possibly sanctioned by that learned body," it may be as well to inform him that the authors of papers which appear in our *Monthly Notices* and *Memoirs* are alone responsible for any statements they may contain, and that the Society *quâ* Society does *not* sanction officially either their statements of fact or possible mistakes. By the bye, a sentence seems to have dropped out of Mr. Wood's communication altogether; for in the sentence beginning: "In *Nature*, Vol. V. p. 422," he speaks of "Observations pertaining to this subject." What subject?

I may tell "Rota" (query 96759, p. 168) that legally perambulators have no more right on a footpath than bicycles, both being wheeled carriages, but that the police wink at their presence. The Highway Act contains the information your querist needs. I have before now invoked the aid of the police to remove a perambulator when the footpath has been obstructed by two of them being driven abreast.

It happened, oddly, that a very short time since, an old friend of mine, a well-known astronomer, in writing to me, asked substantially the same question as that put by Mr. Hindawser (in query 96773) on p. 169; but I could only tell him as I now tell my querist, that from the day that the announcement of the alleged discovery of a ninth satellite to Saturn was made down to the instant of this present writing, I have heard nothing whatever more about it. If my memory serves me, its discoverer pronounced that it must either be a ninth attendant on the ringed planet—or something else; the former for choice. Dickens speaks of "Theatrical stars, who come out—and go in again," an example, apparently, followed by "Phœbe."

A Fellow of the Royal Astronomical Society.

α LYRÆ: TO MESSRS. ESPIN AND ELLISON.—ϵ LYRÆ.—LIGHT POINTS ON THE MARE CRISIUM: TO MR. GOODACRE.

[42897.]—May I, as a small telescopist, express my gratitude to Mr. Espin for his interesting data and diagrams about α and ϵ Lyræ in his letter No. 42873? These objects are beautifully situated just now for the amateur's evening hours, and the information so kindly tendered by Mr. Espin is just what I wanted, in common, no doubt, with many other owners of small telescopes. Though with apertures much below 4in. we can hardly follow him into the regions of the Debilissima, yet the other objects are not out of our reach, as I can assert from my own experiences, for on Sept. 27, about 10 p.m., when the air was beautifully clear after the thunder-shower which had passed over London, I succeeded in distinctly glimpsing the companion to Vega with power 50 of my 3¼in. Gregorian by Short, making sure about it by estimating its P.A. and distance exactly as now given by Mr. Espin, without any previous knowledge of its whereabouts whatsoever; and on Sept. 30 I glimpsed it again with the same power. This I owe to an excellent advice most kindly given me by Mr. Ellison—viz., to use low powers for faint *comites* to bright stars. In the same way I have now succeeded in seeing the companion to Polaris, though before it resisted all attempts with high powers. I am sure I have Mr. Ellison's sanction in repeating his most useful hint for the benefit of others, knowing what a delight this amiable and experienced observer takes in assisting students with inferior instrumental means.

As regards the other object dealt with by Mr. Espin, ϵ Lyræ, the two doubles must certainly be within reach of small achromatics, as my Gregorian divides them both neatly. The 10th-mag. star between them, not depicted by Mr. Espin, is conspicuous, but of the Debilissima I have as yet seen none. The mystery surrounding the supposed fainter *comites* of Vega, *seen* by so many experienced observers in common with Mr. Ellison, and *not* seen by equally great observers in common with Mr. Espin, seems very fascinating. My further enlightenment on this subject will, I am sure, interest all who delight in gazing at that incomparably beautiful sun "Vega."

I should like to take this opportunity of asking Mr. Goodacre, or anyone else, for kind information about the following observation on the moon. On Aug. 22, at about 10 p.m., 1½ day after full moon,

I noticed, in very clear air and with p. 135, on the southern part of the Mare Crisium, a number of faint points of light, perhaps a dozen or more. On looking more intently, these points appeared to be crossings or bends of still fainter lines of light, running parallel and cutting one another in almost regular rhombs. They were plainest in the south-eastern part, gradually dying away towards west, and not visible northwards of Picard. Any explanation will be gratefully received.

C. H. Stielow.

THE GROUP ε LYRÆ.

[42898.]—The Rev. T. E. Espin will find a diagram of this group, accompanied by an exhaustive historical account up to that date, in the *Observatory* for Dec. 1880, by the late Mr. Henry Pratt, of Brighton, and Mr. J. Gledhill, of Bermerside. Two of the stars shown in Mr. Espin's diagram, preceding the Debilissima, appear to be Lamont's stars, marked H and I in Mr. Pratt's diagram, in which there are also some stars following the Debilissima that seem to be missed by Mr. Espin, one of them (H) being seen by the late Mr. H. Sadler and myself independently.

Belfast, Sept. 30. Isaac W. Ward.

[42899.]—In the *Astronomical Register* for December, 1864, is a drawing of this group by Dawes, which agrees very fairly with that of Mr. Espin. It represents the group as seen at Admiral Smyth's Observatory (apparently) in 1833. In Mr. Dawes' drawing a star is given north preceding Mr. Espin's No. 5, which is not in Mr. Espin's sketch. The rest of his stars correspond with Mr. Espin's. There is a sketch by A. Hall in Chambers' "Handbook," 4th ed. Vol. III. p. 42, which differs somewhat from both. R. J. Ryle.

VARIABLE STAR OBSERVATIONS, SEPTEMBER, 1899.

[42900.]—T Cassiopeiæ has been declining for the last five months, and is now nearly at minimum brightness. It was observed 11·3 magnitude, September 27.

R Aurigæ. This star has gone down more than five magnitudes in four months. The light curve being very regular, on September 28 it was 12·4 magnitude, and for the next two or three months will be a very faint and difficult object. The minimum will probably occur in November.

T Aurigæ. The place of this variable is again coming into a convenient position for observation. It was looked for on September 26, and no trace of the star could be seen, though the air was very clear. On February 12, 1892, this star was 3 6 magnitude, and now it has completely disappeared.

S Coronæ has gone down about four magnitudes during the last seven months, and was 11·8 magnitude September 26. It was small, faint, but well defined, and is getting toward a minimum.

R Ursæ Minoris has of late been unusually faint, and was 10·4 magnitude on September 26—this is the faintest record since observations began, Nov., 1891. The entire light-range of this star is less than two magnitudes.

T Draconis passed a maximum, 8 0 magnitude, August 16. The interval since the previous maximum, July 2, 1898, is 410 days.

S Cygni having now been invisible for five months, the reappearance may be looked for during October.

Instrument in use 6·4in. equatorial refractor. Weather has continued favourable, and observations been made on sixteen nights. C. E. Peek.

Rousdon Observatory, Lyme Regis.

THUNDERSTORMS.

[42901.]—Noticing some letters in "Ours" recently relating to lightning phenomena, I think that perhaps the following may interest your readers.

During a thunderstorm which occurred one day in August of last year, a gamekeeper took shelter in a cart-shed adjoining some other farm buildings situated upon the top of a hill in the parish of High Beckington, N. Devon. At a distance of about 15 yards, and under the spreading branches of a tall elm-tree, a number of fowls were clustered together, sheltered by a bank and some elder-bushes. The keeper was looking at the poultry, when a vivid flash of lightning occurred, followed instantly by a crash of thunder. Simultaneously he received an electric shock, which he describes as "though someone had struck him violently over the knees." He then noticed that two of the fowls were lying dead upon the ground, and several others a few feet distant were seen to "spin round and round and flutter on the ground"; but they speedily recovered. That evening I had the unique experience of dining off a pair of fowls killed by lightning.

I visited the scene immediately after the storm, and what struck me as remarkable—knowing that an electric discharge always follows the line of least resistance—was that neither the elm-tree nor the adjacent buildings were struck, and that the fowls were killed beneath foliage which escaped injury. Singed feathers upon the dead birds marked the course of the electric discharge.

Could this have been a secondary discharge due to induction, the primary flash occurring between clouds immediately overhead?

R. Greenwood Penny.

[42902.]—There was a thunderstorm here (Dublin) on the afternoon of the 30th ult. I noticed while watching the lightning that the smoke from the chimneys was crossing the street in the opposite direction from the clouds. After a time there was a change in the direction of the smoke, which seemed to move in the same direction as the clouds. On this change the thunderstorm ceased, except for one long peal several minutes later. I shall be glad to know if anything similar has been noticed elsewhere. W. H. S. Monck.

ABSOLUTE ZERO OF TEMPERATURE.

[42903.]—There have been numerous references to the above in letters lately, and the arguments supposed to establish the existence of the zero have been put forward more or less completely. Now, I ask, is an absolute zero conceivable? Can we possibly imagine such a degree of cold that it can be no colder? I contend that it is as impossible as to conceive of time, a time before which was no time at all. Has anyone gone to the other extreme and put a limit, or fixed an *absolute maximum* of heat? It would seem quite as logical. "J. M. W." (letter 42894, p. 162) says the absolute zero can be looked upon "as a point where all motion of the molecules and atoms ceases," and goes on to say "and consequently as a temperature below which we cannot go." Does this follow as a consequence at all? I cannot see the connection. Would it not be as truthful to say that at a temperature of so and so everything with which we are acquainted exists in a state of gas, *therefore, nothing can be one degree hotter?* "Fahrenheit" based his thermometric scale on a supposed absolute zero, bringing it into a good deal of ridicule, and making it meaningless. Will not the same fate overtake those who assume the latest "zero," found a scale upon it, and say that ice melts at 273·14 "absolute"?

Perhaps it is my obtuseness that prompts these questions, or it may be that a "little knowledge, &c.," according to the old saying; but may I ask if this latest theory bears examination, and satisfies such men as your correspondents "F.R.A.S." or W. H. S. Monck? F. J. G.

GENIUS AND HEREDITY.

[42904.]—On p. 152, Prof. Axenfeld's theory that all men of genius are first-born sons is mentioned; and the list of great names which follows seems to afford great corroboration. On testing the hypothesis, however, one finds it somewhat delusive, for many eminent men have not enjoyed the advantages of primogeniture. Thus, amongst those who were not, I think, the eldest sons were Dalhousie, Clarendon, the Pitts, Walpole, Wilberforce, Gladstone, Bach, Bellini, Mozart, Cherubini, Wagner, Schubert, Calvin, Butler, Taylor, Milman, Chateaubriand, North, Montaigne, Beaumont, De Quincey, Coleridge, Scott, Boyle, Humboldt, Bacon, Franklin, Thackeray, Sheridan, Tennyson, Van Dyck, Rembrandt, Sherman, Washington, Wallace, Peter the Great, Wellington, and Napoleon I. Indeed, it appears to me that the hypothesis would be quite untenable were it not that men of genius who never had any brothers or sisters are included amongst the "first-born." One is obliged to admit, however, that these other children must have been nonentities, because they weren't even born.

J. Dormer.

THE RAT AS A PROPAGATOR OF DISEASE.

[42905.]—When the Health Officer of Manchester recently proposed, as a precaution against plague being introduced by means of vessels from the Mediterranean, that rats should be extirpated, the proposal was in certain quarters derided. These attempts to ridicule the suggestion do not, however, seem to have found an echo in Bombay, where the evidence in favour of what may be called the rat theory is regarded as quite unassailable. The subject is referred to in some of the Indian papers to hand by this week's mail, and it is mentioned in support of the Manchester official that in Canton the local authorities paid large rewards for the destruction of these unpleasing rodents, 20,000 of which were as a consequence accumulated outside one gateway alone. I am told by a gentleman who has made a profound study of the plague, and who has intimate personal experience of one of the Bombay epidemics, that no possible doubt can exist as to the mild manner in which the disease first presents itself. There is, it appears, one type of plague known as *Pestis benignans*, the virus of which is not of sufficient strength to endanger human life until a generation of rats has been killed and a generation of men mildly attacked. This is followed by malignant plague, when all but a few of the sufferers are carried off. Then comes the period of decline, the various stages covering in the case of the three Bombay epidemics just thirty weeks—from October to April.

I suppose we are all familiar with the old wives' notion that the advent of rats to a house is the precursor of death? I wonder if superstition in this case, as in so many others, rests on a misunderstood fact? Alec.

TOOL-GRINDING MACHINE.

[42906.]—It is possible this is the only one on the market, and that Mr. Ilsley is an independent inventor. If sold cheaply, it may have a ready sale.

I wish, however, to point out that it appears (to all intents and purposes) in Vol. XX., at p. 21. I made one then in wood, and have used it occasionally during the last 20 years, adding to it a device to prevent the stone wearing through unequal pressure. I now grind entirely by hand, and without guide, unless for slide-rest tools, when I sometimes use the block suggested by "J. K. P." No. 7.

MILLWRIGHT'S WORK.

[42907.]—Figs. 58, 59, and 61 (p. 150) exhibit a defect in design which is only too common. I allude to the bevelled ends of the set-screws.

Though less important, perhaps, for loose collars than when employed to fix work through which power is transmitted, as a matter of principle, the end of a set-screw should always be turned cylindrical for a distance, say, $\frac{1}{16}$th greater than the depth of a corresponding cylindrical hole in the shaft. When properly fitted, there is no tendency to wedge the screw out as in the common plan, and there is no comparison if, as is sometimes the case, any power has to be transmitted through the screw-point.

Here again, however, would be bad practice: a screw-point should not be used to prevent rotation under such conditions, but merely to prevent sliding, the rotary force being transmitted by a key.

Glatton.

LEVERAGE OF THE LOCOMOTIVE DRIVING-WHEEL.

[42908.]—The last three lines of the article with this title (see p. 154) are incorrect. A locomotive piston is *always* moving in one direction, though at varying velocities, in relation to the ground—including the dead centres. Glatton.

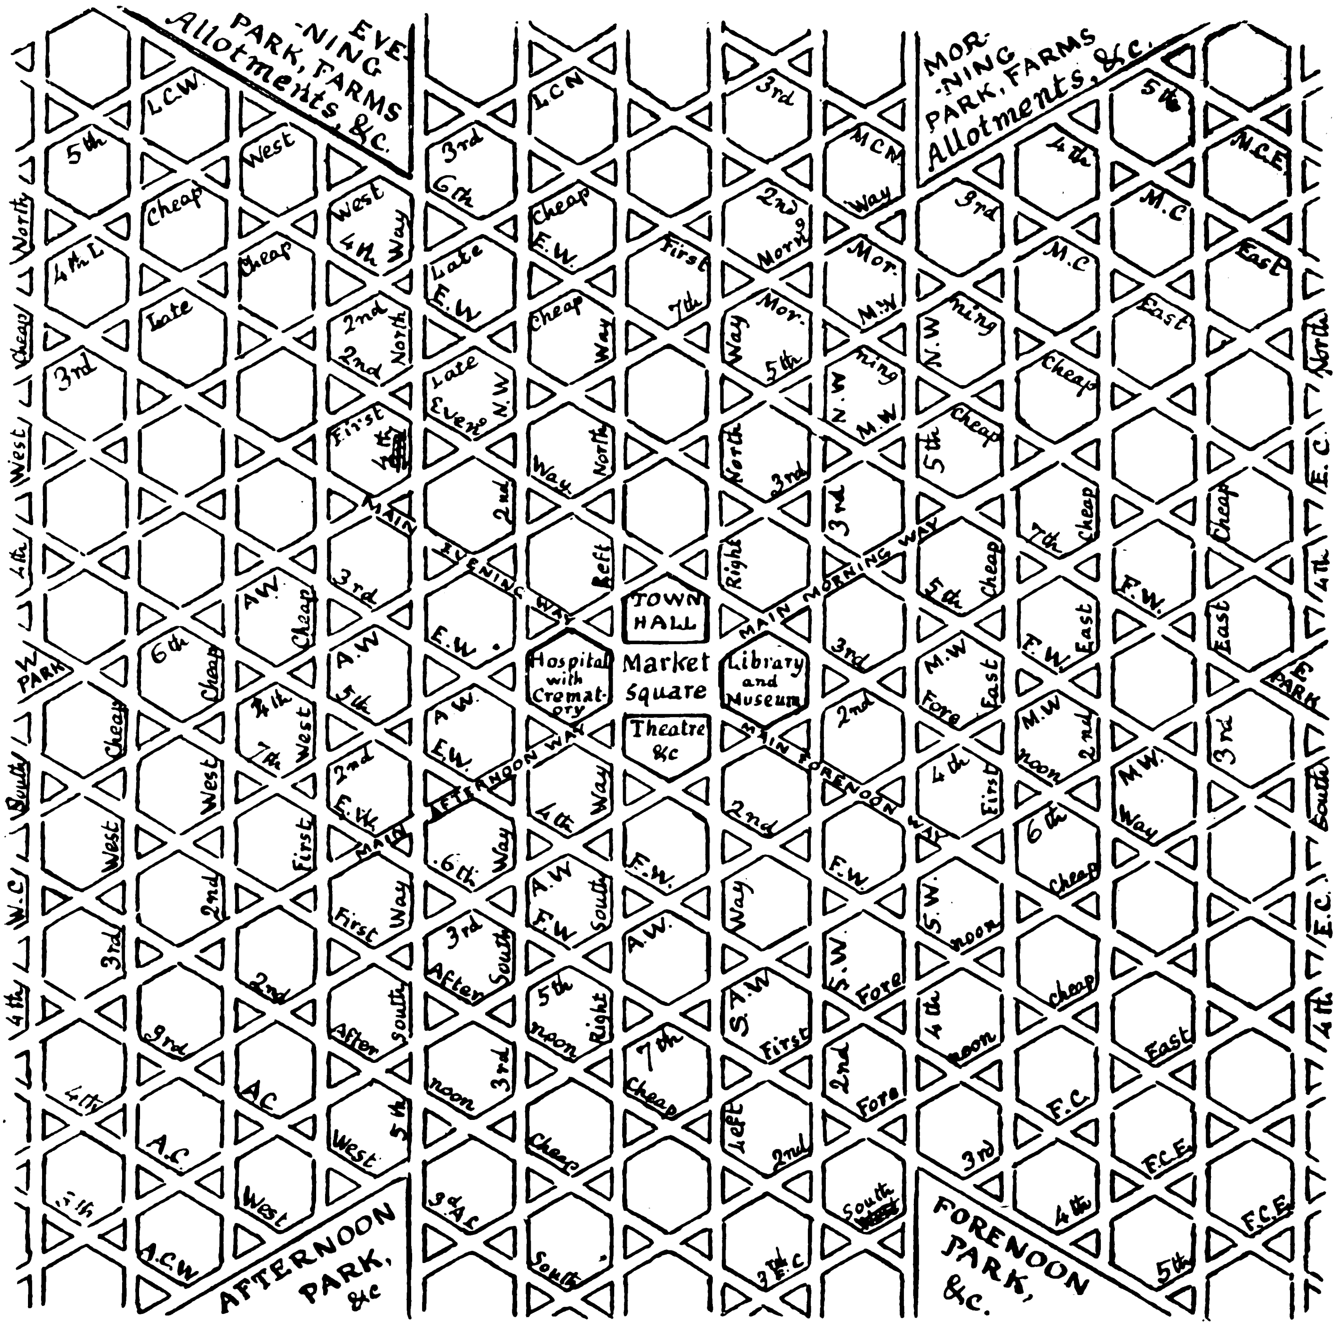
COLE'S BICYCLE BRAKE.

[42909.]—Please allow me to thank Mr. Burton for his expression of approval of my bicycle brake, and for his kind suggestion of improvement. I cannot, however, say that it commends itself to the judgment of The Inventor.

IMPROVEMENT OF HOWARD'S "GARDEN CITY."

[42910.]—Mr. Edward Howard's book called "To-morrow" gives a scheme for purchasing about 6,000 acres of land, and building on 1,000 of them a model city for 32,000 people, which is never to increase, but be confined to a circle of 2,480 yards diameter. A railway incloses this circle, and immediately within it are sites for factories, about 50 yards deep and above four miles long. Within them the dwellings form a town about half a mile deep, surrounding a park of 145 acres. In the very centre of all are six detached buildings, not planned but marked town-hall, concert-hall, library, museum, theatre, and hospital. They are thus far removed from the town, but six roads called *boulevards* lead from their centre to its railway boundary. Five circular *avenues* cross them, and there are 12 minor *roads* and 18 *streets*, cutting up the dwellings into blocks of some 8 or 10 acres apiece. The two boulevards shown are named after Columbus and Newton; the two roads after Shakespere and Milton; and the three streets after Kelvin, Edison, and Froebel.

To the whole arrangement of the city, thus turned inside outward, and to the naming and all details, I have the strongest objections, and submit a widely different plan. Any railways or canals ought, I think, to run *through* the city instead of *round* it. They should be in its thoroughfares, of which he really plans only three. If its size be as unalterable as an old fortified city, the public buildings would be better on the six gates of entry; but I think limited cities are of the past, and that modern ones should be free to expand. The parks should be outside, between the expanding arms, which may very well be six in number, the town being not allowed to spread in all directions, but only like a six-rayed star. Then the thoroughfares should be universal, every road extending all through. But I oppose every curved road, making all rooms wedge-shaped as in our "crescents." Circular streets were never



in any old city, I believe; and Victoria-street, Westminster, was planned circular, but reduced in building to two straight lines. If roads were only straight, and in only two directions, as in most American towns, an obvious improvement, making them a "Garden City," would arise if we think the chequers coloured like a chessboard, and then take up the white and place them on the black squares, leaving the white mere gardens, and giving every house the benefit that those in London squares have now. This would specially improve those towns, whose streets run to the sub-cardinal points, as Boulogne and some few English towns on the old Watling-street and Fosse Way. Fronts looking north-east and north-west get the sun every day, even in mid-winter. But most English cities have been led by their large churches to face near the cardnai points, so that the north fronts get no sun in the winter half-year. They do not front mathematically to the cardinal points, though the ancients saw the advantage of this, for Silchester is oriented exactly.

But the advantage of turning an angle northward applies to blocks of any form, therefore to hexagons when the roads have three directions. Hence one of these three ought to be meridional, and the others inclined 60° thereto. The two north faces thus escape indeed any sun in December and part of January, but still have all the sun that roads in three directions allow. We thus exclude east and west roads in our latitudes—that is, the colder half of the world. I am not speaking here of the warmer half, or latitudes below 30°, as very different rules would there apply; but here the general direction of buildings' lengths should be meridional, each face getting sun half the day at all seasons. Roads crossing then at angles of 60° leave only two forms of blocks, hexagons and trigons. Now every smaller block or trigon I would make only garden. If its sides be 225ft., the perpendicular may be called 195ft., and the area over half-an-area. Surround this with roads of 52ft. I take multiples of 13 because they so nearly approximate the perpendicular to a trigon of 15. The hexagon for building has then sides of 285, a width approximating 494, and area nearly five acres. If railways enter the town, the roads containing them might be 65ft., adding 13ft. for them, or for canals 26ft.; otherwise I hold 52ft. ample for each road, with footways and sunk front area to the building, which is never on both sides. Having said why a town should grow unlimitedly, but only in six directions, the north and south rays have an even number of roads, or an odd one of hexagon blocks. I have drawn them only five, but the other rays six.

In the centre, two trigons are absorbed in a rectangular market square, of 598ft. by 345ft.; but if canals entered, they might here form a tank. The portions of hexagons, north and south, of near four acres, are for the town hall and the theatre, the latter having room also for baths and wash-houses. The whole hexagons east and west are for a library and museum one side, and hospital with crematory on the other. A model city can have no burials. The four adjoining trigons can be covered as markets, or bazaars if an Asiatic plan is adopted.

The naming of roads is of primary importance, the modes now prevalent in Europe being mischievous. Streets in Paris are named after great Frenchmen, and occasionally even foreigners, as Columbus and Newton. In London we can only substitute huge landlords, their country estates, usurious employers, or even great rascals as Roupel and Paul. Mr. Howard would imitate the Parisian mode, but such names as Newton-boulevard, Shakespeare-avenue, and Milton-street give nobody the least hint where to find them. My notion is that an address should enable a citizen with a map before him to put his finger on the spot. As we have no streets—that is, carriageways between buildings—we have to exclude that name. Roads that lead out towards other towns I would call *ways*, and name their six directions as North, Morning, Forenoon, South, Afternoon, and Evening as leading towards the sun at those hours. The central Morning, Forenoon, Afternoon, and Evening ways are called main; those to the right of them 2nd, 4th, and 6th; to the left 3rd, 5th, 7th. As there are two main North and South ways, they are called Right and Left.

Now another name than Way is needed for the roads that terminate in Parks. The Saxon word *Cheap*, meaning a market, has named many towns, and two London streets. We might name those eastward, 1st, 2nd, 3rd, &c., East Cheaps; those westward, 1st, 2nd, &c., West Cheap. Those toward the Morning, Forenoon, and Afternoon parks I would call Morning, Forenoon, and Afternoon Cheaps; but as Evening Cheap would have the initials of East Cheap, I prefer to call them *Late* Cheaps. Every road is now named, and with different initials, except the bits connecting north and south ways between the main ways. These we might call Long and Short East and Long and Short West. The East and West Cheaps beyond the second are divided by the parks into North and South. Similarly the Morning cheaps, beyond the third, are divided into North and East; the forenoon ones into East and South; the Afternoon into

South and West; and the Lite cheaps into West and north

Though we have no carriage streets, or ways between buildings, each hexagon, having all its inner buildings meridional, the courts for lighting them may resemble footway streets, entered at their north and south ends. This will be so at least where the hexagon consists of dwellings, not of factories. Those adjoining the main ways, that have railway or canal, will be factories. Where there are schools, these courts will serve as playgrounds. Now it becomes important to limit the heights of buildings, except at the six corners, which might be allowed any height as towers. Round any court, we might allow once and a half its width; but the north end higher, and the south limited always to 10ft. The four outer fronts of a hexagon, looking east, west, and north might be allowed 30ft.; but the bits blocking the south ends only 10ft. The backs of these would then be the only walls getting no sun.

Sept. 29. E. L. Garbett.

USEFUL AND SCIENTIFIC NOTES.

To produce 1lb. of ice requires an amount of energy equal to about 4¾ tons lifted 10ft. high.

IN France cement has been employed for years past in the protection of iron railway bridges from the fumes of locomotives. In Austria a protective wash made with Portland cement and a small proportion of sharp sand is used.

Igniting a Jet of Hydrogen.—C. G. Hopkins describes a method by which a jet of recently generated hydrogen can be ignited with absolute safety and without loss of time. As soon as the action begins, collect the escaping gas in a test-tube, and, when the latter is thought to be full of pure gas, remove it 2ft. or 3ft. from the generator, and ignite the hydrogen in it; then immediately attempt to light the jet of hydrogen with the hydrogen flame contained in the test-tube. If the gas is explosive, it will explode in the test-tube, and leave no flame. If, on the other hand, a flame remains in the test-tube with which the jet can be ignited, it is certain that the gas in the generator is no longer explosive. By adopting the precaution, therefore, of never lighting the hydrogen jet except with the hydrogen flame obtained as described above, absolute safety can be insured. Attempts may be made to ignite the jet by this method as often as thought proper, and if the hydrogen is properly generated, the gas will be ignited in less than a minute.—*Journ. Am. Chem. Society.*

Bacteria as Destroyers of Masonry.—Bacteriology has shown how we may count alike upon friends and foes amongst the myriads of bacteria known to us. The friendly species, however, are decidedly in the ascendancy, but comparatively few pathogenic organisms having been isolated and recognised. Recent researches have shown how important is the *rôle* of the bacterium in many industrial processes, especially where the production of articles of food is concerned. Ascertained facts would seem to teach that bacteria after all may serve us as tiny engineers who can perform stupendous work when associated in myriads so long as they are placed under a favourable environment. The disposal of sewage by purely bacterial agencies, which under suitable conditions convert an offensive material into simpler and innocuous materials, is perhaps the best case in point. But the disintegrating action of bacteria, though perhaps an indirect one, must, according to recent observations, be reckoned with as a source of mischief. At first sight it would seem hardly possible for bacteria to be concerned in the breaking down of a stone wall, yet such would appear to be the case according to some ingenious observations directed to the nature of the decay of cement. The gradual disintegration of the cement-mortar used in water-supply reservoirs is one of the serious troubles met with by water engineers, and a trouble which so far they have not been able to avoid with any measure of practical success. Hitherto this action was supposed to be the result of the solvent property of carbonic acid and other mineral substances commonly present in a water-supply. The cement gradually disintegrates and becomes a kind of mud which slowly detaches itself. This strange process is due to the action of none other that that bacterium known as the nitrifying organism. An examination of the mud shows it to be teeming with these organisms. The organism, however, cannot flourish in the absence of nitrifiable pabulum. In its presence, however, nitrous acid is produced which leads most probably to the disintegration of the cement lining of the water reservoir. The nitrifying organism is the one upon which so much depends in the purification of sewage and effete matters. On this account its growth should be encouraged, and, it is curious, therefore, to find that the organism appears as an objectionable factor in the attempt to supply and store an abundance of pure water for drinking purposes.—*Lancet.*

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[96295.]—**Bookcase (U.Q.)**—"Amateur" need not go to the expense of a box made with partitions. Go to a wine-merchant and get a dozen empty champagne cases; cost is generally 4s. 6d. a dozen. These cases are made of willow wood and dovetailed in a rough sort of a way, and are of a very handy size for packing books, and very strong. It is best to remove the wire nails from the lids to replace with screws, as they will serve many times. Then wrap each book up in a newspaper and pack tight. Any empty space, fill with newspaper rolled tight. WILLIAM GATRELL.

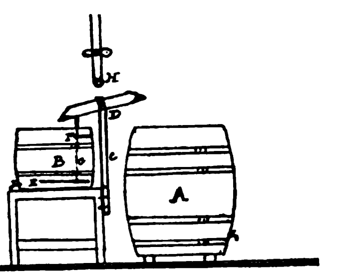
[96297.]—**Reflected Object (U.Q.)**—Put a long-focus convex spectacle-lens at B, and receive the image on a piece of ground glass which has been slightly oiled and rubbed off. But with a ½in. tube this will give a very narrow angle, so it would be best to make a funnel-shaped opening in the wall. To get the objects in focus at different distances you will need to make C movable back and forth. To observe image, either exclude light from room, or hang a black curtain over C and pop your head under as the photographer does.

WILLIAM GATRELL.

[96374.]—**Lamp for Firing Tube Motor.**—This is just the thing I am wanting; but would "Monty" kindly explain method of setting same, running, of course, to burn petrol?

W. E. PITCHER.

[96423.]—**Filtering Rain-Water.**—I inclose a rough sketch of a tilting apparatus as suggested by "M. T.," on p. 118. A is the rain water-butt to contain clean water. B is to collect the first of the rainfall in, which will be contaminated by the dirt of the roof and pipes. To the stand of cask B is secured an upright C, directly under the delivery nozzle H, and to the top of C is fastened a V-shaped holder, in which a V-shaped shoot D is pivoted to deliver the water to either cask. To the inside of



cask B a bracket F is fastened, through which the upright G works, which has at the lower end a float E secured. In dry weather the cask B should be kept almost empty, and then, on rain falling, the supply will first be emptied into B, until the float E automatically tilts the shoot, when the cleaner water will be collected in A. I have not seen the previous notes on this matter, but probably some such method is the one adopted. Of course the quantity B is to contain will depend on the roof surface; shortening G at its upper end will allow for different quantities.

JAS. W. NEWMAN.

[96430.]—**Spots on Negatives (U.Q.)**—They are probably caused by pouring an energetic developer slowly on plate; or perhaps there is a spot on the ruby glass of lamp that is defective; or perhaps a bottle has been interposed between the red light and developing-plate, and so caused the concentrated red light to exert an unequal action on the plate. Adding the accelerator to the developer in the dish, or a warm finger applied to the plate whilst developing would also cause the spots. WILLIAM GATRELL.

[96439.]—**Quadratic.**—The "little boys" referred to by "Ontario" are certainly smart, and the fact that they can easily reduce his equation to a biquadratic suggests the probability of their perceiving that it cannot, for that very reason, be a quadratic at all. They also might be assumed to know (*a*) that $9m^2 - 45$ is not necessarily a square number; (*b*) that its root, even on that assumption, is not necessarily $3x - 3$, for it might be $3x + 3$, or $3x - 5$; (*c*) that the values of m and x obtained from these false premises do not necessarily satisfy the original equation, for we can only affirm that $x = 6$ after testing the equation by it, and not before. The indeterminate equation $a^2 - x - 3 = 0$, which Mr. Donnithorne substitutes for the original, could not lead to any solution other than by trial, and is quite inadmissible. As "Ontario's" friend has not made good his assertion, we must conclude that he has by this time discovered his error.

West Norwood. HENRY T. BURGESS.

[96439.]—**Quadratic.**—"Ontario's" mathematics are not good, although somehow he gets the correct value of m and x. The square root of $9m^2 - 45$ is, algebraically speaking, not $3m - 3$, either with or without a remainder. We require to find the numerical value of $\sqrt{9m^2 - 45}$, which is to be a whole number. This may be put in the form $m\sqrt{9 - \frac{45}{m^2}}$. Now the only square number represented by m^2 which will divide 45 exactly is 9, so that the terms under the radix represent 4, and the whole expression = 6. Suppose, however, that the expression had been $\sqrt{16m^2 - 351}$. This may be put in the form $m\sqrt{16 - \frac{9 \times 39}{m^2}}$. Now if we put $m^2 = 9$, the expression becomes impossible; but it may be put in this form, $\frac{m}{2}\sqrt{16 \times 4 - \frac{4 \times 9 \times 39}{m^2}}$. Now make $m^2 = 36$, and the whole reduces to 15.

Bath. M.I.C.E.

[96503.]—**Shire.**—Generally speaking, the word "shire" is applied to an artificial division of the land for administrative purposes, whilst those counties which do not have this suffix are survivals of petty kingdoms which have not been subdivided.

J. DORMER.

[96555.]—**Equation.**—In my solution, p. 163, I see that the fraction $\frac{182}{945}$ is not in its lowest terms; divide both numbers by 7, which gives $\frac{26}{135}$; using this instead of the other, we get easier numbers to deal with, and the result of the quadratic equation for y will be less unwieldly.

Bath. M. I. C. E.

[96555.]—**Equation.**—I simply suggested to Mr. Harding the easiest mode of obtaining a solution of his equation because the strict algebraical process was extremely involved and irksome. But since he desires the latter, I now give it. Substituting letters for the known quantities, we have—

$$\left.\begin{aligned} a x^2 + b y z &= p \\ b y^2 + c x z &= q \\ c z^2 + d x y &= r \end{aligned}\right\}$$

Put— $$y = m x, \quad z = n x,$$

then— $$x^2 (a + b m n) = p \ldots\ldots\ldots\ldots \text{(i.)}$$

$$x^2 (b m^2 + c n) = q \ldots\ldots\ldots\ldots \text{(ii.)}$$

$$x^2 (c n^2 + d m) = r \ldots\ldots\ldots\ldots \text{(iii.)}$$

From (i.) and (ii.) by division, we get—

$$p (b m^2 + c n) = q (a + b m n)$$

and—

$$n (p c - b m q) = q a - b p m^2.$$

$$\therefore n = (q a - b p m^2) \div (p c - b m q).$$

From (ii.) and (iii.) by division, we get—

$$q (c n^2 + d m) = r (b m^2 + c n).$$

Whence, substituting the above value of n in the last equation, we obtain, after the necessary reduction, a biquadratic in m, from which we at once get n, and therefore x, y, z, since—

$$x = \sqrt{(p \div a + b m n)}.$$

If Mr. Harding experiences any difficulty in solving a biquadratic, I shall be most happy to assist him, but I apprehend this will not be the case.

West Norwood. HENRY T. BURGESS.

[96558.]—**Injector.**—Without entering into special details, it may be explained that the injector works by the steam coming into contact with cold water, when it is condensed and, rushing in to fill the "vacuum" so-called, acquires so much momentum that it forces the water into the boiler against the pressure. It is much the same as trying to pump boiling-hot water. When the plunger in that case makes a sort of vacuum, the hot water does not follow, because it becomes vapour, and fills the pump-barrel, so that the plunger simply works low-pressure steam — not solid water. Query 96634 seems to be of a similar nature; but the question has been answered many times, and is explained in any work on the injector. N. F. J.

[96601.]—**Telescope.**—To magnify 60 times with distinctness and sufficient light, your object-glass must have 60 times the diameter of your pupil—say, 5in., or near 6in. for 70 times. The same power applied to celestial objects may not need half this width of glass. The distance at which houses can be seen over sea is often much further than geometry makes it appear, reckoning the earth's diameter 7,920 miles. Thus I have often seen the objects on Beachy Head from the cliffs of Boulogne, 58 miles off. They are not 150ft. high, nor Beachy Head above 500, and a straight-line view would not reach 44 miles. E. L. GARBETT.

[96619.]—**Electric Organ.**—As you seem still determined to connect your two organs by electricity, I should advise you to insert a query in "Ours" addressed to Mr. Bottone or other good electrician, I do not feel confident that my reply in the matter would satisfy you; for although I have experimented at times in electric-organ work, I am afraid

I am hardly competent to advise in the matter. If you adopted tubular pneumatic action, I am afraid there would not be room in the American organ for the pallet-box or motors, and then you must remember that your bellows in that instrument are exhaust bellows. How do you propose to blow the two organs at the same time? That will be rather a serious question. The work I referred to is "A Practical Treatise on Organ Building," by F. E. Robertson, C.I.E., and published by Sampson Low, Marston, and Co. The price is 31s. 6d., which is rather a high figure, but the book is well worth it. But as I stated in answer before the articles originally appeared in the ENGLISH MECHANIC, in "The Organ," by Hopkins and Rimbault, there are very good chapters on electric-organ work with diagrams. This is also an expensive book; but if you like to advertise your address in the Address column of "Ours," I will write you, as I know where a cheap one (second hand) is for sale.

DIAPASON.

[96631.]—**Eight Queens Problem.**—I used to think, with others, that the solutions of this problem were exceedingly numerous; but seeing it down again as a query in the "E. M." I tried to discover systematically all the solutions. As a result, I find that there are certainly only twelve different solutions. The four given by Mr. Webb (Sept. 22) are only four versions of one arrangement of the queens —the fourth on the list I give below. In fact one has merely to twist the board round so that every edge becomes in turn the bottom edge, to get these four. Mr. Webb might have mentally turned the board over, and, treating it as transparent, put down four other versions. Thus there are eight versions for every arrangement. Mr. Tupman's is the sixth on the list, and Mr. Bucknell's are the eleventh, eighth, second, first, third. A simpler notation than Mr. Bucknell's is the following:—Take the board as consisting of eight columns and eight ranks; speak of a queen according to her column, thus—first queen, second queen, &c. Then to express any arrangement it is sufficient to write down the ranks of the first, second, third, &c., queens as digits of a number: for example, 2 5 7 1 3 8 6 4 would mean that first queen is in rank No. 2, the second in rank No. 5, and so on. Having discovered all the ways in which the first queen is in the first rank, all those in which she is in the second, in the third, and in the fourth, one need not go further; for in any case in which she is in a rank above the fourth, we can, by turning the board over so that what was at the top edge is now the bottom, reduce her rank to one below the fifth; for example, in the arrangement whose number is 7 4 2 8 6 1 3 5, the first queen would on turning over the board appear in the second rank. The following list gives the twelve arrangements:—

(1)	1	5	8	6	3	7	2	4
(2)	1	6	8	3	7	4	2	5
(3)	2	4	6	8	3	1	7	5
(4)	2	5	7	1	3	8	6	4
(5)	2	5	7	4	1	8	6	3
(6)	2	6	1	7	4	8	3	5
(7)	2	6	8	3	1	4	7	5
(8)	2	7	3	6	8	5	1	4
(9)	2	7	5	8	1	4	6	3
(10)	3	5	2	8	1	7	4	6
(11)	3	5	8	4	1	7	2	6
(12)	3	6	2	5	8	1	7	4

If anyone finds an arrangement not included in the above he will be rewarded—with thanks. H. O.

[96631.]—**The Eight Queens Problem.**—It seems odd there should be 12 solutions of this with the common board, as I can only make one with a board of 49 squares or of 36. With a board of 25 there are two; with 16 only one, and with less than 16 none. The Russians give a queen a knight's move, and this makes the problem impossible with 8. A query is, Can nine Russian Queens be placed on a board of 81, or 10 on a board of 100? E. L. G.

[96633.]—**Green Water.** — Rather indefinite. The water, it appears, turns "green" after a week; but how many bathers have used it during that time? The water should be sent for analysis to an expert—say, two gallons, when it is first pumped into the bath, and two gallons when it becomes to "get green and turbid." Some of the water with the "vegetable growth" should also be submitted to the analyst. I do not see how anyone can give a useful answer without specimens of the water at the various stages. M. T.

[96642.]—**Irritation.**—If you go to your druggist for a penny packet or box of prepared fuller's earth, ask him to put it into a clean mortar and add as much gum myrrh in powder as will be picked up upon a sixpence and half as much powdered nut-gall and well triturate it up for you, then hand it over to you. Now when troubled take as much as will be picked up on a sixpence. Wet with clean cold water to about the consistency of cream, and apply when wanting. Use no greasy ointment; it only makes matters worse. If it is as kind to you as it has been to me you will have cause to be thankful. I can likewise recommend it for piles. JACK OF ALL TRADES.

[96647.]—**Knife-Handle Cement.** — If the ordinary mixture will not do, it might be worth while to try plaster of Paris mixed with alum-water, or, as the handles are metal, perhaps a mixture of white-lead and putty would answer. Try the plaster of Paris and alum-water, which dries comparatively slowly. If that, or the other, does not answer, might try jeweller's cement; but that is, of course, affected by water of high temperature. Perhaps the mixture of lime, in powder and slaked, mixed with very fine sand and a little litharge, and kneaded up with linseed-oil would be found effectual. Take, say, two parts of the lime powder, one part of fine sand, and just a "pinch" of litharge comparatively, and mix up with boiled linseed-oil. Would take some time to harden. Report results, please, if tried. METOPS.

[96647.]—**Knife-Handle Cement.**—If you make the tang hot in a fire or over a lamp, fill the hole with powdered alum, then force your tang into it, it will never come out unless you use extraordinary violence.

JACK OF ALL TRADES.

[96650.]—**Trick Matches.**—The following is the usual recipe given for the above:—Take 1 part of glue, and allow it to soak in 5 parts of water. Melt the glue at as low a temperature as possible, and while still hot stir in 1 part of fulminate of mercury. Apply the composition to the matches, while it is warm. If you cannot obtain the fulminate from the chemist (which is most likely), it can be made as follows:—Dissolve some mercury in strong nitric acid, and while the solution is still hot (due to the strong chemical action) add some alcohol. In a short time effervescence takes place, and the fulminate is precipitated as a white crystalline solid, which, when dried, explodes violently on heating or percussion. J. STRACHAN.

[96658.]—**Rheumatism.**—What is meant by "keroseine oil." Is it the common lamp oil petroleum, which is probably not pure oil, or is it a special preparation of the chemist purified for internal use? ADAMS.

[96669.]—**Mercury's Mass.**—Harkness (1891) gives mass of Mercury

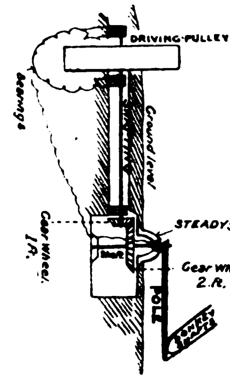
$$= \frac{1}{8{,}374{,}672 \pm 1{,}765{,}762} \text{ of sun's mass.}$$

From this I find (taking diameter of Mercury at 3,000 miles), mean density (water = 1) = 4·00, or about the same as that of Mars (3·95). If we take Barnard's value of the diameter of Mercury—viz., 2,765 miles—the density of the planet would be a little greater than 4·00. J. E. GORE.

[96677.]—**Voltage.**—It is hardly possible to give "Ivanhoe" any useful information in the limited space which can be devoted to that end in these columns; but as his query betrays a very slight acquaintance with the properties of an electric current, I would recommend him to peruse some elementary textbook, and thoroughly master "Ohm's Law. A. H. AVERY, A.Inst.E.E.

Fulmen Works, Tunbridge Wells.

[96694.]—**Circular Saw.**—I think this sketch



will give you a good idea, and also be cheap.

G. BARTON.

[96679.]—**Dynamo.**—To MR. AVERY.—I fear "Dudley" has rather overestimated the possibilities of his dynamo. The normal output of a machine of the size illustrated, if built with cast-iron carcase and drum armature, would be 30 watts at 2,800 revs.; it might be possible to get 50 watts for a short time, but would lead to injurious heating. For a 100-watt 10-volt machine the dimensions should be:—Armature, 2½in. diameter by 3in. long, 12-teeth cogged drum; fields, 6in. high by 7½in. wide by 3in. deep; pole-pieces, 2in. high by 1½in. of winding space; thickness of yokes, 1in.; distance between yokes and pole-pieces for wire, 1in.; armature winding, 10oz. No. 16 S.W.G.; fields, 3lb. No. 17 S.W.G. in shunt; speed, 2,400 revs. for 10 volts 10 ampères. A. H. AVERY, A.Inst.E.E.

Fulmen Works, Tunbridge Wells.

[96690.]—**Dynamo.**—For a machine of the Lahmeyer type, and of the dimensions given, the following will be the correct windings to obtain an output of 65 volts 2 ampères at 2,400 revs.:—Armature, cogged drum 16 teeth, wound with 12oz. No. 24 S.W.G.; fields wound with 3½lb. No. 25 S.W.G. It would be impossible to get 1½lb. of wire on this armature, and much more so to get 10lb. or 13lb. on the fields (as advised in one reply to this query), nor is it in the least necessary; for the Lahmeyer will give an output equivalent to any other type of machine with but half the amount of copper in its construction.

A. H. AVERY, A.Inst.E.E.

Fulmen Works, Tunbridge Wells.

[96698.]—**Scene-Painting.**—Use canvas on rollers or wood frames. Colours in powder by the pound or less can be obtained cheaply at an oil and colourman's. Mix with water into a thin liquid and add about an equal quantity of size, after having dissolved it over a slow fire. Apply the colour thinly and before it has time to congeal, which it does when quite cold. When congealed, it can be rewarmed; but a good plan is to keep a bucket of size liquid on a fire whilst at work, and add to the colours as needed. Remember the colours dry much lighter than when first put on, and keep them strong accordingly. Use the biggest brush you can.

BARMSTA.

[96700.]—**Flow of Water from Cistern.**—In the case of water being discharged through an orifice in its base, the water flows through the orifice because the upward pressure of the orifice (equal to the atmospheric pressure) is less than the downward pressure (equal to the atmospheric pressure together with the weight of the water above the orifice). Hence it is evident the higher the column of water above the orifice the greater the velocity of flow. Now the time of discharge is inversely proportional to the velocity of flow, and the velocity of flow is, as just shown, a function of the head. In fact, $v = c_v \sqrt{2 g h}$ where v is the velocity of flow, h the head, g the acceleration due to gravity, and c_v a coefficient of velocity depending on the form of orifice. The velocity of flow is not, however, constant during the process of emptying, for the head gradually becomes less and less, so that in order to compare the time of emptying in the two cases mentioned in the question the formula—

$$T = \frac{\Omega}{c\, w} \left\{ \sqrt{\frac{2 H}{g}} - \sqrt{\frac{2 h}{g}} \right\}$$

must be used; where T = time of emptying, Ω = area cistern floor, c = a coeff. of discharge depending on shape of orifice, but generally about ·97, w = area orifice, H = head at start of discharge, h = head at time T. Thus if T_1 is time without 10ft. pipe, and T_2 time with 10ft. pipe, disregarding the time taken to empty pipe itself—

$$\frac{T_1}{T_2} = \frac{\sqrt{H}}{\sqrt{H} - \sqrt{h}} = \frac{\sqrt{3}}{\sqrt{13} - \sqrt{10}} = \frac{1{\cdot}73}{{\cdot}47} = 3{\cdot}69.$$

Hence it should take more than 3½ times as long to empty tank in the first manner than it takes to empty it in the second manner. This is neglecting the time taken to empty the pipe itself and the extra resist. of pipe, but both errors should be small. If the pipe was long and of a large bore, the time taken to empty it would be $\frac{1}{c}\sqrt{\frac{2H}{g}}$, H being its length. The time of discharge in the second case would be the same as the time taken to discharge the first 3ft. of a cistern 5ft. × 4ft. and 13ft. deep through a similar hole in its base.

C. W. J.

[96702.]—**Glue.**—What is the object of this query? For what purpose is the glue to be used? That is the subject of importance. A little nitric acid mixed with the glue might answer, or possibly some plaster of Paris would be of more use. It entirely depends on the purpose to which the glue is to be applied, and that is not stated by the querist. T. L.

[96702.]—**Making Glue Insoluble in Water.**—The advice given by "Regent's Park" will, I think, cause the querist some loss of equanimity (and of glue) if followed, as it would result in rendering the glue specially hygroscopic, and extra soluble in water, which is just the opposite to the effect desired. Obviously, the well-known effect of bichromate of potash in rendering gelatine (i.e., glue) insoluble and non-hygroscopic after exposure to light is what is needed; the glue will never swell or dissolve again, even in hot water. But it must be a good glue, a clear, light-coloured sort, which will take up a large proportion of cold water on soaking. Dissolve the potash bichromate crystals in about the proportion of ½oz. weight to a pint of water. When all dissolved, and if in hot water, wait until quite cold, break up the glue into small chips, and, in the dark, let it soak and swell for a day or two in the solution. Pour off the solution not absorbed, and warm the jelly (not boiling it) until the excess of water is evaporated, and the glue as thick as needed for its work, and, still in the

dark, or by gaslight, or in a dimly-lighted room, use the glue as intended, and put it out in strong daylight to set, for some hours. It will get more insoluble daily, but if not sufficiently so, use stronger solution of bichromate. Thinking that numerous photo. men would reply to this query, I refrained; but I hope this may prevent the querist from spoiling his glue and temper by mixing glycerine with the former, as advised by "Regent's Park."

GERARD SMITH.

[96704.] — **Polishing Ivory.** — Your correspondent "Regent's Park," in his reply to this question, has omitted to mention the best and most usual method of polishing ivory—namely, by whiting and water mixed to the consistence of cream, and applied on a thin rubber of folded rag. For full instructions, see Holtzapffel's "Turning and Mechanical Manipulation"—a standard work —Vol. IV. p. 474 for plain turning, and Vol. V. p. 21 for ornamental work.

DROOB.

[96713.]—**Test for Arsenic.**—Wall-paper may be tested for As as follows:—Take a fairly large piece of the paper, so as to include all parts of the pattern; cut it up and put in flask with small quantity of dilute hydrochloric acid, warming up nearly to boiling-point. Now take a small piece of perfectly bright and clean copper foil and suspend in flask by means of a piece of thin platinum wire. After boiling for some time, remove copper, and rinse repeatedly with water to get rid of all acid. On no account handle the copper with the fingers. If there be much arsenic present, the copper will be coated a dark steel colour after the lapse of a short time. If no discoloration appears, the paper may be accepted. Assuming that discoloration has appeared, the copper should now be placed in a short test-tube, loosely stopped at the mouth with cotton-wool, and the bottom heated in the Bunsen flame. A sublimate will appear on the cooler part of the tube, and should be examined under the microscope, when, if small octohedral crystals appear, arsenic is present.

Ipswich. B.Sc.

[96713.]—**Test for Arsenic.**—In the replies to this query on page 167 it should be stated that the accidental inhaling of the arseniuretted hydrogen gas evolved will probably prove fatal. Several instances are recorded of deaths from inhalation of a very small bubble of this gas, which none but a practised chemist should meddle with.

J. P. WRIGHT.

[96723.]—**Electrical.**—To MR. BOTTONE.—Without mentioning any particular make of arc lamp, which would be invidious, it may be fairly stated that any good arc lamp that would run with from six to eight ampères at 50 volts pressure would suit you. In this case two such lamps placed in series could take the place of 12 incandescent lamps, and would necessitate no change in the wiring, except, of course, that the branch wires leading from the mains must also be able to carry at least 12 ampères. Unless specially made, or fitted with special resistance coils, you would not be able to use a single arc lamp in place of six incandescents, and even were you so to do you would incur great waste.

S. BOTTONE.

[96725.]—**Geometrical Progression.**—Let the first number be x, and the common factor also x, then by the common formula—

$$\frac{x\,(x^5-1)}{x-1} = 62, \text{ and } x^5 = 62\left(\frac{x-1}{x}\right)+1$$

$$\frac{x^2\,(x^{10}-1)}{x^2-1} = 1{,}364, \text{ and } x^{10} = 1{,}364\left(\frac{x^2-1}{x^2}\right)+1$$

But $$x^{10} = (x^5)^2$$

$$1{,}364\left(\frac{x^2-1}{x^2}\right)+1 = 62^2\left(\frac{x-1}{x}\right)^2 + 2{\cdot}62\left(\frac{x-1}{x}\right)+1$$

Subtracting 1, and $\div$ by $62{\cdot}2\ \frac{x-1}{x}$

we get $$11\left(\frac{x+1}{x}\right) = 31\left(\frac{x-1}{x}\right)+1$$

$$\text{or, } 11\,(x+1) = 31\,(x-1)+x$$

$$\therefore 42 = 21x, \text{ and } 2 = x$$

The numbers are therefore 2, 4, 8, 16, 32. We may also treat 32 as the first number, and ½ as the common factor, which obviates the necessity for making the latter identical with the former.

HENRY T. BURGESS.

West Norwood, Sept. 29.

[96725.]—**Geometrical Progression.**—

$$a + ar + ar^2 + ar^3 + ar^4 = 62 \ldots\ldots (1)$$

and— $$a^2 + a^2r^2 + a^2r^4 + a^2r^6 + a^2r^8 = 1{,}364 \ldots (2)$$

where a is first term of the "G. P.," and r is the common ratio. Dividing equation (2) by equation (1), we get—

$$a - ar + ar^2 - ar^3 + ar^4 = 22 \ldots\ldots (3)$$

Adding equation (1) to equation (3), we get—

$$2a + 2ar^2 + ar^4 = 84.$$

i.e.— $$a + ar^2 + ar^4 = 42 \ldots\ldots\ldots (4)$$

Subtracting equation (3) from equation (1) we get—

$$ar + ar^3 = 20 \ldots\ldots\ldots\ldots (5)$$

Multiply equation (5) by r, and subtract from (4), then—

$$a = 42 - 20r.$$

Substituting this value of a in equation (1), then—

$$42 + 22r + 22r^2 + 22r^3 + 22r^4 - 20r^5 = 62. \quad (6)$$

And also substituting the value of a in equation (3), then—

$$42 - 62r + 62r^2 - 62r^3 + 62r^4 - 20r^5 = 22. \quad (7)$$

Adding equations (6) and (7)—

$$-40r + 84r^2 - 40r^3 = 84r^4 - 40r^5 = 0.$$

$$\therefore 10 - 21r + 10r^2 - 21r^3 + 10r^4 = 0 \ldots (8)$$

Unless $r = 0$ (but it is not).

$$\therefore (5 + 2r + 5r^2)\,(2 - 5r + 2r^2) = 0.$$

$$\therefore (2 - 5r + 2r^2) = 0, \text{ or } (5 + 2r + 5r^2) = 0.$$

(This last equation may be neglected.)

$$\therefore (2 - r)\,(1 - 2r) = 0, \ \therefore r = 2 \text{ or } \tfrac{1}{2}.$$

And because $a = 42 - 20r$, $\therefore a = 2$ or 32—

$\therefore$ series is 2 . 4 . 8 . 16 . 32.—Ansr.

Lancaster. J. SHAW.

[96725]—**Geometrical Progression.**—Let the numbers be a, ar, ar^2, ar^3, and ar^4,

Then— $$a\,(1 + r + r^2 + r^3 + r^4) = 62 \ldots\ldots (1)$$

And— $$a^2\,(1 + r^2 + r^4 + r^6 + r^8) = 1{,}364 \ldots (2)$$

Therefore— $$\frac{a^2\left(\frac{r^{10}-1}{r^2-1}\right)}{a\left(\frac{r^5-1}{r-1}\right)} = \frac{1364}{62} = 22$$

Therefore— $$a\,(r^5+1) = 22\,(r+1) \ldots\ldots\ldots (3)$$

Also from (1) $$a\,(r^5-1) = 62\,(r-1)$$

Therefore— $$2a = 84 - 40r$$

Or— $$a + 20r = 42 \ldots\ldots\ldots\ldots (4)$$

But "a" and "r" are integers,

Therefore— $$a = 2 \text{ and } r = 2$$

And the numbers are 2, 4, 8, 16 and 32.

A. O. S.

[96725.]—**Geometrical Progression.**—If n numbers are in G.P., their sum being S, and the sum of their squares Σ, it is easily shown that $\frac{(r+1)\,(r^n-1)}{(r-1)\,(r^n+1)} = \frac{S^2}{\Sigma}$, where r is the common ratio, and the first term is given by $a = S \times \frac{r-1}{r^n-1}$. If $r = 5$, the first equation becomes—

$$(S^2 - \Sigma)\,(r^4 + r^2 + 1) = (S^2 + \Sigma)\,r\,.\,(r^2+1).$$

$$\therefore (S^2 - \Sigma)\,(r^2 + 1 + r)\,(r^2 + 1 - r) = (S^2 + \Sigma)\,.\,r\,.\,(r^2+1).$$

$$\therefore (S^2 - \Sigma)\left(1 + \frac{r}{r^2+1}\right)\left(\frac{r^2+1}{r} - 1\right) = S^2 + \Sigma$$

For brevity write—

$$\frac{r^2+1}{r} = x,\ S^2 - \Sigma = Q,\ S^2 + \Sigma = P.$$

$$\therefore \left(x - \frac{1}{x}\right) = P,\ \therefore\ x^2 - \frac{P}{Q}x = 1 \ldots\ldots (i.)$$

A quadratic to find x, and putting $\frac{r^2+1}{r}$ equal to the roots of this equation, we have another quadratic to find r, whence a can be determined from the equation $a = S \times \frac{r-1}{r^5-1}$. This is a general solution applying whether the five quantities are fractional or integral, and gives the solution for any given values of S and Σ. In the example given $\frac{P}{Q} = \frac{21}{10}$, which gives $x = \frac{5}{2}$, or $-\frac{2}{5}$, whence $r = 2$ or $\frac{1}{2}$ (the other two values of r are imaginary), and $a = 2$ or 32. These two solutions give the same five numbers—viz., 2, 4, 8, 16, 32.

C. P.

[96726.]—**Induction Coil.**—To MR. BOTTONE.—For a core 6in. long, ⅝in. diameter, the heads should be 2¼in. diam., ⅜in. thick. Having fitted these on and drilled the holes for the primary wire to pass through, dress the iron core with one layer of silk ribbon laid on spirally. Fasten down with a stitch, and varnish over with shellac. When dry, coil on two layers of No. 20 d.c.c. Baste with hot melted paraffin wax. Now procure a sheet of thin ebonite about 1/16in. thick, 5¼in. wide, and 7in. long. Soften this by holding it at a little distance in front of a glowing fire, and rapidly wrap it tightly and evenly round the wound primary. Tie it round with tape so as to retain it in position until cold and hard again. Remove tape, drill hole in one edge for passage of beginning of secondary, then wind on 8oz. No. 36 silk-covered wire in perfectly even and close layers, interleaving each layer with one turn of paraffined paper. Each layer should diminish by about ⅛in. at each end. It will not be advisable to sectionise so small a coil. For full instructions for building large coils in sections see my book "Radiography." A suitable condenser will consist of fifty sheets of tinfoil 2in. by 4in., interleaved with paraffined paper. The two ends of condenser are connected to contact screw and vibrating hammer respectively.

S. BOTTONE.

[96732.]—**Paint.**—1. If you were to buy your paint of a house-painter, or that is, have it mixed to order, you will get over the difficulty, as so many colours and tints are used in house-painting. Perhaps it would interest you to know that hundreds of tints in use have no white lead in them because of it destroying the colour one wants to get. 2. "Elementary Decoration," illustrated, price 2s., from Crosby Lockwood and Son, 7, Stationers' Hall-court, London, E.C.

Bromsgrove. HOUSE PAINTER.

[96732.]—**Paint.**—Both "Poor Man" and "Anxious" can easily make their own paint with white lead, boiled oil, turpentine, and driers, or "terebene"—a very convenient liquid driers. Put these ingredients into a tin-pot, and twirl a brush round between the hands till all are incorporated. Plenty of books on subject. See advts. for such. Experience is necessary for good work.

HOUSE PAINTER.

[96732.]—**Paint.**—"Poor Man" does not say so, but I presume he wishes to put a fresh coat of paint on something that has been painted before. The first thing to do is to get off all dirt, removing any nails or scutcheons of locks, door-plates, &c. If any places are greasy, remove grease with turpentine. White-lead may be taken to be the body of all paint, as flour is the body of pastry, cakes, &c. For the first coat, take as much white-lead as you require, and add gradually enough of the following to make it of the right consistency: three half-pints of turpentine and half-pint boiled linseed-oil; then add a tablespoonful of patent driers. If you require it coloured, get the stiff colour, and mix it in with the white-lead. When the consistency seems about right, get an old woman's stocking, slit stocking up the seam, stretch stocking over an old can, and tie it around the can. This is to filter the paint through. Help it through by brushing, and continue till all is filtered. The paint is now ready for use. This coat will dry somewhat dull-coloured. For the next coat, mix the white-lead and colour with boiled oil 2 parts and turpentine 1 part. A little driers must be added. These two coats will be found quite sufficient, and the last coat should dry with a nice gloss. About four days—more or less, according to season—should elapse before applying second coat.

WILLIAM GATRELL.

[96733.]—**Gas and Oil Engines.**—The trunk form of piston, as now generally adopted in gas and oil-engines, is used in order to save weight, to have as few working parts as possible, and to cool piston by having front end of cylinder open to the atmosphere. Double-acting cylinders for gas-engines have not proved successful in practice, owing to the great difficulty of keeping the piston and piston-rod (which is surrounded at the moment of explosion by burning gases at a temperature of about 1,600° C.), sufficiently cool to allow of lubrication.

H. F. L.

[96733.]—**Gas and Oil Engines.**—Because the piston would "bind," as there is no "crosshead" interposed between crank and piston; being generally single-acting, there is no necessity for this. There is a wide difference between gas or steam, the latter not requiring compressing, which is necessary with gas for effective working.

LINER.

[96733.]—**Gas and Oil Engines.**—Since gas and oil engines are nearly all single-acting, it is only necessary to have one end closed. The trunk piston suits this admirably, doing away with the piston-rod, and greatly economising space and amount of material used in the bedplate. The double-acting cylinder has been tried, but not with very great success or economy. There are only a few in use.

THISTLE.

[96734.]—**Nerve in Tooth.**—Arsenious acid powdered in very small quantities—say one-fifteenth to one-fortieth grain. Some use it dry, but most generally it is bought in a kind of paste ground up with creasote, oil of cloves, carmine, morphia, cocaine, &c. It requires expert skill in application, as the least bit of arsenious acid will cause rapid necrosis of any living tissue it comes in contact with.

WILLIAM GATRELL.

[96734.]—**Nerve in Tooth.**—Creasote is generally employed for this purpose. A little pledget of cotton-wool twisted round the end of a fine stick, is moistened with the creasote, and inserted into the hollow of the tooth.

S. BOTTONE.

[96734.]—**Nerve in Tooth.**—To destroy the nerve of a tooth means to lose the tooth itself very

soon. Why not see a good dentist and save the tooth?

West Didsbury. M. COLE.

[96735.]—**White Paint.**—The dry white lead (carbonate) kneaded with linseed oil, say 8lb. of oil to 100lb. of lead. Thin with turpentine to milk-white fluid, stir all well together, then set aside for a day or two, at end of which time a large share of the oil with some turpentine will be free of lead on surface; pour this off. If washed sufficiently by this, add to the washed lead a little rubbing varnish of light shade—say 1 gill to a quart of softened lead. This gives bending and drying qualities. Stir well; if too thick, add a little turpentine. Two coats over light ground should make a solid foundation. REGENT'S PARK.

[96735.]—**White Paint.** — Vide my reply to query 96732, and you will see that all you require is boiled linseed oil, as you have the other ingredients. WILLIAM GATRELL.

[96735.]—**White Paint.**—To make your paint for glasshouse, use for first coat half turps and half linseed-oil mixed with white lead to the proper consistency for use. Very little driers is needed for white, say 1lb. driers to 10lb. of white-lead. If you intend giving three coats use same paint as for the first. Do not put the first on too thick. Last coat use all linseed-oil or half boiled-oil and half turps. Just a little blue in the last coat is preferred by some.

Bromsgrove. HOUSE PAINTER.

[96736.]—**Crystoleum.**—There is a lot of information in back numbers about this. Various makers give special names to their preparations; those used in the inquiry are, I think, made in Lancashire—but Canada balsam will be found best of all for the purpose.

West Didsbury. M. COLE.

[96738.] — **Gas-Heating Soldering-Iron.** — Take a piece of iron gaspipe, say, about 6in. long and about ¾in. bore; screw both ends; on one end screw a cap, on the other a connection for rubber tubing; drill a number of ⅛in. holes about ⅜in. apart. Drill a hole, or holes as required, near connection, and as far from last hole to prevent lighting back. Fix on bench by some means, and rig up a suitable stand for soldering-iron.

GAS-FITTER.

[96738.]—**Gas-Heating Soldering-Iron.**—The best way is to use a small gas-stove and two irons, one on stove while other is used. This is far better than the self-heating ones. You can get a gas-stove that will do for 1s. or so, and make a cover of sheet iron lined with asbestos board ⅛in. thick.

West Didsbury. M. COLE.

[96740.]—**Electrical Contrivance for Deaf Person.**—To MR. BOTTONE.—What is usually sold for this purpose is simply a telephone, when, of course, the transmitter must be fixed somewhere near the minister in the pulpit. But, practically, I have found this arrangement of little or no service, if the user is really deaf. S. BOTTONE.

[96741.]—**Heating Room by Electricity.**—I should advise the querist to communicate with Messrs. Crompton and Co., of Chelmsford, who make all kinds of heating appliances on the system devised by Mr. Dowsing, the heat being developed by passing current through a network of high-resistance wires imbedded in a special enamel. Or Mr. Bowden might apply to Mr. G. Braulek, of 217, Upper Thames-street, E.C. A simple form of radiator would merely consist of a set of "recstene" resistance-coils inclosed in perforated iron case, and warmed up to a "black heat" by passing current through them. If the querist will state the voltage and ampèrage of his dynamo, also the dimensions of the apartment to be heated, further assistance would probably be forthcoming. A. H. AVERY, A.Inst.E.E.

Fulmen Works, Tunbridge Wells.

[96741.]—**Heating Room by Electricity.**—This can be done economically only when you can get current for nothing. It is, of course, possible to heat a room by electricity, just as it is possible to cook a dinner with £5 notes.

West Didsbury. M. COLE.

[96742.]—**Bore of Cylinder.**—The bore of the cylinder will depend on the stroke and the pressure developed in cylinder by the explosion of the gases. To find the horsepower of gas-engine—

Let— P = mean pressure as found from indicator diagram.
L = length of stroke.
A = piston area.
n = no. of explosions per min.

Then— $$\text{I.H.P.} = \frac{\text{PLA}n}{33{,}000}$$

The oil-engine is found in a similar manner.

THISTLE.

[96743.]—**Wimshurst.**—To MR. BOTTONE.—No; the oppositely charged sectors would discharge across to one another. S. BOTTONE.

[96744.]—**Celluloid.**—Articles made of celluloid can be stuck together by means of a cement made by dissolving celluloid in amyl alcohol. This can be bought ready-made under several fanciful names, as "Zapon," &c. S. BOTTONE.

[96744.]—**Celluloid.**—Dissolve 25 parts shellac in 25 parts spirit camphor; add alcohol, 90 per cent., 100 parts. Fine celluloid shavings dissolved in 90 per cent. alcohol. REGENT'S PARK.

[96744.]—**Celluloid.**—Can be joined by a cement of celluloid dissolved in acetone. The C. can be bent when heated in hot water; but be careful not to over-heat.

West Didsbury. M. COLE.

[96745.]—**Flagstaff Problem.**—The letters in your question seem to be slightly mixed: you have taken A to mean the elevation of the highest point of the tower, and also the distance of the first observation from the base. Let the height of the tower be m, the length of the flagstaff l, suppose the first observation to be made at a distance b from the tower base, and the second observation at a distance c further on. Let the elevation (at the first position) of the top of the tower be A, and the top of the flagstaff a. Then the elevation of the top of the flagstaff in the second position is $\frac{a}{2}$. As a and A are complementary, tan. a = cot. A.

$$l + m = b \tan. a = b \cot. A$$
$$m = b \tan. A$$
$$\therefore l = b(\cot. A - \tan. A) = b\,\frac{1 - \tan.^2 A}{\tan. A}$$
$$= 2b \cot. 2A.$$
$$l = b(\tan. a - \cot. a) \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$
$$l + m = b \tan. a = (b + c) \tan. \frac{a}{2}$$
$$\therefore c \tan. \frac{a}{2} = b\left(\tan. a - \tan. \frac{a}{2}\right) \quad \ldots\ldots (2)$$

Eliminating b from (1) and (2)—

$$l\left(\tan. a - \tan. \frac{a}{2}\right) = -c \tan. \frac{a}{2}(\tan. a - \cot. a)$$

Putting in the value—

$$\frac{\sin. a}{1 + \cos. a} \text{ or } \frac{1 - \cos a}{\sin. a} \text{ for } \tan. \frac{a}{2}$$

$$l\,\frac{1 - \cos. a}{\sin. a \cos. a} = -c\,\frac{\sin.^2 a - \cos.^2 a}{\cos. a(1 + \cos. a)}$$
$$= -c\,\frac{-\cos. 2a}{\cos. a(1 + \cos. a)}$$
$$\therefore l = c \cdot \frac{\sin. a \cos. a}{1 - \cos. a} \cdot \frac{\cos 2a}{\cos. a(1 + \cos. a)}$$
$$= \frac{\sin. a}{1 - \cos.^2 a} \cdot c \cos. 2a = c \operatorname{cosec}. a \cos. 2a.$$

C. W. J.

[96745.]—**Flagstaff Problem.**—(i.) If h be the height of the tower—

$$\frac{h}{a} = \tan. A, \quad \frac{x + h}{a} = \cot. A$$
$$\therefore \frac{x}{a} = \cot. A - \tan. A = 2 \cot. 2A$$
$$\therefore x = 2a \cot. 2A.$$

(ii.) The distance a being unknown—

$$\frac{h}{a} = \tan. A, \quad \frac{h}{a + c} = \tan. \tfrac{1}{2} A.$$
$$\therefore a \tan. A = (a + c) \tan. \tfrac{1}{2} A,$$
$$\therefore a = \frac{c \tan. \frac{1}{2} A}{\tan. A - \tan. \frac{1}{2} A} = c \cos. A.$$

Substituting this value in the result of (i.), we have—

$$x = 2c \cos. A \cdot \cot. 2A = \operatorname{cosec}. A \cos. 2A.$$

C. P.

[96746.]—**Grammaphone.**—Examine the connection between the stylus lever and the diaphragm, and see whether they are separate. If not stuck together, of course the voice would suffer. The cement used is ordinary beeswax. Berliner's name sounds like a German, but I have not the pleasure of his personal acquaintance, so cannot say where he was "raised." It sounds awfully conceited to say so, but you should read my articles on the Grammaphone in the last volume of "Ours." You will find everything you ask about mentioned in them. The diaphragm is usually mica, but celluloid will answer. R. A. R. BENNETT.

[96749.] — **Electro - Magnets in Series.** — Either of two things may be the matter:—(a) the iron of the cores may be of very different magnetic quality, or (b) in one of the magnets the coils may be short-circuited somewhere, and the current does not pass through the whole number of turns.

A. H. AVERY, A.Inst.E.E.

Fulmen Works, Tunbridge Wells.

[96749.]—**Electro - Magnets.** — It is highly probable that the core of one of them is of hard iron; better test.

West Didsbury. M. COLE.

[96753.] —**Acceleration.** — Acceleration is expressed in velocity per time-unit, hence the time-unit must be mentioned twice. Assuming 25kils. per hour means 25kilo. per hour per hour, the velocity v at the end of any distance s is given by the fundamental dynamical formula—

$$2fs = v^2$$

Hence in this example—

$$v = \sqrt{2fs} = 20\sqrt{2} = 28{\cdot}28\text{kilo. per hour.}$$

C. W. J.

[96753.] — **Acceleration.** — Any textbook on mechanics will show that $v^2 = 2fs$, where f is the acceleration, and s the space passed over; in this case—

$$v^2 = 2 \times 25 \times 16.$$
$$\therefore v = 20\sqrt{2} \text{ kilomètres per hour.}$$

B. W. LOVEJOY.

[96753.]—**Acceleration.**—25 kilo. per hour = $\frac{625}{9}$cm. per second.

$$v^2 = u + 2fs$$

where— v = final veloc.
u = initial veloc.
f = acceleration.
s = distance travelled.

$$v^2 = 0 + 2 \times \frac{625}{9} \times 1{,}600{,}000\text{cm.}$$
$$= \frac{3{,}200{,}000 \times 625}{9}$$
$$= \frac{2{,}000{,}000{,}000}{9}$$
$$v = \frac{4.473}{3}\text{m. per sec.}$$
$$= \frac{4.473 \times 3}{250} = \frac{13\,419}{250}$$
$$= 54 \text{ kilos. per hour.}$$

THISTLE.

[96753.]—**Acceleration.**—With the usual formula $S = \frac{1}{2}ft^2$ and $v^2 = 2fs$; with our units of space and time as 1 kilomètre and 1 hour, we have $t = \frac{4}{5}\sqrt{2}$, and $v = 20\sqrt{2}$ kilomètres per hour.

C. P.

[96754.]—**Problem.** — Let x^s be the value of prize. Then, if number of bound volumes be y, the number of unbound volumes for same money will be $(y + 10)$. Therefore, $\left(\frac{x}{y}\right)^s$ is cost of one bound volume, and $\left(\frac{x}{y + 10}\right)^s$ is cost of one unbound volume. Therefore, $\frac{x}{y} - \frac{x}{y + 10} = 6$. But if half the volumes are bound and the rest unbound, $\frac{y + 4}{2}$ are bound, and $\frac{y + 4}{2}$ are unbound, and cost of $\frac{y + 4}{2}$ bound vols. is $\left(\frac{y + 4}{2}\right) \times \frac{x^s}{y}$, and cost of $\frac{y + 4}{2}$ unbound vols. is $\left(\frac{y + 4}{2}\right) \times \left(\frac{x}{y + 10}\right)^s$, and total cost is x shillings.

$$\therefore \quad \frac{y + 4}{2} \times \frac{x}{y} + \frac{y + 4}{2} \times \frac{x}{y + 10} = x.$$
$$\therefore \quad \frac{xy + 4x}{2y} + \frac{xy + 4x}{2y + 20} = x.$$
$$\therefore 2xy^2 + 8xy + 20xy + 80x + 2xy^2 + 8xy = 4xy^2 + 40xy.$$
$$\therefore \quad 80x = 4xy. \quad \therefore y = 20.$$

and $\frac{x}{y} - \frac{x}{y + 10} = 6$. $\therefore \frac{x}{20} - \frac{x}{30} = 6$. $\therefore x = 360$.

Consequently, the number of unbound volumes which could be got for 360s (the value of the prize) is 30; or 12 bound volumes and 12 unbound volumes could be got.

Lancaster. J. SHAW.

[96754.]—**Problem.**—Let—

x = number of volumes all bound, then—
$x + 10$ = number of volumes all unbound, and—
$x + 4$ = number of volumes half-bound and half unbound.

Next let— y = price per volume unbound,
then— $y + 6$ = price per volume bound.

Now, since the value of the books is the same in each case, we get—

$$x(y + 6) = y(x + 10) = \frac{(x + 4)}{2} + \frac{(x + 4)(y + 6)}{2}$$

From the first two we get, by clearing—

$$3x = 5y, \text{ or } x = \frac{5y}{3}.$$

By clearing No. 3 and substituting the value of x we get the following quadratic in y—

$$5y^2 - 3y = 108.$$

Solving, we get, therefore—

$$y - \tfrac{3}{2} = \pm \tfrac{21}{2}.$$

Therefore— $y = 12$, or -9,

the positive value being only available. Therefore,

by substitution, we get $x = 20$. Therefore the required numbers of volumes are:—20 vols. at 12s. + 6s. (or 18s.) per vol. = 360s. = £18; 30 vols. at 12s. per vol. = 360s. = £18; 24 vols., 12 at 18s. and 12 at 12s. = 360s. = £16.—*Q.E F.*

INDUCTORIUM.

[96754.]—**Problem.**—Let x = value of prize in shillings, and y = number of books, if all are bound.

Then— $\frac{x}{y}$ = value of bound volume,

and— $\frac{x}{y} - 6$ = value of volume unbound,

and, from the terms of the question, we have also—

$\frac{x}{y+10}$ = value of volume unbound.

$$\therefore \frac{x}{y+10} = \frac{x}{y} - 6 \text{ ....(1)}$$

$$\therefore xy = xy + 10x - 6y^2 - 60y.$$

$$\therefore 6y^2 + 60y = 10x.$$

Or— $3y^2 + 30y = 5x$ ....(2)

Again— $\frac{y+4}{2} \times 6 + (y+4)\frac{x}{y+10} = x.$

Or— $3y^2 + 30y + 12y + 120 + xy + 4x$
$= xy + 10x$, or from (2).

$$5x + 12y + 120 = 6x.$$

Or— $12y + 120 = x$..............(3)

$$\therefore y + 10 = \frac{x}{12}$$

Substituting this result (1) we obtain—

$$12 = \frac{x}{y} - 6$$

$$\therefore \frac{x}{y} = 18s. = \text{value of bound volume,}$$

and— $18y = x.$

Then from (3)— $12y + 120 = 18y.$

$\therefore 6y = 120$, and $y = 20$. $\therefore x = 18y = 360s.$

Hence value of prize is 360s. = £18.
Number of bound books = 20.
Number of unbound books = 30.
Number if half are bound = 24.
Value of bound volume = 18s.; ditto unbound 12s.

J. E. GORE.

[96754.]—**Problem.**—Let x represent the prize in shillings, and y the value of an unbound book.

$$\therefore \frac{x}{y} = \frac{x}{y+6} + 10, \text{ and } \frac{x}{y} = \frac{x}{y+3} + 4.$$

Here the only solution is $x = 360$, $y = -18$. There is, therefore, no solution to the original question, the conditions being impossible as ordinarily understood, and this is obvious; for if $2n$ represents the number of unbound books he can buy with his prize, then—

$2n - 10$ bindings are worth 10 books
$\therefore \quad n - 5 \quad$ „ „ 5 „
but— $\quad n - 2 \quad$ „ „ 4 „

Therefore by subtraction -3 bindings are worth $+1$ book. The algebraical solution gives: Prize, £18; value of an unbound book, -18 shillings; number of books he can buy -20 unbound, -30 bound, or -24 half-bound. The only interpretation we can give to this result is that the books are already in his possession, but are so far an impediment that he is willing to give 18s. each to have them removed, provided he is allowed 6s. for each binding taken away. If he uses his prize in getting rid of these books, he can dispose of 20 unbound, 30 bound, or 24 half-bound; that is, the number of books he will have left will be 10 more if he disposes of unbound instead of bound books, and 4 more if he gets rid of half-bound.

C. P.

[96754.]—**Problem.**—Let x = value of the prize in shillings; y = price of a single unbound book in shillings. Then numbers of books purchased, none bound $= \frac{x}{y}$; numbers if all bound $= \frac{x}{y+6}$; numbers if half-bound $= \frac{x}{y+3}$. Hence from the question—

$$\frac{x}{y} - 10 = \frac{x}{y+6} = \frac{x}{y+3} - 4$$

Multiplying out, we have—

$$5y^2 + 30y = 3x$$
$$6y^2 + 18y = 3x$$

Hence— $12y = y^2$, and $y = 0$ or 12.

The value 0 would not apply to the question, hence—

$$y = 12 \text{ and } x = 360.$$

The value of prize is £18, and the numbers of books obtained is 30, 20, and 24 respectively.

C. W. J.

[96754.]—**Problem.**—Let xy be the amount of the prize in shillings; y the cost of a bound volume in shillings. So that x would be the number of bound volumes obtainable. Then, since $y - 6$ is the cost of unbound books, and $y - 3$ average cost of books of which half are bound, we have—

$$xy = (y - 6)(x + 10) = (y + 4)(x - 3).$$

Therefore— $10y - 6x = 60$
$\quad\quad\quad\quad 4y - 3x = 12$

Therefore— $2y = 36$ and $y = 18$ shillings.

Also— $18x = 12(x + 10).$

Therefore—$x = 20$ and $xy = 360$ shillings.

The prize is £18; and it would buy 20 bound volumes, 30 unbound, or 12 of each kind.

A. O. S.

[96756.]—**Ornamental Blocks.**—Don't use paste, but gum the paper with best quality gum arabic. Allow to dry, then moisten the surface of gum and apply the silk. It will not then strike through. Rubber cement is sometimes used.

West Didsbury. M. COLE.

[96758.]—**Sharpening Files.**—Acid methods are no good, and very expensive. The following will not resharpen, but will enable you to get some more work out of your files. Boil the files in an iron pan in water to which you have added a pound or two of soda, a little caustic soda or potash, and a bit of soap. They want boiling for 15 to 20 minutes, and then rinsing in warm water, and then, using a good file-card, you can get the teeth cleaner by far than dry.

WILLIAM GATRELL.

[96759.]—**Bikes and Prams.**—This is a matter of by-laws in most cases. There is (or was) one street in Brighton where perambulators were not allowed on the footpath.

West Didsbury. M. COLE.

[96761.]—**Ginger-Beer Plant.**—This is no "Mrs. Harris," but a very tangible reality. It looks very much like large grains of rice. You put it into a bottle, and add a solution of sugar and some ginger. The only part the plant plays is to cause fermentation. It turns out excellent ginger-beer. I do not know its scientific name.

R. A. R. BENNETT.

[96761.]—**Ginger-Beer Plant.**—Is *Mycoderma saccharomyces*, and is quite distinct from other torula and bacteria. I used to grow it largely. When healthy it occurs as large roundish white grains, resembling raw tapioca. It is extremely interesting to cultivate, as all the phenomena of propagation by fission, as they occur in the bacteria, can be studied by the naked eye. It grows freely in a solution of sugar flavoured with ginger, giving rise, at the same time, to a very pleasant ginger-beer. To succeed in its cultivation, dissolve ¼lb. light-coloured moist sugar in one quart of water. Add to this ½oz. of crushed ginger; place in any wide-mouthed glass vessel (a 4lb. plum-jar will do very well), add to this about two tablespoonfuls of the ginger-beer plants, and allow the whole to stand in any warm place (not in direct sunlight, which kills the plants), at a temperature from 60° to 80° Fahr. In twelve hours the liquor will be ready to drink. Keep muslin over top of jar to exclude dust, &c. From time to time remove excess of plants that have grown, and renew the ginger.

S. BOTTONE.

[96761.]—**Ginger-Beer Plant.**—Many years ago, when quite a lad, I saw one of these "plants," and tasted the ginger-beer it produced. On the kitchen mantelpiece was a wide-mouthed glass jar, holding some 60oz. of water, and at the bottom was the ginger-beer plant. It had the appearance of a wet piece of wash-leather, and appeared to be agglutinated. "Ex nihilo," &c., and Mrs. G. B. P. did not make omelettes without eggs, for I was informed that when the liquid had been drunk till near the bottom the vessel was filled up with cold water, and some sugar added, and about once a week some ginger. I drank a glass of the "brew," and found it fairly good. The flavour was not so good as the "brewed" old-style ginger-beer; but there was evidently some CO_2. I was informed that the "fungus" was purchased at Covent Garden Market, and it would be interesting to know if it can still be had there. Perhaps some of the *habitués* of the Market will kindly say?

WILLIAM GATRELL.

[96761.]—**Ginger-Beer Plant.**—The substance known by the above name occurs in white, jelly-like lumps, of varying size from a pin's head to a plum, which possess the property, when introduced into a sugar solution containing ginger, of transforming it into an acid effervescing liquid, ginger-beer. The substance was investigated some years ago by Prof. Marshall Ward, who found it to consist essentially of a *Saccharomyces*, *S. pyriformis*, and a *Schizomycete*, *Bacterium vermiforme*, together with numerous other micro-organisms, some of which were probably casual intruders. Marshall Ward proved experimentally that the two species named were the only essential ones necessary to produce the fermentation, since he could only bring about an effect like that produced by the ginger-beer plant when he induced a fermentation by them together. His experiments point to the view that the yeast and bacterium live together in a state of true symbiosis, forming an organisation like a lichen. For further particulars about this matter, which does not in the least savour of Mrs. Harris, consult Marshall Ward's paper in *Philos. Trans. Roy. Soc.*, Vol. CLXXXIII. B. p. 125.

A. PRICE, B.Sc.

[96763.]—**Salicin.**—Is a glucoside from the willow (Salix species), having the composition $C_{13}H_{18}O_7$. Under the influence of ferments it splits up into grape-sugar and saligenine.

S. BOTTONE.

[96764.]—**Charging Accumulators.**—TO MR. AVERY.—The plant necessary to do this would consist of a No. 1 Lahmeyer dynamo and some source of motive power, such as a small oil or gas-engine or a water-motor. Or possibly Mr. Weldon would find it more convenient, and less expensive, to get two sets of accumulators, and send one set to be charged at the address below whilst the other is in use. If Mr. Weldon will give me a call, I shall be pleased to advise him personally.

A. H. AVERY, A.Inst.E.E.

Fulmen Works, Park-street, Tunbridge Wells.

[96767.]—**Wireless Telegraphy.**—TO MR. BOTTONE.—Yes; but you must arrange a spark gap between the balls of the prime conductors and connect the transmitter balls to the *outsides* of the Leyden jars on the Wimshurst. The relay recommended by me will do nicely. Your coherer appears to be rather long in the tube, and this is not an advantage, as there is a larger mass of filings to be moved. On the relay circuit two dry cells are usually sufficient; but if your relay is not very sensitive, you may use more. In fact, you may put on as many cells in series as will just not actuate the relay when the wave is not sent. One good cell is ample on the bell circuit. It wants considerable knack in turning and stopping to get intelligible signals with the Wimshurst; still, it can be done. About 1½in. spark between the main discharges, and ¼in. between the three balls of the transmitter should be sufficient. Your wings are correct.

S. BOTTONE.

[96768.]—**Ironmould in Copper.**—If you make a paint with oil, or a distemper with water of the mineral known as magnesite, or petrifite, and do your copper with one (or two if requisite) coats, you will get a smooth, adherent, and clean covering capable of bearing great heat, much more than boiler heat.

REGENT'S PARK.

[96768.]—**Ironmould in Copper.**—If your cast-iron washing-copper is sound, get a tinker to come in and tin it for you. He will have to scour it out with fine sand, and when it is perfectly clean and brilliant, will heat the copper from below, and tin it by the aid of a rich tin-solder, assisted by salammoniac, and rubbing round with tow.

S. BOTTONE.

[96771.]—**Wall-Papering.**—What "Paper" suggests is the proper thing to do, only he must be sure and damp the canvas well and paste it down well at the edges and it will dry tight as a drum.

WILLIAM GATRELL.

[96771.]—**Wall-Papering.**—Fill up cracks with magnesite or other cement, or canvas, as you fancy, and paper over.

REGENT'S PARK.

[96771.]—**Wall-Papering.**—Yes, the best way for you to paper your partition is to paste strips of calico over them, allowing them to come over the cracks about 3in. each side. Well stretch, and nail the edges down with small copper tacks; iron ones will rust through. Let the calico get fairly dry before you paper over or your paper will be darker where it is so long drying. Before sticking on strips of calico size boards with ½lb. size to three pints of water, boiling.

Bromsgrove. HOUSE PAINTER.

[96774.]—**Isle of Man Steamers.**—The P.S. *Mona's Queen* was built by the Barrow Shipbuilding Company in 1885. Her dimensions are as follows: Length (b.p.) 320ft., breadth 38ft., depth moulded 15ft. 1n., depth of hold 14ft. 6in., gross tonnage 1,465 tons, and net 525. She is fitted with two pairs of compound oscillating engines, having one high-pressure and one low-pressure cylinder acting on each crank; each of the high-pressure cylinders are 50in., and the low-pressure each 88in. in diameter, the stroke being 6ft., I.H.P. 5,000. The *Peveril*, which has been recently sunk in collision off the Manx coast, was built in 1884. She was 207ft. long, 26ft. beam, and 13ft. deep. Her gross tonnage was 595, and nett 243. Her engines developed 1,100I.H.P. The *Tynwald* was built in 1891. Her length is 265ft., breadth 34ft. 6in., moulded depth 14ft. 6in. Her gross tonnage is 946. On the Liverpool run she carries from 800 to 900 passengers. Her engines are triple-expansion, and the cylinders are 22in., 36in., and 57in. respectively; stroke 3ft., pressure 160lb. per sq.in. She is twin screw, and maintains a sea-going speed of from 18 to 19 knots. I.H.P. about 5,000.

RED ADMIRAL.

[96772.]—**Probability.**—I think "Scorpio" is wrong in assuming that the chance of getting nine

heads "at least once" in 512 groups is nearly certainty. It appears to me to lie between $\frac{3}{5}$ and $\frac{3}{4}$. In each group the chance of getting "nine heads" is $\frac{1}{512}$, and the chance of not getting nine heads is $\frac{511}{512}$. In the case of 512 groups, the respective probabilities that a group of nine heads will occur never, once, twice, three times . . . . . 511 times, 512 times are given by the successive terms in the expansion of the binomial expression $(\frac{511}{512} + \frac{1}{512})^{512}$. Therefore the chance of getting a group of nine heads—

(1) at least once is $1 - (\frac{511}{512})^{512}$.

(2) exactly once is $512 (\frac{511}{512})^{511} (\frac{1}{512})$, or $(\frac{511}{512})^{511}$.

"Scorpio" will notice that the chance of getting the nine heads "exactly once" very slightly exceeds the chance of never getting them at all. The chance of getting two groups of nine heads is about one-half of the chance of "one" or "none." The chances of three, four . . . . groups diminish very rapidly. Of course, in the general question, the chances are—

(1) at least once is $1 - \left(\frac{n-1}{n}\right)^n$

(2) exactly once is $\left(\frac{n-1}{n}\right)^{n-1}$

A. O. S.

[96772.]—**Probability.**—The probability that the event happen is $\frac{1}{n}$. Therefore, the chance that it fail is $\frac{n-1}{n}$. If each trial is an independent event, the chance that it fail n times running is $\left(\frac{n-1}{n}\right)^n$, and the probability that it happen at least once in n trials is $1 - \left(\frac{n-1}{n}\right)^n$. The chance that it happen at the first trial, and fail in the remaining $n - 1$ trials is $\frac{1}{n} \times \left(\frac{n-1}{n}\right)^{n-1}$; and this is evidently the chance that it happen only at an assigned trial (say at the nth trial), out of n trials. These probabilities are dependent; therefore the chance that it happen at *some* one trial out of n, and no more, is n times the above, or $\left(\frac{n-1}{n}\right)^{n-1}$. This is the same as the chance that the event fail $n - 1$ times in succession, which is clearly the case, for it matters not at what stage we suppose the one success to occur. In the example quoted by "Scorpio," (i.) becomes—

$$1 - (\tfrac{511}{512})^{512} = 1 - \log.^{-1} 512 (\log. 511 - \log. 512)$$
$$= 1 - \log.^{-1} \bar{1}\cdot 56526 = \cdot 6325 \pm$$

and (ii.) becomes—

$$(\tfrac{511}{512})^{511} = \log.^{-1} \bar{1}\cdot 5661099 = \cdot 36822 \pm$$

"Scorpio" will therefore see that these chances are by no means the certainties he supposed, being roughly $\frac{5}{8}$ and $\frac{5}{14}$, say 5 to 3 on the first event, and 9 to 5 against the second. Suppose x is the number of trials required to give a probability of 100 to 1 that the first event will happen, we get $1 - (\frac{511}{512})^x = \frac{100}{101}$, which gives $x = 2360 \pm$, so that more than two thousand trials would be required. "Scorpio" will notice that (i.) is not the same as the chance that we get at least nine successive heads at least once in 9×512 tosses. C. P.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered, are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[96776.]—**Wickless Paraffin Lamp.**—My lamp, "Primus No. 5," persists in burning with a smoky flame, and on unscrewing the top portion I find there is a hard scale formed inside the tube, which doubtless causes the trouble by obstructing the oil passages. I should like to know if there is any way of removing this scale, say by soaking or boiling in some solution which will not injure the metal?—Steelyard.

[96777.]—**Balloon.**—Having what is thought a new arrangement for aërial navigation, I should like to try some experiments, and should be glad if any of your correspondents could give the following information? What sized balloon (cigar-shaped, filled with coal-gas) would lift a weight of 1lb., and what material should the balloon be made of?—Aerial.

[96778.]—**Barometer.**—Having omitted to screw up bucket at foot of the tube of a mercurial barometer before taking it on a sea-voyage, the mercury now so fills the tube as to prevent weather indications. Will someone state by what means a normal condition could be restored, or will it be necessary to send it to an expert?—S. Durant, St. Croix.

[96779.]—**Boiler.**—Would Mr. Allinson or some engineer friend say if copper tube would do instead of brass? Also, what gauge should it be (working pressure 75lb., tested 150lb.)? How do you keep the proper water level? I should think it wants constant attention. I intend trying to make mine self-regulating. Can this be done in practice? It seems easily done on paper.—Aston.

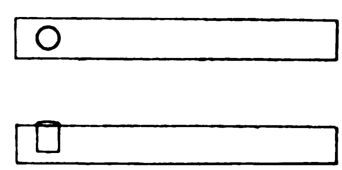
[96780.]—**Irish Degrees.**—(1) What Irish universities confer the degree of Mechanical Engineer? (2) What subjects are necessary to obtain it? (3) Of what practical use is it in the mechanical world?—A Subscriber.

[96781.]—**Electric Lighting.**—Could Mr. Bottone or other readers tell me if, when running a 50-volt 4amp. shunt-wound dynamo, I should require a pilot lamp, or not? Please explain the use of a pilot lamp? Also, what would be the result if a lamp or two were suddenly switched off or on, as required? Would a resistance coil be an advantage, or not? Kindly give size of the best wire to use for a resistance coil made clock-face pattern, with a hand to alter from 1 ohm upwards? Kindly say feet to 1 ohm, then I can make according?—E. M.

[96782.]—**Magneto Ignition Gear.**—Would someone kindly give sketch and particulars for making a "magneto ignition gear" for a two-cylinder 4H.P. horizontal petrol engine? If coil is necessary, size of that as well?—W. E. Pitcher.

[96783.]—**Motor.**—Would some kind reader give sketch of tube ignition to a Dion motor which I have? I note there is a hole for sparking-plug, which I shall not use, as the inlet and exhaust pipes would foul. Also, what arrangement can I make to prevent compressed gases escaping at ignition-hole? Also, in starting carburettor, is it necessary to warm the petrol?—Aeria.

[96784.]—**Grate Front.**—I want to make a pattern for a stove grate front with vertical bars, and I want to have the holes left right through in the top rail of the casting, as per sketch, and about three-parts through in the



bottom of same, so that I can thread some pieces of round iron through for bars. Perhaps some kind reader will kindly help me?—An Old Subscriber.

[96785.]—**To "Monty."**—Will "Monty" please say whether burner (96374) makes a loud noise or not? Also, can he give design of one suitable for common petroleum which will give less noise than the usual "Etna" lamp?—F. M.

[96786.]—**Motor-Car.**—Will "The Writer of the Articles" please say what diameter of wheels, size of spokes, and what width of pneumatics are suitable for a motor-car to carry four persons?—F. M.

[96787.]—**Gas Battery.**—Will some reader be kind enough to give me a few particulars about gas batteries? I have a sort of notion that they are composed of carbon electrodes immersed in some gases; but what the gases are I don't know. Also, what current and voltage will they give?—L. B.

[96788.]—**Railway Waggons.**—Would some reader give full detailed dimensions of a G.E.R. coal-waggon?—Loco.

[96789.]—**Sundial.**—Would some astronomical reader kindly inform me as to the method of drawing a sundial showing time of sunrise and sunset, and a dial giving the time of rising and setting of the moon?—Achernar.

[96790.]—**Hot-Air Engine.**—Is it possible to get or make a hot-air engine for a boat about 14ft. long? What power ought it to be, also what dimensions? Would it be more reliable and easier to make than an oil-engine?—R. W. E.

[96791.]—**Dynamo.**—Could any correspondent kindly inform me as to the winding of the armature of following dynamo (undertype)? Magnets 3¾in. by 3⅜in. by ⅜in.; armature (cog drum) 3⅜in. long, 1½in. diam., six slots ⅜in. deep by ⅜in. wide, to be wound as Gramme ring. Magnets wound with 10 layers (600 turns) of ·036 d.c.c. What influence would winding armature with wire double the size have on voltage and current, and what is the correct size of wire for armature with present winding of magnets to give about 15v. 5a.?—A. S. Hooppell.

[96792.]—**Dynamo and Engine.**—I have a 4N.H.P. vertical engine with 3ft. flywheel; also dynamo with 6in. pulley. The engine runs about 160 revs. per minute. I have also got a 10 to 12N.H.P. engine. I want to make a little change. What size pulley will I want for counter-shafting to run dynamo 20ft. from 4H.P. engine, and how can I find out what size dynamo pulley and what size flywheel for large engine, as I intend getting large dynamo? If I shift the small dynamo to large engine, which has a very large flywheel, 5ft. to 6ft., how can I calculate the speed and size to put on, as I have some spare ones? About how much will dynamo cost to light 50 to 60 lamps? Any information will greatly oblige.—Foreman.

[96793.]—**Speed.**—How can I give a rough guess of speed of engine without speed indicator?—Foreman.

[96794.]—**Bluing.**—How can I obtain the steel blue colour on iron as seen on the furniture of sporting guns?—T. Gallyon.

[96795.]—**Varnish and Stain.**—I should feel obliged if someone could give me a recipe for a good varnish, and state how I should use it? It must be hard, durable, and brilliant. I have tried a good number of varnishes, but some would not stand the wet, and others cracked and chipped off?—Varnish.

[96796.]—**Marine Condenser.**—I have a 1½H.P. vertical multitubular boiler which I intend putting into a boat for sea and harbour use, but am told that it is absolutely necessary that a condenser be used in order to clear the water of salt, muddy sediment, &c., before it enters the boiler, otherwise both the boiler and the engine will soon be entirely ruined. Will someone please tell me the kind of condenser that is required, its mechanism, and how it works? Also the size, weight, and probable cost of same?—Old Colonial.

[96797.]—**Motor-Tricycle.**—Is there any way of constructing a motor-tricycle to pass a somewhat narrow doorway of a private house? Could trike be turned on its beam-ends for this purpose with safety? This is the only drawback that deters me from making a motor-cycle from the excellent description now being given in "Ours." How would a steel liner do for the cylinder instead of boring?—Mechanic.

[96798.]—**Gelatine.**—(1) Can gelatine be dissolved in any liquid besides water without losing its property of solidifying or cooling? If so, name of solvent will oblige. (2) Can anything be mixed into liquid gelatine to make it dry waterproof without affecting its transparency?—Experimentalist.

[96799.]—**Acetylene Gas.**—Will a friend help Cape Colonist out of Queer-street? Some time past I asked how much carbide it would take to generate gas sufficient to fill a five-gallon nourishing tank? I forgot to ask if the gas-tank should be filled with water; if so, will the gas mix or go through the water? A friend of mine tells me that as soon as the gas generates it will force through pipe into gas-tank, strike the water, and end in a blow-up, as there will be a greater pressure in gas-tank. I don't wish to be blown to Pretoria.—Cape Colonist.

[96800.]—**Acetylene Carriage-Lamps.**—Could any reader kindly tell me how to make generator suitable to fix and burn in ordinary carriage-lamps? A sketch would be greatly appreciated.—R. Colin H.

[96801.]—**Pump.**—Could any reader inform me of the best, cheapest, and simplest pump for country use (well 40ft. deep), to throw water to top of house, 25ft. from surface—in all 65ft.—to pump about 100 gallons a day, and where pump could be obtained? I shall be obliged for all information, as it is for a countryman's use.—Thomas Ball.

[96802.]—**Lights in Observatory.**—What kind of light is used in observatories for reading the circles, &c.? Chambers recommends a bull's-eye lantern, covered with red silk or paper. I have one, burning colza-oil; but I find a difficulty in reading printed matter with it. Will some fellow-reader of "ours" who owns an observatory kindly advise?—Oculus.

[96803.]—**Equatorial Adjustment.**—I should be glad to learn what is the matter with an equatorial mounting which gives correct declination when the telescope is on the west side of the pillar, but is between 3 and 4 minutes too low when the instrument is on the east side. After repeated adjustments, I fail to eliminate this error. The mounting—German style—is by one of the best firms in the kingdom, but is thirty years old. May the difficulty arise from unequal wear on the declination axis?—Oculus.

[96804.]—**Hertzian Waves.**—Will some brother reader kindly tell me where I can find a simple account of Hertz's experiments with oscillators (rings and plates of metal)? I have seen Lodge's "Work of Hertz," but that is too technical and advanced. What I want is full particulars of his early induction experiments which led up to the wonderful signalling through space.—H. B.

[96805.]—**Geological.**—Through the crown of the Thanet chalk, about half a mile from the sea, in the greensand, at about a thousand feet deep, the Corporation of Margate have bored, and found water; but it is reported to be salt water, and they are abandoning the costly and hopeful experiment. Will some of "ours," posted in geology, say where else has salt water been found in the greensand, or how its presence below 1,000ft. of chalk is to be accounted for?—W. L. S.

[96806.]—**Ram Supply.**—Would any reader kindly send me a rough sketch of the most efficient ram that can be made with a 2ft. fall, to throw up a ¾in. or 1in. column of water, about 2½ft. above the level of the ram supply? I want to know the proportionate sizes of drive pipes, valves, and air-chamber. Is it possible to do it with a lower fall than this even?—H. C.

[96807.]—**Motor-Cycles.**—I have followed with great interest the able articles that have appeared on this subject, and argue that details for the construction of sparking coil have not been given. Perhaps "The Writer of the Articles" can see his way to fill the gap, as no doubt many situated as I am would be glad to construct their own coils?—J. P.

[96808.]—**Dynamo Switchboard.**—I have just received my 69th volume from the binders, and on p. 42 Mr. Bottone sends a sketch showing how the accumulators, &c., are arranged, and adds that particulars of

working will be found in his book, "How to Manage the Dynamo." I have this book, but cannot find the slightest reference; so perhaps he will kindly give details of using the switches, &c., there sketched, and oblige.—A Subscriber since 1866.

[96809.]—**Bacilli.**—In works on bacteria, where measurements are given, I frequently see the letter "μ" used. For example, where speaking of lactic acid ferment, it is stated the bacilli is "$1 - 1{\cdot}7\ \mu$ by ${\cdot}3 - {\cdot}4\ \mu$." What is the μ or its measurements? Again, in works on organic bodies when submitted to the polariscopes—say, for example, a certain solution of starch—it is stated: "Its specific rotatory power is for $[\alpha]_j = 222{\cdot}0°$; $[\alpha]_D = 200{\cdot}4°$." What is the meaning of $[\alpha]_j$ and $[\alpha]_D$?—Grateful.

[96810.]—**Finder.**—Will some reader be kind enough to tell me what is the best material to use for the cross wires of a finder telescope, and what is the most effective method of fixing them to the brass frame that carries the wires? I have tried human hair, and tried to fix them with sealing-wax; but the former stretches, and the latter fails to hold them.—N. Maclachlan, Routenburn, Largs, N.B.

[96811.]—**Converting Objective.**—Would Mr. Caplatzi kindly tell me whether a 1/10 water-immersion objective can be used as an oil-immersion without further alteration by the makers, and whether such alteration, if necessary, can be cheaply effected? Is cedar-oil used because its refractive index approaches most nearly to Canada balsam or to glass? The objective is a Swift.—T. H. M.

[96812.]—**Winding ½H.P. Motor.**—To Mr. Bottone.—Will you please tell me the best quantity of wire, and sizes of same, to wind a ½H.P. set of castings as a motor to run on a 50-volt circuit, upright type of fields, each limb 2in. square, winding space 4in. on each, to take laminated ring armature 4in. diameter by 2in. long, 12 cogs? How much current will this motor consume at 50 volts, and will same give ½H.P.? I am also making dynamo. Please state size and quantity of wire for same to give 15 volts and about 10 or 12 ampères? Simplex type, cast in one solid piece soft iron, to take laminated drum armature 2¾in. diameter by 4½in. long, with eight cogs. Should I wind armature with two sets of wire in each space for an eight-part commutator, or with single coils for a four-part commutator, as recommended by you in your book on "The Dynamo"? What advantage shall I get if I wind for eight-part commutator, as your mode of winding seems much simpler? How many ampères can I expect at 15 volts? Also speed to run same, and H.P. required? I have your book on "The Dynamo."—Old Reader.

[96813.]—**Oxidised Steel and Iron.**—By what process is the black surface popularly termed "oxidising" produced on iron or steel? I mean such as is seen on the steel cases of watches sold under the name of "oxidised steel."—Gerard Smith.

[96814.]—**Acetylene.**—Will any reader kindly oblige by answering the following questions? (1) What size of burner will be required to give an 8c.p. light? (2) What weight of carbide will be required to supply the above per hour? (3) Acetylene is said to be readily soluble in alcohol. Does the solution thus formed burn with a luminous flame?—J. S.

[96815.]—**Malleable Castings.**—I keep a small foundry, and want to make a few malleable castings. Will some reader say how I am to go about it? What pig-iron should I use, and what grades, if more than one? Can I melt in an ordinary cupola with fan blast? Should there be coal-dust in the moulding-sand, as for ordinary castings? What kind of furnace should I have for the annealing, and how long does the process last?—Malleable Novice.

[96816.]—**Musical Box.**—Will someone kindly tell me what is the cause of a barrel musical box scratching and whistling whilst it is playing? I fancy it is the pins scraping the comb. Is this right? I have been told it cannot be taken out without it going to Paris. I have thoroughly cleaned all the parts, &c., but it squeaks as badly as ever. Should be obliged for any information as to cause.—S. R., Bromsgrove.

[96817.]—**Electric Bell.**—Will one of your readers tell me the reason of the following? I put a bell up with two Leclanché cells to ring it from front door, which it did very well, and then a week after I heard it did not ring, and had only done so for a few hours; so I went and had a look at the battery, and was amazed to find it all full of crystals. I put two new cells, and then found out that the wire was short-circuited through an overdriven staple. Would that cause it, or was there something in solution? I may say the zinc rods were rotted clean away.—S. R., Bromsgrove.

[96818.]—**Square Thread.**—I wish to cut some ⅝in. square threads, 8 threads per inch. As the hole will only be ⅜in. diam., a tool in the lathe to give necessary depth will be very weak. For a depth of 1in. could they be tapped? If any reader having tackled such a job would reply, I should be glad.—B. A. R.

[96819.]—**Coil, Transmitter,** &c.—To Mr. Bottone.—Some little time ago you gave instructions in reply to a query of mine as to how to use a 1in. spark coil in connection with a Marconi transmitter as follows: A half-pint Leyden jar coated 2in. up on either side of transmitter, outside coatings of jars connected with each other, knobs of transmitter connected to brass knobs of Leyden jars, and knobs of Leyden jars to secondary terminals of coil (with a tapping key intervening). I have connected my coil up this way, but on pressing key I cannot get any spark. I have the contact-breaker screwed up tight, so as not to vibrate. I should be glad if you will kindly say where I am at fault? The coil appears to be in good working order, giving a good spark. In wireless telegraphy does it matter if the transmitter is, say, 10 or 12 yards from vertical wire, connected thereto by an insulated wire, or should the vertical wire be connected direct to transmitter without branch wire?—A. M. L. S.

[96820.]—**Sand-Blast.**—I should be pleased if any reader would give a few instructions for making apparatus for sand-blasting purposes on a small scale. I have plenty of power at my disposal.—Blast.

[96821.]—**Ignition.**—Would some friend give me dimensioned sketch of Bunsen and chimney to heat ½in. ignition-tube? I want burner to stand perpendicular with chimney, instead of horizontal. Does it work as well thus? I want to use as little gas as possible with efficiency. Please give internal diameters and lengths to chimney and burner, and size of air-holes and gas-nipple.—Joyce.

[96822.]—**Flashlight for Interiors.**—Having to take photos. of (or in) rooms about 12ft. to 16ft. square, I should like to know what apparatus I should want so as to be able to take them in a few seconds? It takes me now sometimes an hour, as I have to stop my lens down to F 32, and sometimes F 45. If magnesium is used, how much should I have to burn?—Optical L.

[96823.]—**Wimshurst.**—I purchased about twelve months ago a Wimshurst electrical induction machine, and for about a month it worked splendidly; ever since I have not been able to get a spark from it. I have always kept it in a dry room. The plates are not glass, but are black, made from a substance like papier-mâché.—Spark.

[96824.]—**Pains in Head.**—Can any of "ours" say what is the cause of the following? A friend of mine has for the last four years suffered from acute pains over and round his right eye. It comes on, lasts for not more than a minute, amd then passes off; this occurs at irregular intervals. He describes it as if the eye was being torn out, and rolling over and over in the socket. The agony is so intense that the attacks cause him to lose flesh rapidly. The local doctors are unable to give him relief, and confess they do not know the cause. He has, under their advice, had teeth drawn and his jaw scraped, but without avail. He is 58, leads an active outdoor life in bracing climate, rather intemperate, had a bad fall from a horse some years ago which cut his head open on that side and left a scar. I write because among the numerous readers of "Ours" there may be some who have suffered similarly. Any doctor's name who would be likely to cure would be gladly received.—R. W.

[96825.]—**Meteorites.**—Can any of "ours" give me, or refer me to, a more complete list of meteoric falls in the British Isles than that contained in the National History Museum Guide?—J. H. Pledge.

[96826.]—**Polishing Oak Floor.**—Can any reader tell me what to do to make an oak floor look properly dark and polished? It has been covered up with oilcloth in places and has become dull, and is worn away in others. I wish to restore it to an even bright surface, as it must have originally been. With what ought it to be treated to procure this result? Being oak, it would not, I presume, require any stain?—R. A. R. Bennett.

[96827.]—**Trepanning Bar.**—Will "J. H.," or any of your numerous readers, please give detailed sketch, dimensioned, of a trepanning bar to take out solid core of 4in. It is done, I believe, at the Arsenal.—B. A. R.

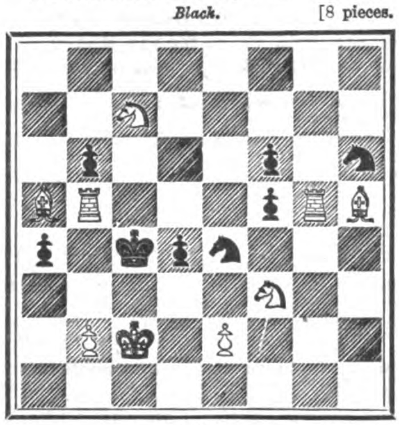
[96828.]—**Rontgen Rays.**—Can any reader give any particulars of the following, which I cut from a London evening paper?—"M. Le Bon, in the *Science Francaise*, announces that by the aid of a simple petroleum lamp it is possible to realise all the marvels of the Röntgen rays. For this experiment all that is required is a petroleum lamp, which is inclosed in a case made of sheet iron, and a fragment of any journal. This paper is placed in a wooden box, which is then so arranged that it stands close against the metal sides of the case containing the lamp. With the aid of the light the paper can be read without any difficulty."—Simon.

CHESS.

All communications for this column to be addressed to The Chess Editor, at the Office, 332, Strand.

PROBLEM No. 1695.—By C. A. Gilberg.

Black. [8 pieces.



White. [9 pieces.

White to play and mate in two moves.

(*Solutions should reach us not later than Oct.* 16.)

Solution of Problem No. 1693.—By C. Planck.

Key-move, Kt-Q 5.

NOTICES TO CORRESPONDENTS.

Problem No. 1693.—Correct solution has been received from Richard Inwards, T. Clarke, E. C. Weatherley, Whin Hurst, A. Tupman, Rev. Dr. Quilter, G. W. Underhill ("The difficulty of the problem lies in the great variety of Black's second moves"), Geo. Christie ("Q-K Kt 3 would almost do, the black pawn at K 7 becoming a Kt being the only move to prevent it; the use of the same puzzled me for some time").

J. E. G.—Only solution as above.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries, put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Oct. 4, and unacknowledged elsewhere:—

Brewed Ginger.—W. Schooling.—No Sirrah.—G. A. R.—A. Clark.—J. E. Gore.—A. O. S.—B. W. Lovejoy.—Jack of All Trades.—Viri.—Primrose Hill.—Paradox.—R. T. P.—Miner.—A. Desportes.—Synosique.—R. S.—Spinster.—M. Phillips.—W.—Temperance.

Steelyard.—For information about the Turkish bath see pp. 43, 69, 113, 312 last volume. See, among other replies, one on p. 466, No. 1581, July 12, 1895; also a letter on p. 141, No. 1359, April 10, 1891.

J. M.—Bonetti's induction machine without sectors was illustrated on p. 404, No. 1526, June 22, 1894.

F. J. Norman.—The pipes should be 3in. in diameter at least, as radiating surface is required. Then, if so placed as to give a quick circulation, such a heating arrangement might answer in the South of England. See a little book published by B. T. Batsford, 94, High Holborn, W.C., on "Hot-Water Heating," by F. A. Fawkes.

W. H.—You can find all about liquid air in the back numbers. See, for example, p. 399, No. 1734, June 17, 1898; p. 423, No. 1735, June 24, 1898; p. 577, No. 1767, Feb. 3, 1899; and for the latest form of plant for making it see p. 551, No. 1793, Aug. 4 last.

S. W. A.—The articles on organ-building which appeared in Vol. LXII. and following volumes were published in a revised form by Sampson Low, Marston, and Co., St. Dunstan's House, Fetter-lane, E.C., in two volumes, text and plates, price 31s. 6d.

Anxious.—Address the query to the Admiralty, Whitehall, S.W., and you will receive full particulars. You can also obtain some useful information by referring to pp. 310, 337, 360, 380 of the last volume, which you can no doubt see at one of the free libraries in Birmingham.

G. Calver.—Fear we cannot go into that. We think ourselves from experience that it *is* more nourishing and more easily digested than white bread; but discussions about the merits of patented flours and breads so soon degenerate into mere advertisement that we have no room for them. We always eat wholemeal bread of some sort, giving the preference to that made on Dr. Allinson's formula, which many bakers in town and country work to now.

T. W. L.—The paragraph about aluminium for cooking vessels (p. 113) is given for what it may be worth. The authority for the statements made is quoted, and the results will be known later on—after experience. At any rate, the metal is not injurious to the human economy. High temperatures are necessary for the alkalis to act on the metal; but the chlorides attack it.

Enquirer.—Kerosene is the name applied to the burning oil (lamp oil) obtained from petroleum, commonly called paraffin oil.

Wind Guage.—How can anyone say what the anemometer gauges without more particulars? Probably the first dial shows the rate of the wind in feet per second, and so on, the last showing "miles per hour." But that is only a guess. Surely there is some indication on the apparatus.

E. D. P., Ontario.—The articles on "A Practical Treatise on Organ-Building," by F. E. Robertson, commenced in No. 1597, and concluded in No. 1664.

W. J. Woodhouse.—Perhaps Slingo and Brooker's work, published by Longmans, would suit, or Sir D. Salomons's "Electric Light Installations," published by Whittaker and Co. See many replies in back numbers.

Welsh.—Only by examining the wheels, using calipers, if necessary. If by "phosphorus paint" you mean "luminous paint," that has been described many times, and recently.

Optical L.—A good ordinary silver or carbon print can always be satisfactorily reproduced. It is of no advantage to send the negative, except for photo-lithography.

Ell Hay.—When you have learnt good manners, we shall be disposed to give you another hearing. The first three lines of your present communication effectually bar its insertion. You are evidently one of those half-informed persons who delight to quibble while professing to seek for information.

S. H. Cooke.—November 13. Further particulars will be given in due course in our "Astronomical Notes" at the end of this month. 2. We do not remember one. Ask Macmillan and Co., St. Martin's-street, W.C.

Rustico.—Much larger, we believe. We gave the figures as they appeared in the German paper. 2. We do not know.

NOTICE TO SUBSCRIBERS.

Home Subscribers receiving their copies direct from the Office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary if it is desired to continue their subscription.

Foreign Subscribers will have the Pink Wrapper sent One Month before expiration, in order to give them time to forward fresh remittance before subscription expires.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, post free to any part of the United Kingdom. For the United States, 13s., or 3dol. 25c. gold; to France or Belgium, 13s. or 16f. 50c.; to India, New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-Office Order. Back numbers can also be sent out by the ordinary newspaper post at the rate of 3d. each.

Vols. XXIV., XXX., XXXII., XXXVI., XXXIX., XL., XLII., XLIII., XLIV., XLV., XLVI., XLVIII., L., LI., LII., LIII., LIV., LV., LVI., LVII., LVIII., LIX., LX., LXI., LXII., LXIII., LXIV., LXV., LXVI., LXVII., and LXVIII., bound in cloth, 7s. each. Post free, 7s. 7d.

Indexes to Vol. LI., and to subsequent Vols., except Vols. LIII., LV., LVI., LVII., LIX., LXI., 3d. each, or post free 3½d. Cases for binding 1s. 6d. each.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each post free from the office (except index numbers, which are 3d. each, or post free 3½d.)

ADVERTISEMENT CHARGES.

The Charge for Advertisements in the Columns headed:—

For Exchange.
For Sale.
Wanted.
Addresses.
Situations.

is Sixpence for the first Sixteen Words, and Sixpence for every succeeding Eight or part of Eight, which must be prepaid. *No* reduction on repeated insertions. Advertisers should state under which heading they wish their announcements to appear.

The address is included as part of the Advertisement and charged for. No displayed Advertisements can appear in above columns. Rates for Displayed Advertisements are as follows:—

For advertisements on inside pages, except page facing leader, for less than a quarter-page; per inch single column—

1	6	13	26	52 insertions.
7s. 0d.	6s. 6d.	6s. 0d.	5s. 6d.	5s. 0d. each.

Per Column.—

1	6	13	26	52 insertions.
£3 0s.	£2 15s.	£2 10s.	£2 5s.	£2 0s. each.

	1	6	13	26	52 insertions.
	£ s.	£ s.	£ s.	£ s.	£ s.
Per Page	8 8	7 0	6 0	5 5	5 0 each.
Half-page	4 10	3 15	3 10	3 0	2 10 "
Quarter-page	2 10	2 5	2 0	1 15	1 10 "

Back Page, £10 10s. A few dates open during 1899.

ORDINARY ADVERTISEMENTS.

	£ s.
Thirty Words	2 6
Every Additional Eight Words	0 6

Front Page, Five Shillings for the first 40 words, afterwards 9d. per line. Displayed Advertisements, 10s. 6d. per inch. Paragraph Advertisements, One Shilling per line. No Front Page or Paragraph Advertisement inserted for less than Five Shillings.

All Advertisements must be prepaid, and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.'s.

Advertisements *must* reach the Office by 1 p.m. on Wednesday to insure insertion in the following Friday's number.

For the convenience of advertisers, replies to advertisements (except those in the Exchange and Sale Columns) may be addressed to "——," care of the English Mechanic Office, and will be forwarded by post to the advertiser, for an extra fee of Sixpence per insertion over and above the cost of the advertisement.

All Cheques and Post-Office Orders to be made payable to The Strand Newspaper Company, Limited, and all communications respecting Advertisements should be distinctly addressed to:—

THE PUBLISHER,
THE "ENGLISH MECHANIC,"
332, STRAND, LONDON, W.C.

This is necessary, as there are several papers published at the same address, and unless letters are fully directed, it is impossible to tell for which paper they are intended.

For Exchange.

The charge for Advertisements in this column is 6d. for the first 16 words, and 6d. every succeeding Eight, which must be prepaid.

Special Notice. — *Correspondents are strongly recommended not to send money or goods to strangers. The safest way when dealing with unknown advertisers is to send a Post Office Order made payable —— days after date, when in case of non-arrival of goods, or dissatisfaction, payment can be stopped.*

Exchange ½H.P. Gas-Engine, new, for Typewriter or Electric Motor.—Cadwell, Camborne, Cornwall.

Immisch Electric Motor 1I.H.P. horizontal type, 100 volt, 6 6 amps., shunt, drum armature, 36 sections, very compact, suit small shop or motor-car. Exchange Motor-Tricycle out of repair, or Sell.

Dynamo, overtype, cogged drum, shunt, 55 volts, 12 amps., self-oiling ring bearings, made by Leeds firm. Exchange Motor-Tricycle Components, or Sell.—J. B., 119, Oakfield-road, Liverpool.

Silver-on-Glass Speculum, 7½in. by 7ft. focus, high-class. Exchange for Pinder, 14in. to 2in., four eyepieces, and cash, or apparatus. Also wanted, a Transit Instrument, 2in. to 3in., for cash or exchange.—Carlaw, Architect, Lanark, N.B.

Gent's Bicycle, pneumatic tires, first-class make, new, cash £10, or exchange for Lathe or Scientific Instruments.—H., 19, Canonbury Villas, Canonbury, London.

"English Mechanic," 34 volumes, excellent condition. Exchange offers by letter (no Postcards) to—Books, care of Mr. Watson, Stationer, 107, Lauriston-road, South Hackney, N.E.

Bench Drilling Machine wanted, with vice, small, cash or exchange.—Campbell, 7, St. Anne's-road, Harrow.

Gas-Engine, ½ Butler's. Exchange 3 or 4in. geared treadle Lathe.—Owen, 132, Talbot-road, Southsea.

"English Mechanics," volumes LVIII. to LXVI., complete, unbound. Exchange.—W. Coates, 70, High-street, Willington, Durham.

Dynamo, 50 volts, nine ampères, weight 1¼ cwt., as new, cost £8 15s. Sell £4, or exchange.—Below.

½-horse Vertical Engine. 55s., or exchange. Wanted, Lathe, Typewriter, &c.—Harris, 104, Holdenhurst-road, Bournemouth.

Set 4½ Ardwick Launch Engine Castings, Forgings. Exchange anything useful, sell cheap.—Particulars, Whetman, Richmond.

Flywheel, 39½in. dia., 143lb., 3½ face, turned, bored 1-15 16, curved arms, set screws. Exchange for Bicycle Frame, 22in., with bracket and cranks. Best offer.—10, Clifford-street, Eccles New-road, Salford.

For Sale.

The charge for Advertisements in this column is 6d. for the first 16 words, and 6d. every succeeding Eight, which must be prepaid.

New Illustrated Price List of Screws, Bolts, and Nuts for model work, drawn to actual size, sent on receipt of stamp.—Morris Cohen, 132, Kirkgate, Leeds.

Watch and Clock Tools and Materials. Catalogue, over 1,000 Illustrations, post free, 6d.—Morris Cohen, 132, Kirkgate, Leeds.

Wheel-cutting and Dividing in Brass or Iron to 12in. diameter.—Clegg, Belinda-street, Hunslet, Leeds.

Lathes and Machined Parts, Wheels, Chucks, Fans, Angle-plates. Illustrated list, 2d.—Jarratt, Queen-street, Leicester.

Carving. — Brass, Iron, Burnt Wood, Bamboo, Leather, Fretwork, and Picture Framing. Catalogue free.—Hargers, Settle, Yorks.

Inventions Protected, £2 inclusive. Designs registered, 30s.—Bromhead and Co., Registered Patent Agents, 33, Cannon-street, London. Established 25 years. Send for list.

Eyesight.—All whose sight is in any way defective should send to Horne and Thornthwaite, 416, Strand, for—

"Hints on Spectacles" (Why the Eyes want Help), by Overstall, F.S.M.C. (with distinction), post free.—Above.

Books.—All out-of-print books speedily procured, any subject. State wants.—Baker's Great Bookshop, Birmingham.

50,000 Choicest Microscopical Objects.—Bargains. Catalogues free. Microscopes, cabinets. Collections purchased.—Suter, 10, Highweek-road, Tottenham.

Rubber Outer Covers, 8s. 6d. Prepared Canvas, 90 by 9, 1s. 3d.; rubber solution, best quality, 1lb. tins, 1s. 6d.—Pemberton.

Air Tubes, all sizes, best quality, 2s. 9d. each. Air tubes with Dunlop valves fixed, 3s. 9d.—Pemberton.

Cushion Tires, 3s., 4s., 5s. Solid Tires, 3s. All sizes stocked.—Pemberton.

Detachable Outer Covers (Licensed), 12s. 6d. each; all cycle accessories and cycle rubber goods stocked.—Pemberton and Co., 1, Cardwell-place, Blackburn.

Acetylene.—Send for particulars of the patent "Incanto" Generators, Purifiers, Burners, Carbide, &c.—Thorn and Hoddle, 1, Tothill-street, Westminster. Works, Harris-street, Camberwell.

Inventions Protected and Sold. Inventors assisted. Advice free.—Ely and Co., 43 Southampton-buildings, Holborn, London.

Nuts and Bolts for Model Work. Illustrated List, 2,800 varieties, 3d.—Butler Bros., Haggerston, London.

Screws, Screw-plates, Taps, round and hexagon special steel brass and iron rods. See list.—Butler.

Have You Sent Yet

For Our "Twenty-five Best Books"?

They are Good Value for the Money.

They are Now Ready, and we shall Not Reprint.

Fifty Shillingsworth of Books and a Half-guinea Bookcase for 30s.

For Full Particulars see Illustrated Advertisement on another page.

Best Assortment of High-class Popular Literature ever obtained at the price.

A Splendid Present to a Friend, or a Village Club, or Working Men's Institute.

Guaranteed to give Satisfaction. Well printed, well selected, well bound. Price, all complete, only 30s.

Send Cheque or P.O.O. for 30s. at once to the Publisher of the English Mechanic, 332, Strand, W.C.

Delivered in London Free. Country orders sent carefully packed, by rail, carriage forward. Please write address plainly.

Send at Once to Save Disappointment. Price for the set complete, in oak bookcase, 30s. Obtainable only at the Office of the English Mechanic, 332, Strand, W.C.

Simplex Typewriter, 14s. 6d., delivered. Thousands in use. Illustrated particulars free.—Atkinson and Co., Harehills-avenue, Leeds.

Stereoscopic Views, 1s. doz., list 4,000. Sample 1d. stamp.—Pumphrey, Stanhope-street, Birmingham.

Wheel-Cutting.—Spur, bevel, mitre, or spiral gear, in all metals, to any pitch.—Motogear, below.

Differential and Spur Gearing as illustrated in "E. M." Motor tricycles. Special prices.—Motogear, below.

Accurate Screwcutting and Fine Turning a speciality.—The Motogear Engineering Co., 78, Queen Victoria street, E.C.

"Gem" Gas-Engines.—Still simplest and best for small powers.—Motogear Co., below.

"Gem" Gas-Engine Castings. — Easiest to make up.—Motogear Engineering Co., 78, Queen Victoria-street, London.

"Gem" Oil-Engines.—New designs for launches and vehicles, &c.—Motogear Co., above.

Brass and Gunmetal Castings of finest quality. Prices on application.—Daniel Young, Witney, Oxfordshire.

Foreign Hardwoods for Amateur Turning and Fretwork.—Daniel, 242, Bethnal Green-road, London. List one stamp.

Booker Brothers' Engines and Motors, oil or gas, ½H P. upwards, also castings.—Tyrrell-road, East Dulwich.

Bargain.—Magnificent **Model Vertical Engine.** tubular boiler, glass gauge, whistle, double action, slide-valve cylinder, bronzed stand, exhibition model, silver-plated, high-speed, and perfect. Worth 42s., accept 12s. 6d. free. Photograph 1d.—Manager, Marshgate Chemical Works, Stratford.

"Simplex" Gas and Oil-Engines new series, "Otto" principle, ½B.H.P. to 2B.H.P., from £9. Guaranteed.—Below.

"Demon" Gas-Engines, awarded prize medal, ½B.H.P. to 12B.H.P., low price, high efficiency, economical. Guaranteed.—Below.

"Demon" Gas and Oil-Engines are thoroughly reliable. First-class workmanship.—Pasley and Co., Sherborne, Dorset.

New Engine Castings, ¼-horse, 5s. 6d.; half-horse, 11s. per set. Catalogue two stamps.—Tomlin, Ironfounder, Oldham.

Economical Manufacture! This cannot be attained with common low-priced tools.—Britannia Co.

We are Bona-fide Makers of over 300 varieties of Lathes, Planers, Shapers, Slotters, Drilling Machines.

Special Tools and Machinery Designed or made to drawing. Makers to the British Government.

Call 100, Houndsditch, London. All letters—Britannia Co., Colchester, England.

Heavy Tools up to 20 tons are now made by our heavy tool department.

Machinery Dealers throughout the world should apply for present terms.—Britannia Co.

Cinematograph Films, Second-hand, good condition, best pictures, List free.—8, Liverpool-street, King's Cross, London.

Rubber Outer Covers, average 16oz., Para rubber 5s. each.—Franklands.

Rubber Outer Covers, 3s. 6d. each, 36s. per dozen.—Franklands.

Cushion Tires, 3s., 4s., 5s. Solid Tires, 2s. 6d., 3s. All sizes stocked.—Franklands.

Air Tubes, best quality rubber, 2s. 9d. each. Fitted with Dunlop valve, 3s. 9d.—Franklands.

Air Tube, Para rubber. Marvellous value. Large stock to clear. Perfectly air-tight., 2s. each.; 21s. per dozen.—Franklands.

Cycle Capes, 3s. 6d., 4s. 6d., 5s. 6d. Also a few cycle Capes, guaranteed waterproof, 2s. 6d. each.—Franklands.

Detachable Outer Covers, licensed, 12s. 6d. each.—Franklands.

Saddles.—A clearing line in ladies' and gents' saddles, 2s. 6d. each, 24s. per dozen.—Franklands.

Inflators, 18in., 1s. 6d. each, 15s. dozen.—Franklands.

Bells.—Special line, double gong, usual price, 12s. dozen, will clear 5s. per dozen.—Franklands.

Prepared Canvas, 90 by 9, 1s. 3d. each, 12s. per dozen.—Franklands.

Pedal Rubbers, 6d. per set of four, 4s. 6d. per dozen sets; no rubbish.—Franklands.

Spanners, nickel, usual price, 18s. per dozen. Will clear a few dozen at 7s. 6d. per dozen.—Franklands.

Cycle Accessories and Cycle Rubber Goods. We hold the largest stock in the North.—Franklands, Astley Gate, Blackburn.

Gramaphones, Cycles, and Typewriters by Monthly payments, from 10s. monthly. — Depot, 70, Manningham-lane, Bradford.

Material for Clothbinding "English Mechanic," 9d. Other material equally cheap. Practical advice given.—Alfred Bean, Hartlepool.

W. Probert and Son, Brassfounders, Whateley-road, Handsworth, Birmingham,

Manufacture Brass Fittings in quantity to sample or drawing.

Brass Tubes, Sheet, Rods, Wire or Strip.

Brass Castings to Pattern.

W. Probert and Son, Whateley-road, Handsworth, Birmingham. Works: Tower-road, Aston.

Cycle-Motors.—Castings and Forgings, rough or machined to instructions in the English Mechanic.—Borland, Leeds.

Motor-Cycles. — Carburettors, Castings, rough or machined. Component parts ready shortly.—Borland, Benson-street, Leeds.

Fretwork, Carving. Lists free. Catalogues, 3,300 illustrations, 9d.—Zilles and Co., 19, 21, Wilson-street, Finsbury, London.

Calcium Carbide, 14lb., 4s. 6d. Acetylene Generators, universally best, from £2 2s. Burners, 1s. 6d. dozen.—Houldershaw, Liversedge.

Inventions Worked Out and Models Made.—Henry Gore, Engineer, 7, Wenlock-street, New North-road, London.

Armstrong's Accumulators, highest quality, greatest durability, 6-volt 9-hour, curved, 9s.; rectangular, 7s. 10d.—Armstrongs', Twickenham.

Armstrongs' Scarfoin Set, complete, 7s. 9d.; vastly superior to other makes at 15s. Unprecedented value.—Armstrongs', Twickenham.

Armstrongs' 12-hour Cycle Set, accumulator, leather case, powerful searchlight lamp, complete, 16s. Order at once.

Armstrongs' are makers of over 500 sizes in Portable and Pocket Accumulators. Lists 4d.—Armstrongs', Twickenham.

Cycle-Motor Castings, described in "E. M." Price List 1d.—F. Homer, 93, Hurst, B'ham.

Gear-cutting.—Spur, Bevel, Mitre, or Spiral, in all metals, milling, turning, boring, and screw-cutting. — James, Engineer, Borough-road, Birkenhead.

Cinematograph Films, large variety, new and second-hand, popular subjects, for sale cheap.—Apply 1, Houndsditch, E.C.

Slide-rest Tools, Lathe-dogs, &c. Illustrated list free.—T. W. Meakin, Engineer, Sumner-road, Peckham, London.

Cinematograph Films, Second-hand, good condition, best pictures. List free.—8, Liverpool-street, King's Cross, London.

The English Mechanic

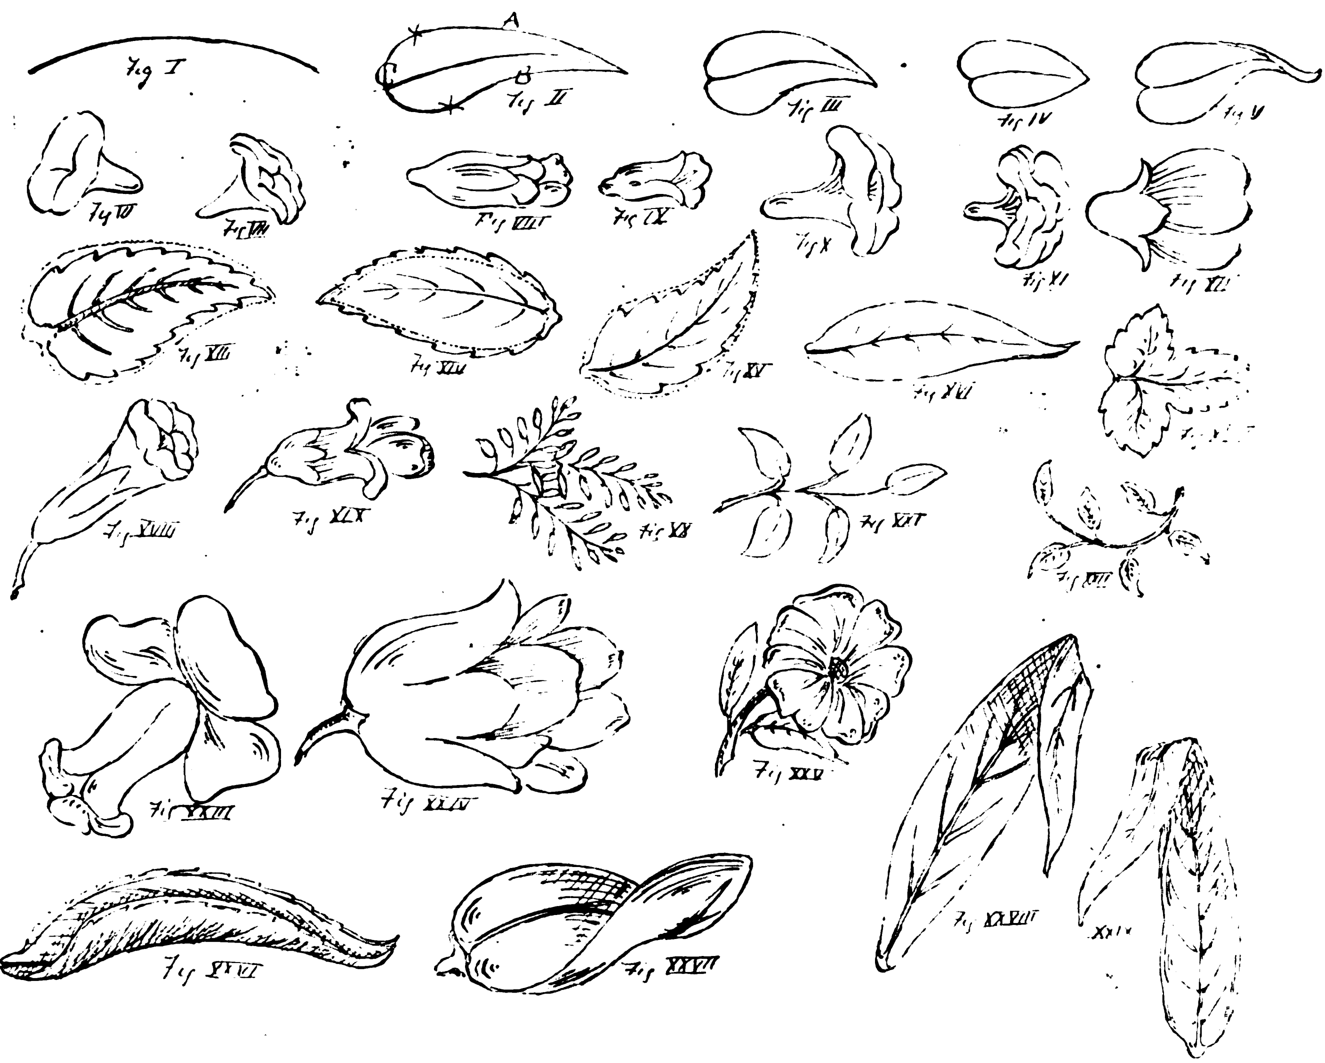
AND WORLD OF SCIENCE AND ART.

FRIDAY, OCTOBER 13, 1899.

INLAYING.—I.

WE have but little to say by way of introduction further than to advise those who intend to take up this fascinating study, to practise well the preliminary stages of drawing with a view to the better handling of the saw.

The reader who studies the examples here set out will have a material advantage over those who, being desirous to hasten on with the cutting, leave the drawing studies till later on.



Another point of great importance to be remembered is that all, or nearly all, our work is in outline. We cannot avail ourselves of the fine touches that the pencil gives on paper; yet proper effect can be given by a few judicious saw-cuts, and the shading shown where it ought to be. We say ought, because many examples of work fairly cut are spoilt by bad shading; and we now point out an error that is unfortunately too prevalent, and that is the overcrowding of a design that would be far and away a better example if it contained less of the unnecessary detail that is worked in. Rather err on the side of insufficient, if of good quality. The charm lies in the happy medium, and good practice will assuredly bring about good results.

Our first batch of drawings will give an idea of what is wanted in the most simple form, either for cutting or drawing. Fig. 1 is the simple stem or vein of a leaf, and we have taken that as our foundation or basis. The curve itself conveys nothing in the shape of beauty, but if we add the top and bottom curves we approach a leaf form. The third curve will complete the leaf. Just a word is necessary to explain why we take the vein as our typical basis. It is for this simple reason that, in whichever direction the vein grows, the outline or contour of the leaf follows with it. Fig. 2 gives the three curves at A, B, and C, although they are seemingly segments of a circle. The use of a compass to obtain them should be avoided: free-hand work should reign predominant. With circles it is different and permissible. The other examples, which are mainly for copying purposes, call for little comment, with the exceptions of Figs. 13, 14, and 15. It will be seen that two examples have the outline dotted outside the leaf proper, the other being within, the object being to decisively show the method of outlining roughly to gain the same inclination of sweep or curve as the vein. Detail is added afterwards according to requirements.

A few words are necessary with regard to turned or twisted leaves ere we close this chapter. Ever aim at depicting the stem first: that will safely guide to the formation of the leaf. It will be easy enough to imagine the course of the vein in Fig. 26, although only just the starting is shown; but with Fig. 27 it will be readily followed, being of longer duration, only a small portion of the leaf being twisted. With abruptly-turned or overlapping leaves, as at Figs 28 and 29, the course of the vein is very distinct, showing almost the entire length of the leaves. In future studies the governing properties of the vein will be fully demonstrated, as also will the grouping of leaves, buds, &c., in their proper order; the above will suffice for this, our first lesson. The method of making the cutting appliances will occupy our attention in the next chapter.

SOME METEOROLOGICAL INSTRUMENTS AND THEIR USES.—VI.

NEPHOSCOPES in the hands of experts prove to be the best means which have as yet been discovered for telling an observer the direction from and the velocity with which the clouds may be moving. These instruments, of which there are many different patterns, by indicating these movements of the clouds, provide valuable information as regards the vagaries of the upper currents of air, and it is from such observations as these that nearly all the present knowledge concerning the winds at high levels is derived. Now, a very few minutes spent in observing such a formation of cloud as that popularly called "Noah's Ark"—a cloud in which there appears to be a central line with offshoots or ribs—will quickly indicate that, in determining the direction from which such a cloud is coming, questions of perspective confuse the judgment; while the same difficulty will be experienced if the attempt be made to define the direction in which the central line and the offshoots are lying. It is for the purpose of eliminating these distortions of perspective that the nephoscope is employed, and, since many of these instruments are very simple in construction and are easily understood and managed, their use is to be recommended as a means of rendering the movements of the clouds more easily understood. If a very minute degree of accuracy is not required, it is by no means difficult to make a nephoscope as will serve for ordinary observations.

In its very simplest form a nephoscope consists of a circular mirror upon which are ruled

two lines to represent the four cardinal points of the compass, the lines being so drawn that they cross exactly in the centre of the glass disc. If the back of this glass be painted black, the clouds may be reflected from it, and their movements followed without distressing the sight. An ordinary observation is made by placing this mirror on a level surface some four feet or so above the ground, so that the observer may examine the reflection of the clouds without undue stooping. The cross lines on the mirror should be accurately adjusted to the points of the compass, and in making an observation the north point of the mirror may be turned towards the southern horizon, for it is the object of these observations to tell, not the direction towards which the clouds are travelling, but the point of the compass whence they are coming. Having, then, thus adjusted the mirror, the image of a small cloud or some well-defined portion or limb of a large one, should be reflected so that its image coincides with the centre of the mirror or the point where the lines cross one another. The image of the cloud should then be watched, and if it is moving at all quickly it will soon be seen to be travelling towards the circumference of the mirror, and the point at which it departs from the field of view indicates the direction from which it is coming. If the cardinal points are not reversed as suggested above, the point at which the image of the cloud leaves the circumference would indicate the point towards which the cloud is travelling, so that in this case the recorded direction would need to be referred to the opposite side of the compass, so that a cloud moving to the south-west would be registered as coming from the north-east. Moreover, the rate at which the clouds traverse the mirror affords a basis for estimating and comparing their velocities, and this much in the same way that one estimates the velocity of the clouds from the rate at which their shadows travel across the fields and the hills. For those lower clouds, therefore, whose apparent motion is so much faster than those at a higher level, a simple nephoscope constructed as above will allow of their direction and velocity being recorded, and its use serves as an admirable introduction to those more complicated methods of observation which are necessary when dealing with clouds at the highest levels.

Between the movements of the scudding clouds which traverse the sky at a high velocity, and those of the apparently slow-moving cirrus cloud which floats far above the highest mountains, there is a great difference as regards the rate at which they move across an exposed mirror, and for the purpose of observing such clouds as the cirrus certain additions to the nephoscope are desirable. It oftentimes takes the image of some of the highest clouds several minutes to journey across an inch on the mirror, and it is necessary to employ a pointer to indicate the distance which the image of the cloud as travelled in a given time. There are numerous ways of adjusting this pointer, but in all of them the object required is that it may be so fixed that its image may exactly coincide with the spot on the mirror where the lines drawn as suggested above cross one another. In one particular nephoscope a stout wire pointer about 1½in. long is fixed to the margin of a disc of metal about 2in. in diameter, the opposite side of the disc being turned flat, and covered with cloth so that it may not scratch the mirror when placed upon it. Supposing now the image of a cloud, or portion of a cloud, is, as before, reflected in the mirror so that it coincides with the intersection of the cross lines, all that needs to be done is so to move the pointer that its image also coincides with this central spot. This operation, it may be said, will be readily understood by holding a pencil at the side of an ordinary hand mirror, and moving it about until its point is exactly reflected at the centre of the glass, and it will then be understood that there may be many ways of adjusting and fixing the pointer of a nephoscope in the desired position. Supposing, then, that this adjustment has been properly made in the nephoscope, the intersection of the cross lines and the images of the cloud and the pointer will all coincide. The eyes may now be taken off the mirror, and the instrument left to itself for two or three minutes. On returning, the image of the pointer being once more made to coincide with the centre of the mirror, it will be seen that the cloud has moved away from the centre, and, as before, the distance traversed and the point of the circumference towards which it has travelled will be an index of its velocity and direction. For scientific purposes nephoscopes are adjusted to a great degree of nicety, and there is considerable elaboration as regards the pointer, the scales and lines, and circles; but, as seen above, it is possible to obtain a fairly correct notion of cloud movement by apparatus of a less pretentious character.

It is a curious fact that it was only at the commencement of the present century that the attempt was made to classify the clouds. Things so familiar as the clouds, it might have been imagined, would have been amongst the earliest meteorological phenomena to be investigated; but until Luke Howard in 1803 published his famous treatise, men were content to look at the different cloud forms without desiring to give them a name. But this psychological anomaly may be left for the consideration of the philosophically-minded. Howard did his work of naming the clouds so well that his descriptions have formed the ground-plan of every system of nomenclature which has since been proposed. So familiar are his cloud names that it need only be repeated that he introduced the three main types. The lower sheet of cloud he called stratus, the middle layer cumulus, and the upper cirrus. These are easily recognised clouds, and their names are no less familiar than the cirro-cumulus, which is the cloud popularly known as mackerel sky, and the cirro-stratus, which is equally familiar as the cloud which is responsible for the haloes which form round the sun, moon, and stars. The term nimbus is reserved for any cloud from which rain is actually falling. These are all clouds which may easily be differentiated from one another, and they are more than sufficient for an observer who is feeling his way, as it were, through the intricacies of the weather by means of observations made in his own locality. From time to time there are international congresses held in different parts of the world to discuss matters meteorological, and the meeting at Upsala in 1894 concentrated its energies on the subject of cloud-observing, and resulted in the compilation of a Cloud Atlas. In this publication are to be found the most recent suggestions for a universal nomenclature, photographs being also given, so that a specimen cloud may serve to illustrate each name. The classification is, of course, much more elaborate than Howard's; but it is to be wished that some such atlas as this might be adopted, so that cloud observations might be more comparable with one another.

It is indeed to photography that the increased interest in the clouds is due, and with its aid it is now possible to measure the height and extent of the clouds and to record their movements, and also to secure a permanent record of their ever-changing forms. In many of the photographs of clouds taken a few years ago it is not always possible to tell which is cloud and which is sky, for in some pictures the cloud is white and the sky brown or black, or vice versâ, and a little experience is required to recognise the kind of cloud that has been photographed. But this also is a matter wherein great advance has been made, and such difficult clouds as the cirrus are now photographed with clearness. By means of yellow glasses also the troublesome action of the blue sky, which has almost the same effect upon the ordinary photographic plate as white light has been overcome and its effects eliminated. Cameras have also been fitted with theodolites, and by photographing a cloud simultaneously at two stations widely separated, the height of such clouds has been determined. The records concerning such methods of research as these are, however, to be found in various reports, and anyone desiring a detailed account of the methods adopted in these most useful photographic enterprises will find full particulars therein.

Now, whether the clouds be observed with or without the aid of apparatus, it is soon borne in upon an observer that there are many different processes at work in forming them. Moreover, admirable as are many of the names which have been given to the clouds, they are nearly all merely descriptive, and only in a few cases do they attempt to indicate the processes by which the clouds are made. Thus a cloud which presents the same appearance during wet weather as in fine, is nevertheless produced by quite a different set of conditions on the two occasions, and will, moreover, float at varying levels, so that the attempt has been made to fit such clouds with names that shall indicate these varying conditions. Many of the processes of cloud formation are now reproduced in laboratories and lecture-rooms, and the most interesting of these experiments are those which show how vapour-laden air condenses into cloud, fog, or mist, when it is suddenly expanded. The researches of Aitken have also demonstrated that the kind of cloud that will be produced depends in nearly all cases upon the amount and quality or texture of the dust-particles in the air. It is said that Londoners nowadays see the sun at noon forty-five days less per year than was the case during the middle of the last century, the increase in atmospheric dust being responsible for these additional cloudy days. Even at the top of the Rigi Aitken found 700 dust-particles in a cubic foot of air, while on another occasion a similar volume of "pure" Alpine air was found to have no less than 4,200 of these dusty nuclei; and without this dust, which varies in texture at various levels, there can be no cloud.

There are numerous ways by which the temperature of a mass of air may be reduced, the most active agents being radiation, mixture, and reduction of atmospheric pressure. The height above the ground at which this reduction in temperature takes place determines also whether the vapour will condense as a minute globule of water or as a tiny spicule of ice. Thus the coronæ which form close to the sun and the moon indicate that the cloud is composed of unfrozen vapour, while those larger circles or haloes, with the accompanying mock-suns and moons, tell that the vapour froze as it condensed. Now, both these clouds are a variety of cirrus; but the one that forms the haloes is at an average of 9,000m., and is called cirro stratus; while the cloud which forms the coronæ is between 3,000m. and 7,000m. above the surface of the earth, and is called alto-stratus. These names, therefore, are intended to indicate something of the conditions in which the clouds were produced. Again, there are strong ascending currents of air rising daily from the ground, which, when they reach a certain level, condense their moisture as the familiar cumulus or woolly cloud. Further, it may happen that this cloud is broken up by strong winds into detached, quickly-moving portions, and the suggested name for these broken clouds is fracto-cumulus, a name that is meant not only to indicate the cloud form, but also that it was produced during the prevalence of strong winds. Not only, therefore, may something be learnt concerning the movements of the clouds by watching their images in the mirror of a nephoscope, but repeated observation of their changing shapes and calculations as to their height will reveal many of the circumstances under which they gained the beauty of their colouring and outline.

ORNAMENTAL TURNING.—XXIX.

By J. H. Evans.

In continuation of our studies of the spherical slide-rest, I have, after consideration, come to the conclusion that it will greatly enhance our advance if we assume that those parts already detailed and illustrated have reached the stage as therein described; this being so, we pass now to the foundation (I will term it) of the second slide. This, it will be observed, by reference to Figs. 1 and 2, is made as a separate slide, and ultimately attached to the top plate of the first slide. Reference to the illustration clearly shows that this, in like manner to all the slides connected with this slide-rest, must of necessity be somewhat limited in thickness, for the reason already explained—viz., that so many working parts have to operate within a given and limited space.

This slide, then, which is 9in. long by 4in. wide, having an interval at the centre, as shown, of about 1½. This is not of great importance as to the exact dimension given. I need scarcely say that it is simply for the passage of the nut of the main screw.

Having the forging of Fig. 1 at hand, all burrs must be removed, which is easily done with an old file; it is then placed and carefully fixed on the planing machine, care being exercised that it does not spring from the surface at any point. It is then accurately planed up all over, and ultimately scraped and surfaced until perfectly true. This is a test of the abilities of the operator, and, with a fair knowledge of how to use them, all that will be required is an accurate surface-plate, and a scraping tool correctly ground and set.

I have seen a good many different men at this particular kind of work. Some will cover the surface-plate with a substance that will fill up

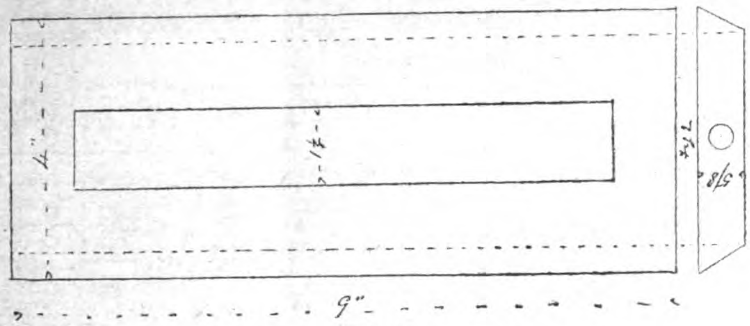


FIG. 1.

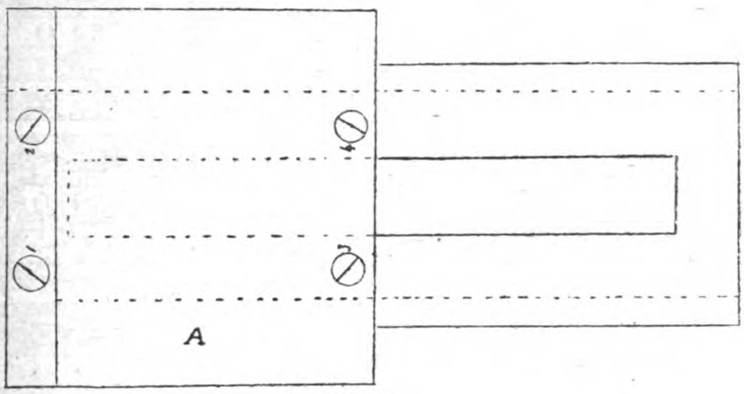

FIG. 3.

nearly all parts of the work when it is applied to the surface as a test. This is a great mistake, as it misleads the operator altogether. The less adhesive substance used the better, and the rubbing together of the work in hand upon the surface plate will at once show clearly the highest parts, which must be carefully removed until the two agree as nearly as possible. This will, no doubt, be regarded by many as a tedious and to some extent an unnecessary proceeding, but it will be found to give an ample reward in the end when the slides are put together.

We will look upon this slide so far as complete, and our next proceeding will be to fix it to the top plate of the lower, or first slide. The first thing to do will be to take the plate A, Fig. 3, which has the one side bar in the solid as shown. The slide, Fig. 1, must be fixed to ascertain the position in which to drill and countersink the four holes, 1, 2, 3, and 4. This done, the slide may be removed while the holes are prepared.

The slide is then again placed in position, with its end flush with the plate. One hole is then carefully marked off, drilled, and tapped, and the first screw got in its place; and now comes the time for the exercise of all the care we can command. On the accuracy of this slide, when fixed, much depends. It will be seen that when fixed this slide lies parallel with the lathe-bed, and should any error exist, it will, of course, be multiplied in accordance with the length of the slide, hence the caution required in fixing it.

Having the one screw in its place, the slide can be held by it to the plate while the others are got in, and when this is completed to satisfaction it is, in reality, an anxious time overcome. Although the slide is limited in thickness, there is ample room to tap a dead hole;—by this I mean the drill should not be taken through the upper surface of the slide, as it is both detrimental in appearance and creates a means of collecting grit or dirt, which might at any time mark the slide if not removed. As there is no necessity it must be avoided. If required, the bottom of the hole may be made flat by the introduction of a small D bit; but this, I think, I may safely leave to the discretion of the person who has the work in hand.

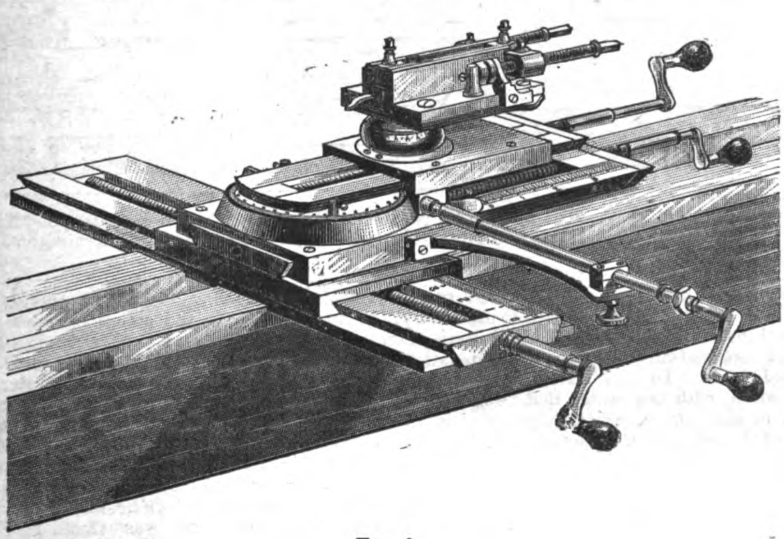

FIG. 6.

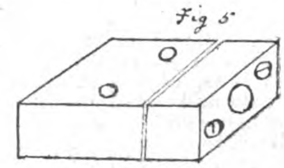
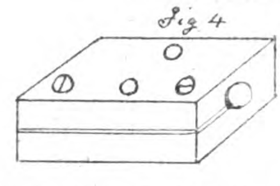
By reference to Fig. 6, which is an illustration of the instrument when finished, I think many points will become much more readily apparent and help the operator considerably—hence its introduction at the present moment. Reference at once to it shows clearly that the plate forming the slide, which works upon that we have just fixed, is exactly the same as that which is fitted to the first slide, and it will be seen that the side which has the angle attached in the solid is placed at the front, the loose strip being, of course, on the opposite side. For this there are two reasons: first, its general appearance; secondly, it is required to carry a gunmetal arm, which will be described as we come to its use and purposes.

I have suggested leaving the fitting of the main screws for one job; but I am rather inclined to think that, having these two slides so far completed, it will be a change in the character of the work if the main screws for these are fitted now.

The screws must, of course, be 10 to the inch,





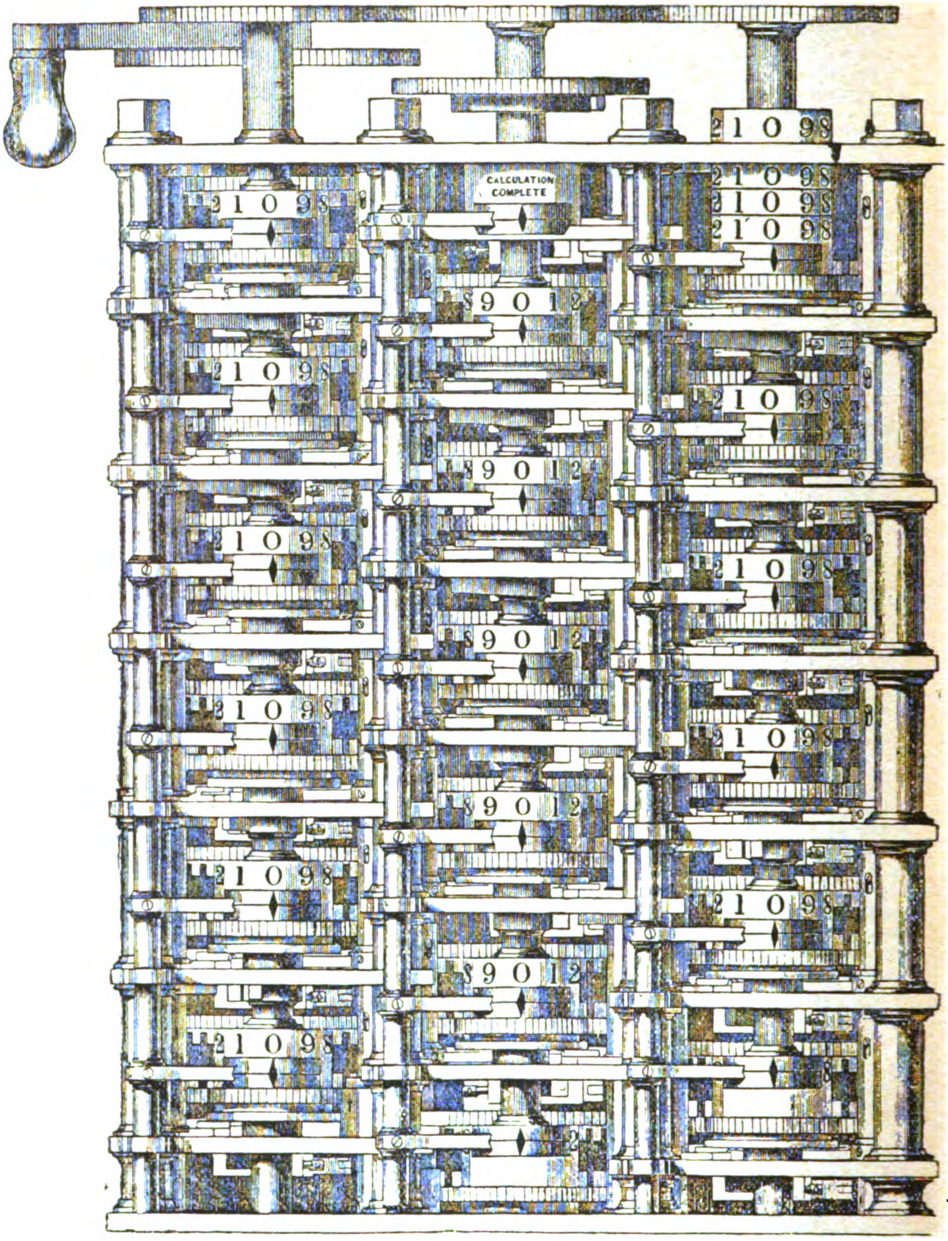
like all others in connection with ornamental turning apparatus. The first thing to do will be to carefully lay out the position and drill the holes in the slides. At the front the size of the holes must be just in excess of the diameter of the screw, while that at the opposite end will be of a size suitable to the end of the screw when turned down to the bottom of the thread. With regard to countersinking of the slide or the metal end-plate to receive the collar of the screw, I feel constrained to say that as long as either be correctly and truly done, I do not think it matters which plan is adopted. The end-plate may be made to the shape of the slide, or simply an oblong plate of suitable length to accommodate the two screws which retain it in its place. On the projecting end of the main screw, and fitted in front of the winch-handle, a micrometer is fitted, but reduced in diameter to allow the slide to pass over it, thus giving a valuable increase in the traverse of the slide, which, with the old-fashioned micrometer of large diameter, was entirely lost. While upon the subject of the main screws, I cannot do better than dwell upon the importance of fitting the nuts in the latest and best way. Having sufficient length, the nut can be made about 1⅜in. long, and the upper surface must be carefully adjusted to just touch surface of the slide, to which it has to be fixed. Having said so much, I may point out that should there be any space between the slide and the nut when it is fixed to the plate, it will draw the screw up in the centre. If very little, however, it may not be felt, especially when the nut is working at the centre of the screw; but as the slide is moved it will be found to become tight at each end. The same will result if the nut is insufficiently reduced, and has to be forced under the slide. I have seen so many amateurs in trouble in this respect, which is easily overcome, of course, if a slight reduction of the nut is all that is required. It is but a few moments' work, and I do not mind admitting that if the reverse is the case the space can be made up. Where a deal of work has been expended, I see no law in mechanics why, if by the careful addition of what is required, the work is saved, it should not be done. These little outrages are, I may say, not confined to amateur's work; however, it is a way out of a difficulty, and it is my aim to assist all I can in this respect; but with these remarks I will retire from the point, not perhaps covered with honours, but with the screw and nut working as if nothing had happened.

One more important feature—one of the most, in fact—is the necessity for the entire immunity from loss of time or back-lash in the screws; the latter being square threads render this a difficult task; unless the nuts are treated as shown in Fig. 5. Before fully detailing this, I will briefly allude to the original mode adopted for setting the nut down to the screw. Referring to Fig. 4, it will be seen that the nut is cut through one side, into the thread of the nut in which the screw works. Two screws are then fitted to pass through the upper part into the lower half, and the tightening of these compresses the nut together. So far as angular threads are concerned, this plan will effect the desired purpose of taking up the wear of the nut occasioned by long service.

We come now to that which is more suitable to the work we have in hand, and is an improvement I introduced some time ago. It must be remembered that we are now dealing with screws that are cut with a square thread, and, to effect the required regulation, the nut must be treated in quite a different way. If we consider it as shown in Fig. 5, it will be seen that, instead of the nut being cut as in Fig. 4, it is separated in precisely the reverse direction. The nut, when whole, should have the placed marked where it is to be severed, which, as seen, is just beyond the two tapped holes by which it is held to the slide. Two holes are drilled through from the front, a plain hole passing the short piece, while the screw is tapped into the other portion. It is better to drill these holes before the nut is cut, as it insures greater accuracy.

It will be at once clearly demonstrated that in the case of a screw having a square thread, which has become worn by continual service, the nut, as made in Fig. 4, would have no effect beyond tightening it round the screw, it would not reduce the back-lash or loss of time; but if we study Fig. 5 it shows that the adjustment of the two screws at the front end of the nut will take up the wear that has occurred in the square thread—that is, the side of the threads between tooth and space—and by this means all such screws can be so regulated that a perfect immunity from the usual loss of time is assured. It will be obvious to all that if, assuming the plan shown in Fig. 4 is adopted, it would simply tighten the nut on to the screw without any other effect than rendering it more difficult to detect; but the error would still exist. I have previously alluded to this, but it is such an important item that I have thought it well to now fully explain the difference between the two ways of operating upon the nuts of screws for the purpose referred to, as the whole operation envolves so little work. I strongly advise that all such screws be treated in this way. A few hints as to the winch handles will enable this part to be completed. The end of the screws should be left perfectly round, and the pipe of the handle accurately fitted. A mortise hold should be cut across the pipe or barrel at the necessary distance, and the end of the screw filed to fit the same; being thus fitted, they are true with the screw, and for such work the old-fashioned square end to the screw has been long since abandoned.

I have now given sufficient details and drawings to enable the rest as far as the second slide to be completed, and for my next will prepare the necessary information for the succeeding rotary motion, &c.



Impression from a Woodcut of a small portion of Mr. Babbage's Difference Engine, No. 1, the property of Government, at present deposited in the Museum at South Kensington.

BABBAGE'S CALCULATING ENGINES.

By Ronald Smith.

It is, perhaps, so much of a commonplace that the first inventor or originator of anything of use to mankind gets the least return that it is hardly worth while repeating. But in the case of Mr. Charles Babbage, the inventor of the Difference and the Analytical engines, better known as calculating machines, it is peculiarly distressing that in return for so much, for so extraordinary an output of brainwork, he got nothing at all. He demonstrated that the whole of the developments and operations of analysis were capable of being executed by machinery; that by mechanism a constant source of error in large numerical calculations, especially in the construction of nautical and astronomical tables, could be completely eliminated. In short, he showed how absolutely correct results could be obtained with the added advantage of economy in time. And this, curiously enough, without human intervention during the course of the operations performed by the machine. Almost needless to say this was the remarkable feature of his invention, for before his day there were calculating machines. There was that of the philosopher and mathematician Pascal, just as there have been many since, and, it may be said, that still they come. But the drawback in the earliest, as it is in the latest, always excepting Mr. Babbage's Analytical engine, is that the mechanical powers in execution require the continued intervention of a human agent. The operations of Pascal's wheelwork calculating machine, which is believed to have been the earliest of its kind, were executed from wheel to wheel by the hand. The removal of this drawback obviously depended on the discovery of a principle so general, that if applied to machinery, the machinery would acquire, as it were, the power of mechanically translating the operations indicated to it. To this Mr. Babbage devoted his attention, with the result that he invented a system of mechanism which required only the nature of the calculation to be executed, or, of the problem to be solved, to be indicated to it. The rest would be done—that is to say, all the intermediate operations would be performed—by the machine's own intrinsic power. Whether it was capable of showing a greater likeness to human intelligence may be reasonably doubted; but there can be no doubt that it was capable of showing something uncommonly like human intelligence when it was known how to order it to perform. Manifestly it could not originate anything; but, as pointed out in the translation of Count Menabrea's sketch of the analytical engine, which Mr. Babbage accepted as true, "the engine is capable, under certain circumstances, of feeling about to discover which of two or more possible contingencies has occurred, and of then shaping its future course accordingly." To the work of designing and planning the essential mechanism of his idea Mr. Babbage devoted the best part of his life, and it may be added, his private fortune, getting in return, as already stated, nothing at all.

Before offering a description of his engines, it may, perhaps, be permitted me to give a brief outline of his life, adding, as stated by his son, Major-General Babbage, that his father never himself wrote a full description of any of his machines, preferring, "while his energies lasted, to devote them to the actual progress and development of the design." Mr. Charles Babbage was born at Totness, in Devonshire, on December 26, 1791. As a boy he was early interested in mathematics, buying, out of his pocket-money, a second-hand copy of Euclid. He was found studying Ward's "Young Mathematician's Guide," when other lads of his years were studying sport. Before he went to Cambridge, where at Trinity College he was entered in his nineteenth year, he was familiar with the "Method of Differences" and the higher mathematics, starting his college career with a copy of La Crox's "Differential and Integral Calculus" in his pocket. One evening in 1812 or 1813, in the rooms of the Analytical Society, a member, seeing Babbage in a dreamy mood, with a Table of Logarithms before him, called out, "Well, Babbage, what are you dreaming about?"—to which he replied, "I am thinking that all these tables [pointing to the logarithms] might be calculated by machinery." This incident may be said to have been the starting-point of his special work, and he was reminded of it later, when it had passed from his own mind, by the late Master of the Temple.

But although the first idea of a calculating machine arose in the inventor's mind at that time, it may be inferred that the opportunity of giving practical effect to it had still to come, he in the meanwhile pursuing his college studies. He took his degree of Bachelor in 1814. Other honours followed, and while at Rome, in 1828, he was elected Lucasian professor for his own

C. BABBAGE.

University. During a visit to Paris he carefully examined the method by which the celebrated French tables had been computed under the direction of Prony. At Paris, too, he came in contact with Didot, from whom he obtained, though at a high price, a copy of his stereotyped table of Natural Sines and their Differences. The French Board of Longitude, with much kindness, allowed him to copy from the tables deposited in the observatory at Paris, the logarithms to fourteen places of figures of every 500th number from 10,000 to 100,000. This appears to have been the fairest period of his life. Well received among distinguished men, and recognised as a mathematician of brilliant promise, no intellectual feat seemed too great for his reach, or no honour worth having beyond it.

The idea of a calculating machine, though it lay dormant for some years, was not to be dismissed, and it was easily aroused on Mr. Babbage observing the almost innumerable errors in printed volumes of logarthms, in the tables in the *Nautical* and other almanacs, and in other tabular works, whose value depended entirely on their accuracy. Navigation, observation, the safety of life and property at sea depended on these tables being produced correctly, and yet they could hardly be taken up and examined without being seen to be full of errors. To design a machine that would not only produce them correctly, but would print them as well, with absolute accuracy was Mr. Babbage's object. He considered the printing of the results, without chance of error, of great practical importance. Indeed it is regarded as doubtful whether he would have undertaken to design a machine to calculate results without also designing machinery to print them. In 1829 Mr. Babbage was working on the drawings of his first calculating engine, and, on June 14th, 1822, he announced to the Astronomial Society that he had completed a machine of two orders of Differences, with which he constructed tables of square and triangular numbers. The Royal Society reported to the Treasury in its favour.

The Government, regarding the invention as of national importance, took it up and directed an advance of £1,500 to be made. Shortly after, the construction of the famous Difference engine was commenced. But troubles arising quite beyond the control of Mr. Babbage, the work was stopped in 1833 and never resumed, the Government finally abandoning the undertaking in 1842, leaving the inventor without remuneration, or even the offer of a suitable appointment. The whole of the money advanced by the Treasury, between £11,000 and £12,000, had been expended in paying the workmen and for the materials employed in constructing the Difference engine, and not one penny of it was ever put into his own pocket by Mr. Babbage. This fact was stated in the House of Commons by the Chancellor of the Exchequer. It is a curious fact in connection with the construction of the Difference engine, that one of the workmen employed by Clement, the engineer, was J. Whitworth, who, as Sir Joseph Whitworth, Bart, became a notable figure in the country. With much penetration he saw, in the construction of Mr. Babbage's engine, the advantages of solid framework, screws to fixed threads, and work to gauge, and with high intelligence developed them to his own profit and the great advantage of the country. Indeed, it is no exaggeration to say that the requirements of this engine led to a remarkable advance in the art of mechanical construction generally, and consequently the invention, apart from its own intrinsic value, was a distinct national gain.

At the stage at which the construction of the engine was stopped, the calculating part was so far completed that Mr. Babbage had a trial piece put together, and it was found to work perfectly. This piece is now in the South Kensington Museum. The second, or printing part, was never put together. In order to afford a clear idea of the calculating part of the Difference engine, Major-General Babbage, the inventor's son, to whom the engines and all the papers relating thereto were left by will, has made the following descriptive outline, which he very kindly permits me to use.

The Difference Engine.

To construct tables to eleven places of figures correctly it was considered advisable to have a machine with six columns of differences and eighteen places of figures in the result. The columns were arranged vertically; the "result" on the right hand, and the differences in order 1st, 2nd, 3rd, &c., towards the left. The mathematician was to give the proper "differences" to be introduced by hand, and the machine, being then set to work, was to produce the terms of the required table, which were to be stereotyped successively as produced on some soft material. To save time, the additions of the odd "differences" (1st, 3rd, 5th) to the result, and even "differences" (2nd, 4th) were made simultaneously first, and then the even were to be added to the odd. The mechanism was supported by horizontal frame-plates, and held firmly together by vertical rods passing through the plates from top to bottom, making the framework massive and rigid, according to the idea of Clement, the engineer who led the way in this direction with so much benefit to the art of construction. The digits 0 to 9 were displayed round the circumference of the discs, and as each figure disc with its attendant pieces was thus inclosed between two frame-plates, each division was called a "cage." The pieces are arranged on five vertical axles on each column; two are merely pivots, on which bent or shaped levers turn; three are revolving axles, to which various arms are fixed. These three axles are moved by the driving apparatus successively one at a time. The pieces in each cage being made to gauge and identical throughout, it is only necessary to describe one cage, and show how a digit in one cage is added to that in the next right-hand column. The figure discs are in the front of the machine, free to rotate on their axle. They have a spiral-tooth wheel, which is in gear with one of double the diameter behind. This wheel is called the "lower adding wheel." Above it is another wheel called the "upper adding wheel," of the same size as the other; this is in gear with the lower adding wheel in the next right-hand column. Between the upper and the lower adding wheels there is fixed on the central axis a small platform on which there is a sliding bolt free to move on the line of a diameter. This bolt always comes to rest in a position perpendicular to the front of the machine. It is shaped symmetrically at both ends, which are cut square, and on the under side near each end there is a round steel stud projecting downwards. In its normal position, when the axle is turned the bolt will not touch any part of either the upper or the lower adding wheels; the bolt remains inoperative if 0 is shown in the figure disc while addition is made in the other cages. In every other case the bolt is shot from behind, and the front end enters between two of the crown teeth projecting downwards from the upper adding wheel. This is effected by a pretty hit-and-miss arrangement. At the back of the machine there is an axle which carries fixed to it an arm in each cage arranged spirally. On each arm there is a wedge-shaped piece which acts on a similar one on another piece, which has two arms, and is pivoted loose on a fixed axle; one arm carries the counter-wedge just mentioned, and the other has a shaped end which engages the rear end of the sliding-bolt above mentioned, and shoots it in all cases except where there is 0 on the figure disc. If the figure is 0, a single-tooth camb on the lower adding wheel will be displacing the double arm and keeping it out, so that the steel wedge passes inside the counter-wedge and misses it entirely. When the bolts are shot, the central axle carrying the bolts is turned a half-circle, and the figure discs in the next column which are to receive addition immediately begin to move with it, showing the numbers one by one successively as if being counted. When the proper number has been added the bolts are withdrawn by an arrangement now to be described.

On the top of the lower adding-wheel two wedges are placed at such a distance from the centre as not to touch the steel stud on the under side of the bolt unless the bolt has been shot. In that case the thin edge of the wedge engages the steel stud, and forces the bolt back to its normal position; the bolt, though continuing its motion, becomes inoperative, and the wheels and figure disc in the next column come to rest. During this time the lower adding wheel has remained firmly locked and the digit on the figure disc unchanged. In those places in the next right-hand column where the figure disc has passed or has come to rest at 0 a click will have been heard, produced by a catch having been released, and an arm carrying a pawl pulled back by a spring. Everything having come to

rest, the axle on which the figure discs are centred is made to turn once round, and a set of arms fixed spirally on it replace the pawl arms under the catch one after the other ready for the next operation.

It should perhaps be added to General Babbage's description of his father's Difference engine, that it was designed to compute nautical and astronomical tables, and that its function being to add only, any other processes except those which it would be possible to reduce to a series of additions, were beyond its reach. Still, the more this remarkable piece of mechanism is considered the greater is the regret that its construction was stopped and the work abandoned by the Government. It is estimated that only a few hundreds—probably not more than £500—more were required to complete, at least, the calculating part, and the Duke of Wellington, who took great interest in the work, recommended its completion. But his colleagues in the Cabinet, seemed at sea in the matter, and would sanction no further outlay. So that the fact remains a lasting reproach, that an invention which astonished the scientific world of that day, which was stamped with the approval of Davy, Wollaston, and Herschel, was denied adequate assistance. Lord Rosse, in his address as President of the Royal Society, declared that he deeply regretted and felt bitterly disappointed that the "first great effort to employ the powers of calculating mechanism in aid of the hmman intellect should have been suffered in this great country to expire fruitless because there was no tangible evidence of immediate profit."

Subsequently Mr. Babbage conceived the design of his

Analytical Engine.

In 1848 he had thought out the principles of construction, and made the drawings and experiments for this his immensely greater work. Unlike the Difference engine, which tabulates only, the Analytical engine can add, subtract, multiply, or divide. All four operations can be performed at the same time or separately—that is to say, without the aid of any of the others. Consisting of two parts, the first part is the "Store," a series of columns each containing a series of wheels. The store may be three or more dimensions: it contains the variables or numbers to be operated upon, also the quantities used in previous operations and returned to the store. Each column in the store corresponds to a definite number to which it is set either automatically or by hand, and the number of digits in this number is limited by the number of wheels carried on the shaft of the column. The wheels gear into a series of racks which can be thrown into or out of gear by means of the cards to be explained presently. The second part is the mill. In this all the computations are made, consequently all the quantities to be operated upon are brought therein. In the mill, not only the fundamental operation of addition, but the combinations of addition, subtraction, multiplication, and division are performed. All the shifting, changing, carrying, and, indeed, all the processes of reckoning go on in the mill, being suitably directed therein by means of perforated cards. Every formula to be computed would consist of certain algebraical operations to be performed upon given letters as directed by the mathematician, and of certain other modifications depending upon the numerical value assigned to those letters. The law of development is communicated by two sets of perforated cards. One set, called "variable cards," are in form like the cards used in Jacquard loom weaving. By means of perforated cards used in the Jacquard system the design of any pattern to be woven is communicated to the loom. Similarly, by means of the variable cards in Mr. Babbage's system, the formula to be computed is communicated to the calculating part of the engine. The numbers (punched) on these cards are transferred to the subject of operation in the mill by a set of wires or axes precisely like the way in which the warp threads are pushed up and down in the Jacquard loom. The other set of cards, called the "operation cards," indicates, by the perforations thereon, the nature and sequence of the operations to be performed. These, on being placed in the engine, act upon the cams and clutches, which direct the gearing of the number wheels of the mill or the store. When these cards have been placed, the engine is special for the particular formula to be computed; and on the machinery being set in motion the variables or numbers required are called into the mill, and the operation is completed by the engine printing as well as computing the numerical results. The calculating power of this engine is such that, reckoning the velocity of the moving parts to be not greater than 40ft. per minute, by its means 60 additions or subtractions could be completed and printed in one minute; one multiplication of two numbers each of 50 figures in one minute, and one division of a number having a hundred places of figures by another of 50 in one minute.

It was of this Analytical engine that Count Menabrea, an eminent military engineer in the Italian service, wrote his sketch, translated by Lady Lovelace, in which he demonstrated from Mr. Babbage's invention "that the whole of the developments and operations of analysis are now capable of being executed by machinery." To the perfecting of this engine Mr. Babbage gave the most of his attention to the day of his death, October 18, 1871.

MILLWRIGHT'S WORK.—XII.

As line shafting runs at a uniform rate of speed, while machines are driven at variable rates, intermediate or countershafts are employed to produce these variable rates. These are short lines of shafting on which pulleys are fixed to transmit definite speeds, greater or less than those of the line shaft. When machines are

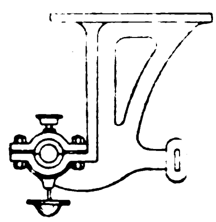


Fig. 74.

fitted with speed cones, the countershaft is fitted with similar cones. The striking gear of a countershaft is that arrangement by which the belt is shifted to fast or loose pulley, to drive, or to leave the countershaft idle.

Of countershafts of this type there are two or three principal classes, each of which finds its application in the work of the millwright. The drum on the line shaft may drive one pair of pulleys, fast and loose on the counter. Or, two drums may drive two pairs of pulleys of different diameters, one set the largest, for driving, the other the smaller for reversing, at a quicker speed, with a crossed belt. Or the pulleys may be used for two speeds of driving. The same results may be obtained by altering the positions of the pulleys, putting two of different sizes on the line shaft, and uniform sizes on the counter.

As regards arrangements of countershaft as a whole, these vary with requirements. The shafts are carried in hangers, or in wall brackets, or on floors, and these fittings, therefore, resemble those already illustrated for line shafts. Many brackets, however, have slots cast in lugs at the back, to receive the sliding fork-bar, Fig. 74, used for shifting the belts. The details of methods

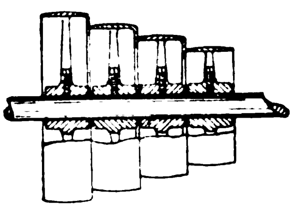

Fig. 75.

of operation vary. A very common device is that of dependent ropes, with handles, which, on being pulled, slide the fork-bar along. Frequently rigid levers are used, while many firms have their own special devices.

The shifting of a belt on the countershaft for stopping and starting machines retains its place tenaciously in English practice, notwithstanding that many friction arrangements have been offered, and are employed to a considerable

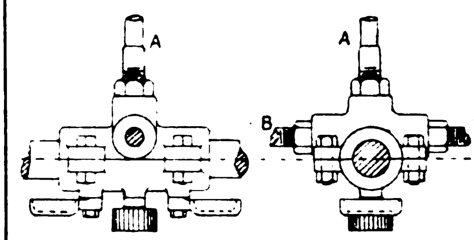

Fig. 76.

extent in place of it. Objections to the common device are more theoretical than practical. It is efficient, though clumsy. The change is a gradual one, as it should be. It is open to question whether it would be advantageous to use narrower belts in order to diminish the time of changing from loose to fast pulley. To use a narrow belt would mean a higher speed to transmit the same power. And it is well known that many machines have to be started gradually.

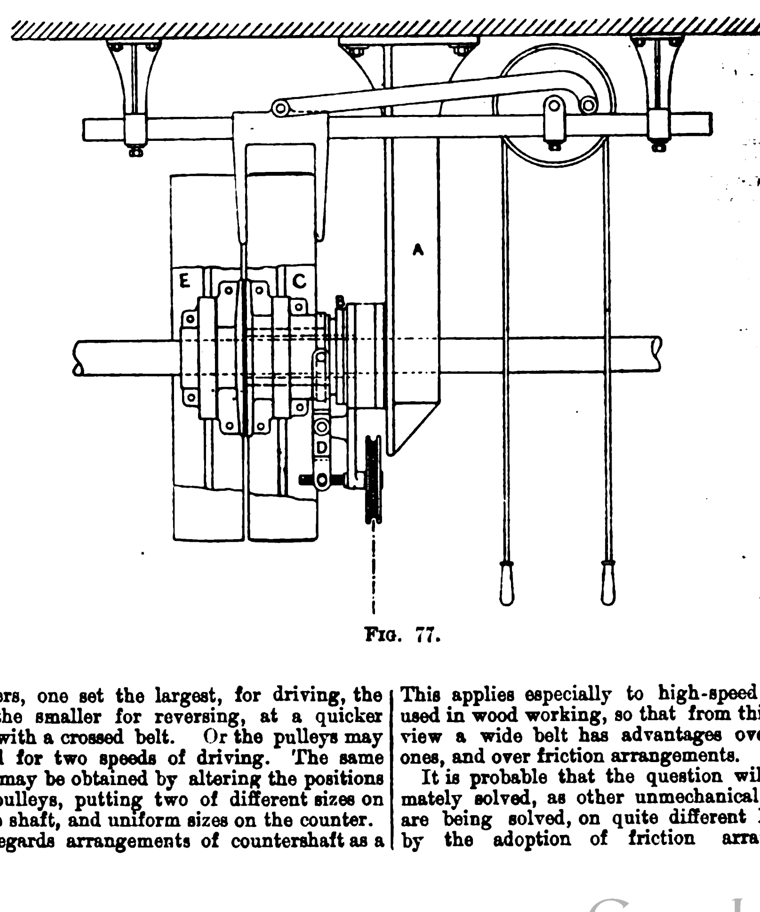

Fig. 77.

This applies especially to high-speed machines used in wood working, so that from this point of view a wide belt has advantages over narrow ones, and over friction arrangements.

It is probable that the question will be ultimately solved, as other unmechanical problems are being solved, on quite different lines; not by the adoption of friction arrangements,

ingenious as they are, but by the abolition of belting, and the substitution of motor driving.

Stepped cones as used for countershafts are generally cast solid. But they are also made up (Fig. 75) by the use of special pulleys, flanged on one side, but cast singly, and fastened side by side to the shaft with set-screws — a method which permits of ready and rapid combinations being effected at less expense than casting the cones in the usual way would involve.

The countershaft, though a very convenient device, is not indispensable. Humpage, Jacques, and Pedersen, of Bristol, have their shops arranged without countershafts by making the cone pulley loose on the main shafting. A clutch on the shaft, operated by a rod which comes down to a footstep bearing on the floor, starts and stops the pulley through the clutch. In this way the countershaft, belts, and bearings, with the beams for attachment, which increase weight and obstruct light, are avoided. This is not an experiment, since the new shops have been in operation about six years.

In this connection, note may be made of a type of adjustable bearing which has been in use for half a dozen years in these shops. It is shown in Fig. 76. It is not a swivel bearing, but is readily adjustable by means of right and left-handed screws. It is of cast iron, four diameters long, and is attached to the principals by an extension of the vertical tie-rods, a right-hand screw being cut on the extended end. A vertical rod A is screwed into a boss on the top half of each bearing, and fastened with a lock-nut. The vertical rod which carries the bearing is attached to the screwed end of the vertical tie with a long sleeve-nut, screwed right and left-handed, and fitted with lock-nuts. It is here that vertical adjustment of the bearings is provided for. Lateral adjustment is provided by casting bosses upon the sides of the upper half of the bearing, and screwing them right and left-handed. Horizontal tie-bars, B B, are screwed into these, and the outer ends of each line of these is brought through a hole in the shop columns and fastened with lock-nuts.

In laying out the shafting, one length was first brought into alignment vertically and horizontally, after which the horizontal adjustment of the others was secured by distance gauges.

The bearing itself differs from others in the fact that the lower half is the one which is removable, so that instead of lifting the shaft out, it is lowered out. Four bolts sustain the weight.

Lubrication is effected by screwing a Stauffer lubricator into the bottom. The pressure of the cap squeezes out the lubricant as required. Two drip-cups, bolted to the bottom half, receive the waste lubricant.

Croft and Perkins, of Bradford, make a special sleeve-fixing, Fig. 77, arranged to carry the loose pulley clear of the shaft, and to bring the driving-belt to rest; also a special starting and shipping gear to set the dead pulley in motion whilst the belt is being shipped.

The illustration shows a sling hanger, A, bolted to the ceiling, and carrying a cast-iron sleeve, B, clear of the shaft, and forming a carrier and bearing for the loose pulley C.

The loose pulley C has a groove turned in the boss on one side, in which a loose strap, attached to the lever D, is placed, and on the other side of the boss a flange is cast, which, covered with leather or copper on its face, is pressed by means of the lever and screw against a similar flange on the rotating pulley E, which is keyed to the shaft, thus putting the belt and loose pulley C in motion. The belt is then shipped on to the pulley E by means of suitable belt shipping gear; afterwards the pressure is released between the flanges of the pulleys, and the loose pulley C comes to rest. The same means is adopted for removing the belt from the rotating pulley E, back to the loose pulley C. J. H.

THEORY AND RULE OF THUMB.

THE winter session at St. Thomas's Hospital was openeds by Prof. Clifford Allbutt, M.D., F.R.S., Regius Professor of Physic, University of Cambridge. In the course of his remarks he said: Many deep thinkers are wont to abuse the Englishman for his stubbornness to new ideas, for his stupid distrust of abstract thought. The ordinary practical man is stubborn and stupid in this respect, yet abuse is no explanation; the ordinary Englishman is by no means a failure in life, and warped as he thus is in grain, and blind as he may be to the decrepitude of the rule of thumb, yet his prejudices are the ossified relics of true and invaluable instincts, and, like other fossil remains, may give us much light if we study them reasonably. Why, then, does the Englishman, successful in politics, successful in business, full of common sense, avoid the man of theory? Why, indeed, has he been busy in his daily conversation to degrade the very word "theory," and to confound theory with visionary speculation and with random guesswork? Indeed, it is with pain that I note some such habit even in scientific men, who, uninstructed in the meanings of language, will not hesitate to make the monstrous assertion, for example, that such and such a matter has been "raised from the position of a theory to that of a scientific fact." What such a speaker means is that the matter has been raised from the position of a conjecture or hypothesis to the position of a theory. Now a fact is something that has happened; a theory is an orderly prediction of what will happen, based upon a formulation of past facts. It is the function of a university, by sifting and testing facts, to arrange them in series whereby to point out what will happen in the further future. When I say that a university is primarily the seat of theory, I imply then that it has a prophetic function. You will demur to me that I am rather departing from an answer to the question why universities are to concern themselves with practical arts, such as medicine, say, and mechanism. It is needful, in my opinion, that they should do so, though I admit that this opinion is not yet general in Oxford and Cambridge—for one reason, concerning the graduate, that the pursuit of theory without touch with practice is apt to become intolerant, and, I will boldly add, is apt to lose its usefulness. Not only so, but without touch of its mother earth it is apt to become too Olympian, and, like the Olympians, to lack bone and blood; gradually to lose life and reality, as scholarship was losing life and reality until scholars learnt lately to dig. For another reason, concerning the undergraduate, unless he be one of the rarer spirits, who, fortunately perhaps, are few, he needs some visible bridge between the truths of abstract thought, or theory, and the needs of the art to which his life has probably to be devoted. I do not hesitate to say, for example, that the great Cambridge school of mathematics has both given and received new life since, unlocked by the labours of men such as Lord Kelvin, the prodigious value of its stores have been realised in the arts. And perhaps I ought to stay here to point out that thus the men of theory, being fed by more solid food, and the men of practice being led to see that out of solid food the most exquisite works of the mind are elaborated, a certain fusion of theory and practice in one institute is the means of the highest education. Yet a university is

Not an Educating Machine only,

it is not only a treasure-house of gathered lore, it is also a factory of new knowledge. Whatever its pretensions, a university which does not produce new knowledge is no university; whatever its humility, a technical school which creates new knowledge, even in one department only, is so far a university. The university should take up so much of the practical arts as enables it to theorise more soundly; the technical school should be conversant with so much theory as to explain the principles upon which current workmanship depends—to explain, that is, the theoretical basis of knowledge empirically obtained. For, although many great and even stupendous arts are now created by foregoing theory, yet mainly in the past the arts have preceded the sciences, and in the fine arts, at least, still precede them. The ground is now prepared for us to understand the practical man among us who flouts theoretical teaching. In the Englishman it is not a fault, but a virtue—though virtue in excess may be a fault—to have a keen and watchful sense of perturbations and contingencies. Even in dealing with nature he has empirically learned, by way of having his knuckles rapped, that general laws are interfered with so incessantly and so largely by laws of less and less generality that the general law or laws may often appear to be of less account than empirical maxims made in practice—that is to say, than the rule-of-thumb. For instance, the laws of cosmic physics, which in astronomy work under disturbances which do no more than test the validity of general laws, in meteorology are disturbed so largely and so incessantly as to make the practice of navigation and the like depend at least as much on rule-of-thumb as upon the most general laws. Day by day, indeed, rule-of-thumb is usually far more valuable to the sailor than knowledge of these fewer general laws. Now, if this be true of an art concerned with so simple a study as cosmic physics, how much more is it true of chemical and of biological practice, and how much more, again, of arts, such as politics, which deal with the incalculable factor of man himself? The Englishman, then, is by general bent an opportunist in all his arts; there is with him a continual sense of the frequency and relative extent of interferences, and by this natural bent to rule-of-thumb he has done mighty works which men versed rather in the wider sweep of more general laws could not have achieved. The failure of the opportunist is not only that he is blind to the broader principles, but that he is blind also to the truth that all secondary and tertiary perturbations are themselves of the nature of law. That a proposition may be "theoretically true but practically false" is a mischievous saw; a theoretical statement which turns out false in application is itself incomplete; its completeness had not been tested again and again by ordinary practice, or by that artificial practice which we call experiment. The moral of this homily is, then, that I would urge upon medical students to learn all their sciences, including pathology and pharmacology, at a university, and to learn the more intimate details of practice at a great hospital, such as that of St. Thomas.

SIR A. NOBLE ON TECHNICAL EDUCATION.

SIR ANDREW NOBLE, delivered the inaugural address of the session for 1899-1900 of the City and Guilds of London Institute Central Technical College, Kensington.

In the course of his address, Sir Andrew Noble said: Technical education properly considered was of the highest importance, both to them and to England. It was only its abuse that they had to guard against. One of the great abuses he took to be that technical education was often begun too early in life, that it was substituted for a general education, and a boy attempted to put his knowledge to practical use before he had learnt how to learn. Another abuse was the divorce of practice from theory and the danger of elevating practical application above scientific knowledge. He wished, therefore, to say a few words about the necessity of acquiring a sound general education before any special work was attacked, and about the necessity of basing all practical work on theoretic knowledge. He attributed the compliment which had been paid him in the invitation to speak at the opening of the session to the fact of his having been connected for many years past with the management of probably the largest engineering firm in England. That position had afforded him exceptional opportunities for observing what educational antecedents were likely to produce the best results in the engineering field. He said exceptional opportunities advisedly, for they at present employed in their various works not far fewer than 30,000 hands. Of those a large number were youths, often sons of workmen, but not unfrequently drawn from the class which he saw represented before him. He was continually asked what education he should recommend for a lad entering Elswick. He always said:—"Send your son to as good a school as you can, keep him there as long as you can, do not curtail his time of schooling, do not stunt his early intellectual growth by narrowing it down to any special study as taught at elementary schools." Science, mechanical drawing, and such like were no doubt very useful, as all knowledge was useful, in their way. These studies might prove an irresistible attraction to minds with a strong bent towards scientific subjects; but he fancied most employers would rather that a lad came to them blankly ignorant of both, so long as he had had a good education, had been taught, and had ability to think and to concentrate his attention on any subject brought to his notice. In nine cases out of ten any knowledge acquired by a boy before he was 16 could have but a slight intrinsic value. Up to that age it was not what he learned that they had to look at, but how he learned; it was the habit of discipline, of mental application, of power in attacking a subject, that were so valuable, not generally any definite piece of knowledge he might have gained. According to his experience the most valuable knowledge that a man had at his disposal was that which he had taught himself. He was not in accord with those who thought that modern languages would supersede the classics as a means of education. Men of science would remember that practically the whole of our scientific nomenclature was borrowed from the Greek and Latin languages. But, whatever might be the fate of the classics as a means, he must take up his parable against a course of education he had seen in several primary schools, where an attempt was made to teach boys, often little better than children, rudimentary chemistry, rudimentary geology, also physiology and electricity. Occasional popular lectures on these sciences might be of very great value to some boys in interesting them in these great subjects and in leading them at some later date seriously to study them; but these sciences, as taught in the schools he referred to, could have but little value in encouraging habits of thought, of application, and of mental discipline. Those men who, with fair abilities, had received a really good education, had been taught to use their minds, and who, by contact with other students, had acquired habits of application amply made up for their late start by the power of mind and grip that they brought to their work. They were fresh and keen

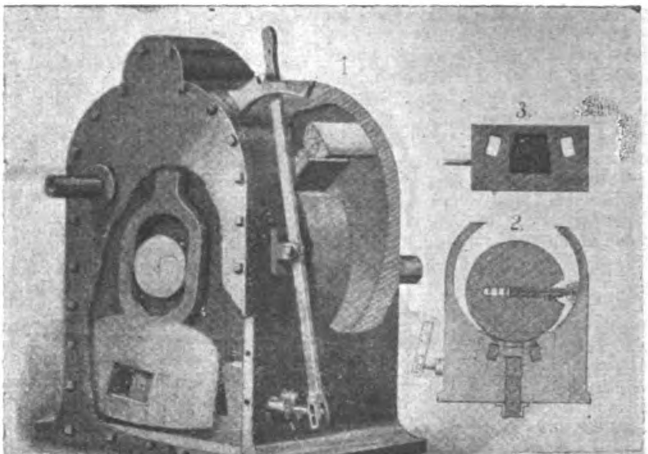
when others, who had been hammering away at semi-technical work from early boyhood, had become stale and were less vigorous, and that reflection moved him to deprecate strongly any attempt to teach seriously practical or electrical engineering in preparatory or elementary schools. As an excellent recreation such studies were no doubt to be encouraged, but to make them a systematic part of education to the exclusion of studies which had a more direct effect in developing the understanding seemed to him to be entirely wrong. He would go further and say that, even in public schools and their equivalents for older boys, what were termed engineering shops were generally a failure so far as any efficient knowledge to be gained in them was concerned. Except as a reasonable diversion for recreation hours such "shops" had, he feared, but little value, and in nine cases out of ten the hours spent in them were subtracted from the time due to more valuable studies. In his judgment the age at which a boy should seriously begin any special studies, with a view to fit him technically for the profession he might decide to follow, should not be earlier than 17 or 18.

Theoretic Knowledge and Foreign Competition.

His next point was that any practical technical instruction and any practical knowledge acquired in the workshop should be based upon sound theoretic knowledge. He was driven to enforce that question, because he found that in this country far too much weight was given to practical skill and what was the rule of the thumb, and far too little to sound theoretic knowledge. In the middle of this century English machinery was immeasurably superior to any other. To their remaining content with that state of things and to their seriously neglecting technical instruction he attributed the very much greater comparative progress that Germany, the United States, and Switzerland had made in the last 50 years; and, if he was not very greatly mistaken, they would have before many years in the East an important commercial rival in Japan, as that country was developing its manufacturing powers with an energy that was as remarkable as it was unexampled. Turning to other departments of industry, no Englishman could observe without regret how certain branches had almost altogether abandoned this country and been in a great measure left to those who had paid more attention to technical instruction. Nearly every requirement of a drawing office could be better and more economically obtained from Germany. From what source did all their pure chemicals come, their filter papers, and most of their glass apparatus? He admitted that the workmanship of many articles made in England could not be surpassed, but if they required any original or special piece of apparatus they were frequently compelled, as he had been, to go to Germany or France for their manufacture. Manufacturing progress had in Germany gone hand in hand with material progress. In the competition of manufacture this country was pressed very hard from steel to watches, from marine engines to scientific instruments. In nothing, indeed, had German manufacturers made more progress than in the making of all exact instruments. In these departments Germany certainly excelled us so far as original and inventive improvement was concerned. All this improvement he felt inclined to attribute not, with Sir William Harcourt, to any linguistic superiority, but to the far greater opportunities of technical study which were afforded in Germany. If this country was to hold its own, the older men must try to multiply these opportunities of study, and the younger men must do their part, by seeking to avail themselves to the uttermost of any such opportunities provided. Older men, like himself, whose careers were approaching their termination, could not but look with envy on the career which might be open to some of those present. It was said of the telescope, which opened to their vision infinite space, that it was balanced by the microscope, which showed them the infinitely small; but small as were those objects, the kinetic theory of gases opened up to their appreciation—he had almost said to their view—molecules whose dimensions were inconceivably smaller. It would be vain to name to them the limiting dimensions of these molecules which had been revealed to them by the labours of Maxwell, Lord Kelvin, Clausius, and others; but he had seen somewhere a statement which might be more easily appreciated. It was something like this: that though the molecules of hydrogen gas were so small that it would take about 50 millions touching one another to make an inch, they were so numerous in a cubic inch of gas at 0° Centigrade and atmospheric pressure that, if the whole of them were formed into a row, they would go round the circumference of the earth more than a thousand times. The molecules also, as they probably knew, were in violent motion. The highest velocity he had obtained with a projectile nearly reached 5,000f.s., but the average velocity of the hydrogen molecules at the temperature and pressure he had named was somewhat more. He once calculated that a few molecules, he forgot in how many millions, might exceed 50,000f.s. Modern science seemed to show that it was equally vain to seek for anything that was perpetually and absolutely at rest. He had alluded to the kinetic theory of gases because they knew more of the constitution of that form of matter than they did of any other, but, having regard to the progress of science to which he had referred, was it too much to hope that some of them would live to see a second Newton, who would give them a second Principia which should clear away the difficulties which surrounded their ideas of the constitution of matter whether ponderable or imponderable?

THE TOENNES ROTARY ENGINE.

ANOTHER rotary engine, described as a "small, compact rotary engine," arranged to utilise steam expansively, has been patented by Richard Toennes, of Boonville, Missouri, and is noteworthy chiefly for the construction of the piston and for the method employed in admitting and controlling the steam. Fig. 1 is a perspective view of the engine, with parts broken away to show the cut-off mechanism; Fig. 2 is a partial sectional front elevation; and Fig. 3 is a view of the reversing-valve. The piston of the engine is eccentrically mounted, and is provided with a spring-pressed piston-head, which consists of a shank made in parts breaking joints, and which is formed at its outer end with a pivot, on which an auxiliary head is mounted to rock, this auxiliary head being likewise made in sections breaking joints. The engine has two main ports, one of which can be used as a supply-port and the other as an exhaust-port. These ports are reversed in function when the engine is reversed.



To change the direction of the piston-motion, a reversing-valve (Fig. 3) is used, having two through-ports and an exhaust-recess or port on one side, designed, as the valve is shifted by the long lever shown in the engraving, to connect either main port with the exhaust-port. The cut-off mechanism comprises a valve superposed on the reversing-valve, and having a swinging arm extending across the engine-shaft. The arm is provided with a yoke, which is acted upon by an eccentric on the shaft to cut off the steam and allow it to work expansively. The steam can be cut off at ¼, ½, or ¾ of the piston-stroke. In lubricating the cylinder, piston, and bearings, oil is fed only at three places. With the exception of the shaft, no moving parts are to be seen on the outside of the engine-casing.

A MARITIME PIGEON-POST.

WITH regard to the moot point as to the practicability of successfully organising a system of correspondence by means of carrier-pigeons between steamers and sailing-ships and the land, some interesting facts relating to what these "messengers on the wing" have up to now accomplished may be appropriate at this moment, says the *Westminster Gazette*.

In England carrier-pigeons, as we all know, are utilised for purposes of communication between the lighthouses and the shore. They are also utilised by the masters in command of fishing-smacks who, having had a successful venture, despatch them with the news to their landing-post. No sooner is the information received than steamers are sent out for the purpose of collecting the fish, so that the masters may continue their fishing operations under favourable conditions.

On the steamers of the Transatlantic Company trading between Havre and New York, the system of communicating by means of carrier-pigeons is now organised. Travellers who wish to communicate with the land write their messages on post-cards, which are photographed on thin tissue-paper the size of a visiting-card, and, inserted in a light tube, secured under the wing of the carrier-pigeon. At daybreak the cage is opened and the pigeon starts for home, where these miniature messages are either retransferred to other post-cards for transmission, according to superscription, through the post, or wired to destination.

At the present time the distance accomplished by carrier-pigeons between the trans-Atlantic steamers and the land is somewhat less than a thousand miles, but it may be considerably increased if the companies unanimously agree to erect pigeon-houses at the extreme south-west point of Ireland on the one hand and Halifax on the other hand.

Several miles out at sea beyond Auckland, New Zealand, lies Great Barrier Island, which has no regular communication either by cable or steamer with the New Zealand Archipelago. But now the idea is being seriously entertained of organising a fortnightly service of carrier-pigeons between it and Auckland. The messages styled "pigeongrams" will have to be written on tissue-paper not larger than a visiting-card. The superscription, written in pencil, like the text of the message, must be at the top of the paper, to which will be affixed a postage-stamp representing a pigeon on the wing with "Great Barrier Island" written over it; "special post" beneath it, and "One Shilling" on both sides of it. A first issue of 1,800 of these stamps has lately been put into circulation.

A service of carrier-pigeons is organised between Sardinia and the Italian coast. By this means Cagliari can communicate with Naples on the one hand, and, on the other hand, the island of Maddalena can correspond with Rome. The distance between Cagliari and Naples is 450 kilomètres, and between Maddalena and Rome it is 270 kilomètres, and it is covered by the carrier-pigeons at the rate of 65 kilomètres per hour.

In America pigeon-houses have been erected on board warships, for the purpose of intercommunication and corresponding with the land. This system is also in vogue on board several French men-of-war. The pigeon-houses on the American ships are most ingeniously constructed. They have two stories, are painted in bright colours in order to attract the pigeons, and are fitted up with every convenience for the comfort of the birds. Not long ago nine of these "messengers on the wing" were brought to London from Boston and set free three months later. Three of them crossed the Atlantic: the one found its way to Boston direct; another was discovered near Boston, and the third was found in Allegany.

In 1877 the Société Colombophile of Saint-Nazaire tried experiments with carrier-pigeons taken out at sea on board the steamers. They were intrusted to the pilots, who were instructed to set them free at increased distances. Many of them returned home, having travelled back 300 kilomètres. But most remarkable of all feats performed by carrier-pigeons was that of the pigeon despatched by Sir John Ross from Assistant Bay on October 13, 1850. It safely reached its home in Ayrshire in direct line across the Atlantic.

IN the Tesla Interrupter, the interruptions are obtained by a stream of mercury impinging upon a rotating disc having projecting teeth. The interruptions take place in a gas under pressure, thus permitting a much higher frequency than would otherwise be possible.

CHUCK FOR FACING OFF WORK OF UNIFORM THICKNESS.*

SOME time ago I had occasion to make the following chuck, which I think is a very good one, and will prove so to anyone wishing to try it. The chuck was, in this case, fitted to a No. 5 bench lathe; but it can be made to suit any lathe of the draw-in collet type. The face-plate A, Fig. 1, is fitted to the spindle of the lathe, and is recessed to receive the split collet B, Fig. 2, deep enough to allow perfect freedom for the collet to grip the work in case of any variation in the size of the blanks to be faced. The collet is milled through its largest part, four or five one-hundredths wider than the bridge C, Fig. 3, to give clearance, the balance of B being sawed with a small saw, as shown, to allow the necessary spring. The bridge C is fastened to the plate A by the screws D, Fig. 6, and is hardened and then ground on its face when in position on the spindle. Figs. 4 and 5 are steel plates worked out to fit the work desired to be faced and screwed to the collet, which is cut after the plates are in place. In this case the parts to be chucked are armatures for relays, which are required to be of a uniform thickness. The collet is spring-tempered and ground to fit the angle of the face-plate, which is 20°. No matter what the variation in diameter of the work is, so long as it is within a reasonable amount, say one-hundredth of an inch, it never can be drawn back with the collet to change its thickness, as the work, when put into the chuck, rests on the bridge, and the collet is then drawn in until it grips it. The complete section—Fig. 6—will show the arrangement clearly, I think, and for many jobs where accuracy in thickness and speed are required it will be found to be a very good chuck.

* By M. LEECH, in *American Machinist*.

ACETYLENE.

CONTINUOUS study is being made of the new illuminant, and to such an extent that eventually it is bound to occupy a position of the greatest importance. Meanwhile, however, the fire insurance offices continue to throw in the way of would-be users difficulties of a harassing and obstructive character. It has unfortunately happened that explosions of the gas have occurred, and naturally the companies, having no practical acquaintance with the matter, set their face against the "new-fangled" process, and will have none of it if they can so arrange. However, coal gas had to face much opposition at its first introduction, and in the present instance the natural conservatism of human nature is intensified by a fear of interference with dividends.

In the early stages of experiments with acetylene it was seen that an important factor of safety lay in the production of as pure a gas as possible, and to this end it is that so many experimentalists have been directing their attention, their various plans being the subject of mutual discussion. The impurities whose presence is hurtful fall into two divisions—those arising from impurities in the raw material, and those produced during the electric fusion. In the former category occur phosphuretted and sulphuretted hydrogen, while ammonia and cyanogen compounds would fall into the latter. Their danger lies in their liability to produce explosive compounds with the metal of the fittings or of the storage tanks, and the tendency in some cases to initiate spontaneous combustion.

With regard to the methods of purifying the acetylene by removing these injurious bodies, those most discussed recently are Luder and Cederkrutz's method improved by Dr. Wolff—the oxidation of the impurities by chloride of lime—or Frank's, consisting of the use of acid saline solutions to absorb them, the ammonia being neutralised by the acid, the phosphuretted hydrogen absorbed, and the sulphuretted hydrogen precipitated as metallic sulphite. The use of acid saline solutions is said by Dr. Wolff to have great drawbacks; but its inventor states that it is by no means necessary to employ liquids, as the materials can be used to impregnate porous bodies such as kieselguhr, a method suitable for a plant of small size. The latter writer points out that acid saline solutions are not, as stated, liable to cause explosions through the formation of acetylide of copper, the copper being precipitated as sulphide long before the whole of the acid is neutralised by the ammonia, even if the latter is

present in large quantities (from 0·05 to 0·15 per cent. by volume being the proportion shown by a large number of experiments).

The purifying material is a very acid solution of cuprous chloride, or an acid solution of ferric chloride of known strength. One kilo of the latter suffices to purify seven to ten cubic mètres of acetylene, or eighteen to twenty-five if the copper solution is used. An advantage in using the latter method is found in the fact that the copper solution can be regenerated by simple boiling and the addition of a little extra solution to make up for the copper thrown down as phosphide. Herr Christian Göttig draws the conclusion that the absorption of phosphoretted hydrogen by easily reducible metallic salts is increased by the presence of an alkaline chloride, whilst the need of using acids to prevent the formation of explosive acetylene metallic compounds is avoided.

With regard to this acetylide, the danger of which is admitted on all hands, mention may be made of Herrn Freund and Mai's experiments. They found that, when dried at 50° to 60° C., and placed in a tube through which acetylene is passed, it explodes after a short time, but does not cause the explosion of the acetylene itself; while, before the explosiveness is developed, the acetylide must have been exposed to the action of oxygen or air while drying.

In the practical use of acetylene one grave source of danger is the after formation of gas in the generators when the carbide has been removed from contact with the water. Dr. Wolff has measured the quantity thus generated from one kilo of carbide when, firstly, pure water was employed, and, secondly, when the carbide reservoir was over petroleum. The results were in the latter case 0·25 litres at the end of half an hour, 6 litres at the end of 24 hours, and 16 litres after three days, no more being then given off. In the case of water the numbers were respectively 7·25, 25, and 30 litres, but the carbide still went on decomposing at the rate of 5 to 6 litres a day. It is thus seen that great risks of explosion occur with small generators, with table lamps in particular. In large apparatus it can be avoided by the use of a sufficiently large reservoir to hold the excess of gas without undue compression. One means suggested for avoiding this constant discharge is the use of a layer of petroleum on the water, but it is open to the objection that a thin layer does not prevent evaporation of water, while with a thicker layer the probability is that it would be absorbed by the carbide, which would then be rendered impervious by water.

It will be seen from this brief account of work that the problem of safety in the use of acetylene illumination is being attacked from all sides, and there is fair ground to hope that eventually we shall have methods available which shall render the use of this most valuable illuminant as safe as the familiar coal gas.—*British Journal of Photography.*

PETROLEUM MOTORS.

THE high economy which may be obtained by the complete combustion of liquid fuel in an internal-combustion motor is now generally conceded, and as a result there have been numerous attempts to design motors which shall prove acceptable for general use. The Dopp motor was discussed at a recent meeting of the Verein Deutscher Maschinen-Ingenieure. Dopp maintains that the high compression advocated and used by Diesel is not necessary to the attainment of superior thermal economy, and claims that equally good results can be secured by the use of vaporised petroleum, drawn into the cylinder with the proper proportion of air, and burned under practically the same conditions as obtain when gas is used in a well-designed gas-engine. It seems to be generally admitted that the main element in the economy of a petroleum motor lies in the combustion of the fuel. While this is secured by providing a compressed atmosphere, it does not appear that it is necessary to use a compression materially greater than is now employed in the gas-engine. The Dopp motor does not differ in general construction from an ordinary gas-engine, except that the petroleum fuel is gasified by the heat of a lamp before it is drawn into the cylinder, and the excellent economy which appears in the regular service is claimed to be due only to the completeness of the combustion, attained by a thorough mixture of the fuel with the proper quantity of air. Herr Dopp gives figures from a number of his motors in daily use, which show a consumption of 0·197 to 0·240 kilogrammes per H.P.-hour, the lower result being obtained with a 10H.P. motor after it had been in practical service for more than 11 months. This result is better than was attained by the Diesel motor of 20H.P. tested by Prof. Schroter, although under less favourable conditions. Herr Dopp maintains, as has been claimed by others, that the Diesel motor by no means realises in practice the theory enunciated by its designer, and shows that some of the fundamental points which, according to the theory are essential to the highest economy, are distinctly controverted in the working of the motor. From this he deduces that the high economy of the Diesel motor shows that the theory is not sustained.

An important feature of the motors constructed by Herr Dopp lies in the fact that they can be constructed and operated in a satisfactory manner for small powers, good results being obtained with motors of 2H.P. to 5H.P., while the construction of the Diesel motor is such that it does not appear advisable to make them for less than 20H.P. Regardless of the theoretical questions at issue, there seems to be little doubt that very simple, efficient, and convenient petroleum motors can be made upon the same general design as that already in public use for gas, and that care in design and in the correct proportion of air to fuel supply can, with a moderate degree of compression, insure such a complete combustion as to leave little or no trace of soot either in the cylinder or in the exhaust gases. Under such circumstances there can be little doubt that the petroleum motor has a most useful future before it, especially for small powers.—*From the Engineering Magazine.*

MANIPULATING HIGH CARBON STEEL.*

THIS subject has in the past been so ably and thoroughly discussed, that it seems to us there is little left to be said. We might go into a lengthy exposition of what we should consider the best method in the manipulation of steel, and yet when we consider the very many brands of this product, and that scarcely any two of them can be treated alike, we almost shrink from trying to lay down any fixed rule for the working of this article.

In looking over the subject, and in reading up the different articles written upon the same, we are impressed with the differences of opinion; one will insist that his method is the only one, and another that his is the true one, and they perhaps are so far apart in their opinions that they can scarcely be reconciled. We shall endeavour in this report to offer some suggestions that can be safely applied in any shop. You may perhaps think they are not new, and right here we might repeat the old maxim, "that there is nothing new under the sun," and yet, admitting there is nothing new under the sun, we can reach out and improve in the manipulation of steel, as well as in any other line of business.

In many instances the reason why steel does not give satisfaction is because the temper of the steel is not suited for the purpose for which it is being used, or that the method of treatment in the hands of the toolsmith is not what the steel requires. This results from the fact that when a smith gets a bar of steel, or a brand with which he is unacquainted, he very often injures the steel for any purpose.

All practical toolmakers know that there are many different qualities of cast steel; what we mean by that is that there are many degrees of carbon. A steel of low carbon cannot be made to do the work that a higher percentage of carbon properly manipulated can do.

One suggestion your committee would offer is, that should the smith get hold of a bar of steel of which he does not know the percentage of carbon, it would be safer to heat it for working too low, rather than run the risk of overheating. To avoid in a measure this trouble all shops should have a well-regulated steel rack, with the steel properly classified, and the key of the rack in the hands of the foreman, or someone competent to take charge of same, and in order that the very best results may be attained in this matter, no purchasing agent should buy any other brand of steel than that asked for by foreman smith.

We believe that it is not so much the brand of steel we use, but the many different brands, that causes no little amount of trouble, and, indeed, in our opinion, is very expensive to those who must foot the bills.

The most valuable property that steel possesses is its capability of being hardened and tempered. The changes in the properties of steel produced by these processes are most extraordinary.

A full knowledge of the degree of heat at which steel containing a greater or less percentage of carbon should be hardened is of very great importance, and can be very easily designated as "dark red," "blood red," and "bright red."

We should not forget that to produce a good tool one of the first things to be observed is the manner in which it is being treated when being forged. Should the steel be subjected to extreme methods in forging, so that the structure of the steel has been injured, it will be almost impossible to secure a good tool. There is no doubt but this is the cause many times when steel is hardened to have what we call fire or water cracks, as the defects caused by severe hammering, and when too cold are not discernible to the naked eye.

Steel should be heated very slowly, and evenly, for it is a well-known fact that to forge it when not heated through evenly, the particles are driven asunder, the colder ones being driven into the hotter ones, and causing a general dislocation of them.

There has been a theory advanced that to harden a tool, a large milling cutter, it should be heated very slowly, which is perfectly proper, and when at the right heat dip in water for a few seconds, and then finish the cooling process in oil. This may be all right; but is it a practical method for hardening a large tool? Where do all our arguments come in as regards having all the particles of steel in an even, easy condition, and without any undue strain.

It makes very little difference in what way you cool a large piece of steel, so as to have sufficient hardness for very hard work, whether you quench it in cold water, hot water, or oil. If the tool is to be made sufficiently hard, it must be dipped at such a heat that will produce the required hardness, and in so doing you have certainly contracted the outer surface, while the inner particles are in an expanded state; this will be the result to a greater or less degree, and the steel will be left in a strain. Now what we want to demonstrate is the fact that any tool to give satisfaction must be in its natural easy state as nearly as possible.

Now, in case of a large milling cutter, after it has been quenched, and, of course, is then in more or less strain, owing to its unequal contraction, is it not a fact that to draw the temper from the inside to the outer surface, that we have relieved the tool of very much of the strain put upon it in the quenching.

I hope the members will express themselves upon this subject, as I think it one of the most important ones connected with tool work.

All tools that have been heated in a common fire, especially large tools, that require considerable length of time for heating, will lose more or less of their hardening qualities upon the surface, and to overcome the effects of the fire there should be enough material turned off, so that none of the decarbonised material remains, and when the tool is again heated for hardening it should be done in a charcoal or wood fire.

We will conclude this article with a few suggestions that can be safely followed, and first will say that the only way a toolsmith can be successful is to study his business and be perfectly conversant with it.

It is very important that the steel should be suited to the work which it is to do.

All steel should be marked the degree of carbon which it contains.

The toolsmith should be very careful in heating, so that it will be thorough and at the proper degree.

Heat tools in charcoal or wood fire or lead for tempering.

In tempering dies, taps, reamers, or any small tool, have the water warm, so that the change will not be too sudden.

Draw temper on piece of red-hot iron, and when the desired colour has appeared, cool in oil.

To anneal steel, make it hot, put in hot ashes or charcoal dust, and cool slowly.

Mark every bar of steel on one end, so that you will know at a glance the percentage of carbon in it.

In forging steel, have the blows sufficiently heavy to affect it to the centre, and decrease blow as the steel gets cooler.

When tempering any tool, like a tap or reamer, do not plunge it into the water as some say, but let it enter the water vertically and slowly, as sudden quenching causes them to become distorted.

And last, but not least, we would recommend that the best method for the treatment of burnt steel is not to burn it. The idea of restoring burnt steel is like trying to subtract something from nothing.

* By M. R. Messimer and E. F. Carter. Report of Committee on "How to Obtain the Best Results in the Manipulation of High Carbon Steel," submitted to Annual Convention of National Railroad Master Blacksmiths' Association, Milwaukee, 1899.

HIGH PRESSURE AND DRY STEAM.

THE most favourable steam pressures for locomotives seem by many to be considered as settled at about present limits, and in recent discussions involving this subject it is made apparent that considerable comfort is being taken from this supposed fact. It is generally believed that simple locomotives should not carry pressure higher than 190lb., and that 200lb. is most favourable for compounds. It has never been clearly demonstrated that either of these limits is correct, and the problem of pressures is unquestionably important enough to warrant specially careful investigation, in view of the great advances in economy which have been made in this direction in marine practice.

It is generally understood that higher pressures permit of improvement in economy at the engines, and that this is the cause of the greatest improvement of modern steam-engineering. It is not so well understood, however, that a great advantage may be gained by increasing the boiler pressure without increasing the pressure in the engines, and yet this is probably one of the most effective of recent improvements in marine work which has accompanied the rise of pressures in the engines. By this is meant that there is a great deal

to be gained by carrying a very high boiler pressure, which is reduced to a proper working pressure at the engines. The worst enemy of fuel economy is wet steam, and this reduction of pressure, which is accomplished without doing work, is an effective and inexpensive method of drying the steam before it goes to the cylinders. If the steam is dry when it leaves the boiler, it will be superheated by this process, and everyone knows the desirability of superheating. The explanation for the superheating effect is simply that when steam passes through a throttled passage in a pipe and reduces its pressure, its pressure changes without a corresponding change in temperature, and it is therefore hotter after throttling than the steam calls for in the tables of the properties of saturated steam. This excess temperature may disappear by evaporating moisture in the steam, drying the steam, or it may remain and the steam pass on into the engines in a superheated condition. This is advantageous because the cylinder is a powerful refrigerator, and the entering steam needs all the heat it can carry, in order to remain dry as long as possible.

The British Admiralty believe that pressures in marine work will go higher yet. Pressures of 250lb. and more are successfully used in marine engines, and when steam is furnished by Belleville boilers it is at a pressure of 300lb., this reduction at the engines being for the purpose of securing dry steam, as explained. Dry steam will do more work than wet steam, and the locomotive is noted for using wet steam. The question raised here is whether there is not enough advantage to be had from dry steam at the cylinders to more than offset the additional weight that would be required in the boiler in order to carry the higher pressures. This is one way to attain an increase in boiler capacity which is generally desirable, and the effect on the economy of working may be very easily ascertained. All that is necessary is the building of one locomotive boiler for a working pressure of, say, 250lb. and a reducing value in the steam-pipe, to throttle the pressure to a proper working point at the cylinders. It would cost so little to investigate the merits of this question as to cause surprise that some enterprising motive-power officer does not take it under consideration. We would like to emphasise what has in effect been already said: That this idea may possibly prove to be a good method for increasing boiler capacities.—*American Engineer.*

SPIRIT PHOTOGRAPHY.

DECEPTION in spirit photography has become a fine art. Many so-called spirit pictures have been taken upon plates that have already been exposed. When these plates are developed, the several faces, of course, are brought out. These prepared plates are held in stock by dealers in photographers' supplies, says *The Banner of Light*, and sold to all who send special orders for them. It is now well known that a certain symbol in the order for plates indicates that "doctored" plates are desired. In some cases, men and women who are perfectly honest with themselves are obtaining what they claim to be spirit pictures. They order their plates themselves, and take pictures of themselves by means of a mechanical device, develop the plate alone, and find faces side by side with their own on the plates. This would seem to justify them in believing the pictures to be likenesses of disembodied spirits. If they would reflect a little, they would not be so certain.

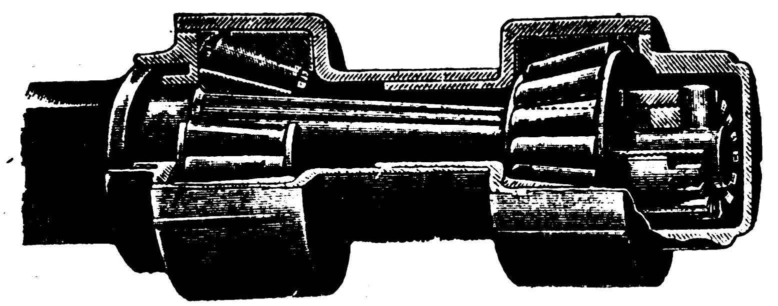
Pretended mediums for spirit photography know of the experiments of these parties to whom we refer. They notify the dealers in photographic stock of the fact, and these dealers send them the prepared plates. The pictures are taken, and the amateur photographer becomes convinced of the truth of spirit photography because they alone were implicated in the experiment. The fact is they have been deceived in their plates through the efforts of some faker who wished to add to his own income, and to maintain his influence over the parties whom he is instrumental in deceiving. It is often done, and many reputable people are thereby victimised.

Occasionally a few of the prepared plates are slipped into the boxes ordered by regular photographers. They are not spiritualists, nor are the majority of their patrons. Everyone is greatly surprised, therefore, to find half a dozen faces upon the proof of a certain plate. When the fact of these specially-prepared plates is made known, the source of the phenomenon is easily determined. The unsuspecting person, however, does not stop to think of possible collusion in the case, and accepts the result as evidence of supernormal power.

THE GRANT ROLLER-BEARING.

IN the accompanying illustration we present a novel roller-bearing made by the Grant Axle and Wheel Company of Springfield, Ohio, which has been used with noteworthy success upon waggons, carriages, auto-mobiles, and vehicles in general.

The tapered rollers of the bearing turn between a cone held upon the axle spindle and an exterior coned ring. The inner cones are not keyed to the spindle, but are loose, so that they turn independently of the rollers. Should the rollers bind, the wheels would not be locked; for the cones could still rotate on the spindle. The method of assembling the various parts of the bearing is so apparent from the illustration that no extended description is necessary. Perhaps the most striking feature of the construction is the simple method provided for taking up the wear.



The adjusting-nut is held on the outer end of the axle-spindle by a pin or cotter passing through the nut and through the reduced end of the axle. The nut is made in two concentric members having threaded connection, whereby the outer portion or shell of the nut may be adjusted inwardly, to take up the wear of the cones. Once set, the nut cannot be jarred or loosened from its position. It is evident that the spindle may be removed from the hub or wheel without in any way disturbing the adjustment of the parts.—*Scientific American.*

THE LATEST TELEGRAPHY.

TELEGRAPHIC marvels abound; or, at all events, accounts of them, which are not quite the same thing. We have wireless telegraphy, which is perhaps not exactly novel. From Vienna comes a glowing description of a new invention by which stencilled messages can be transmitted in very nearly less than no time, along wires, to great distances. The rapidity of despatch is so great that, to parody a well-known bull, the last word of the message is received before the first one has been sent off; and as if this was not enough, we learn from *Pearson's Magazine* that a Pole, named Jan Szczepanik, has invented an apparatus by which he telegraphs pictures in their natural colours. The landscape is at one end of the wires; a ground glass screen is at the other end; and on this screen the picture is produced. We need, perhaps, scarcely add that selenium plays an important part in the invention, for a full account of which we must refer our readers to the magazine which has so far a monopoly of the novelty. The Vienna folk are, we may add, doing nothing more than has been done here daily in the service of the newspaper press for about thirty years. But this, of course, is only a detail.

There never has been a time during the last half century or so when announcements of marvels connected with electricity have not been made. Many of these have been true, and the results of the discoveries or inventions to which they referred have been largely, if not always wholly, satisfactory. Others, however, have been anticipations of desirable things rather than fulfilment; and, reasoning from the past into the present, it is well that all statements concerning telegraphic or electrical wonders should be received with great caution. The daily Press of the country has, we are sorry to say, recently pursued to some extent the vicious practice of the United States newspapers. If news could not be found, let it be made. A dozen times within the last few months we have had to make inquiries concerning paragraphs in our contemporaries which dealt with matters likely to be of some interest to our readers, and in all cases we have found either that they were not true in any sense, or that they were misstatements of truth; or that very small germs of truth were contained in a multitude of words. The principal importance of all this appears when we consider how prone a small section of the world is to the formation of syndicates, and how eagerly a great section of the public will follow a syndicate into financial morasses without the least hesitation. There is always the possibility, of course, that some extremely valuable invention will be made, and those lucky enough to exploit it properly will no doubt secure large fortunes, and will deserve what they get; and it so happens that, because of the mystery which apparently surrounds it, electricity and all its uses constitute a happy hunting-ground for the inventor, and, we may add, the speculator. Our readers may rest assured that in many, we do not say all, but in nearly every case, when information is given to the public of the kind to which we have just called attention, it is promulgated by a speculator, and must be received with caution. We have not the least intention of imputing dishonesty of purpose; yet very frequently the information published is lacking in that scientific accuracy which can alone enable us to pronounce an opinion as to whether the thing is or is not true.

But even when it is certain that a very clever invention has been made, it remains to be seen whether it has any commercial value, and, if so, how much, and what. We may cite, for example, the microphone, an invention or discovery which attracted enormous attention when it first came before the public. It was held to be an extraordinary thing of boundless possibilities, that the footsteps of a fly walking on a carbon-plate in Brighton could be distinctly heard in London. No doubt this was, in a sense, a marvel, but it was a marvel of no utility; and although it is possible that the microphone taught some things of use to the telephone, it has long since passed away into the land of The Laid Bye. Dozens of inventions in electric lighting have travelled the same road, and the inventions and discoveries which have implied the revolution of telegraphy are simply legion. It is, therefore, a good thing when an invention is so far successful that it is talked and written about, to consider what part it is likely to play in the future; what are its possibilities of development, what its limitations. Of course, at this moment, the most prominent invention is wireless telegraphy. At the recent meeting of the British Association it scored a success, messages being sent with much accuracy and certainty through hills and over sea distances. At first sight it seems marvellous that sounds and signals can be produced at a distance of many miles without any visible means of transmission. But we must not let ourselves be dazed by the beauty of the invention, nor blinded by its success. We must ask ourselves first who wants to send messages slowly to somewhere? and next, what are the conditions under which alone they can be sent? Up to the present the field for wireless telegraphy, however important, is extremely limited. Curiously enough, the cost of transmitting messages over a wire in the ordinary way is very much less than that of sending them without wires, and as to speed of transmission, the wireless system is nowhere as compared with the normal work of the post-office. What may occur in the future we do not know; but at present the Marconi system appears to be unable to compete in the least degree with the wire system of telegraphy, to say nothing of the telephone. In a word, for commercial business so far it is quite unsuitable. Indeed, it is fair to say that no one of importance has, so far, suggested that it may supersede ordinary telegraphy. It is claimed for it, however, that it may have an incalculable value in war time and at sea. Thus generals may be able to transmit messages by day and night, and in all weathers, instead of being confined, as now, to the use of the heliograph, which out of the east seems to be of very little use. At sea, again, ships may communicate with each other, and convey information of much value. Thus, for example, a scouting torpedo-catcher might find an enemy and tell the admiral in command of our fleet as much, although the torpedo-destroyer and the fleet were quite out of sight of each other. Again, by wireless telegraphy we can put our lightships in direct communication with the shore. We can blow up mines, probably constructed for the purpose, and accomplish many other wonderful things. All this sounds very well in the lecture-room, and it reads very well in print; but there are limitations. The ether waves are rather delicate affairs, and require dainty handling. They emanate, in the first instance, from a single vertical wire about 120ft. long. At least, that seems to be the best transmitter and receiver. The vibrations are believed to pass in a vertical plane. The receiving apparatus is extremely delicate, and very sensitive to inductive effects. It has long been known that there is no privacy about wireless telegraphy. That which can pass through mountains it is very difficult to stop by a screen. It is true that certain metals check the passage of the vibration; but up to the present no efficient form of screen has been devised, and we are compelled to fall back, in the pursuit of privacy, on some

equivalent of two tuning-forks. That is to say, unless the receiver is in tune with the transmitter, no intelligible message can be sent or received; but it will be readily understood that for military purposes, whether by land or sea, the difficulties to be overcome in carrying this system into practice are very great. This is not all. The wireless telegraph requires isolation in order that it may work. In the early days of the telephone much trouble was caused by induction. But the sensitiveness of the telephone to induction is as nothing to that of the wireless apparatus. It is not too much, we believe, to say that a large induction coil properly used on board a ship would entirely prevent a distant fleet from transmitting signals. It is to the last degree unlikely that two friendly ships could transmit messages at the same time to a third ship without rendering each other unintelligible. We do not wish to say—or intend to say—that these and similar objections to the wireless system will not be got over. We cannot tell. We confine ourselves to facts as they are. Even in the matter of lightships, it is doubtful if the invention is likely to prove of real value. It may not be generally known that for several years various lightships have been placed in electrical communication by cable with the shore, at an annual outlay of about £10,000, and there is no known instance in which life has been saved as a result of this outlay. The lightships, as a matter of fact, have very few opportunities of knowing whether vessels are in danger or not; and in most cases the lifeboat stations are infinitely better situated for receiving information.

We would not have it said that we depreciated the labours of the eminent workers who have achieved such marvellous deeds as those about which we have written. Far from it. But in the present day marvels are fairly numerous, if not quite plentiful; and we are all easily enough carried away by admiration, and so lose our sense of proportion. It would have been a wonderful scientific feat if it had only been possible to transmit one word per hour from London to Edinburgh. The fact that instead of one word an hour, twenty or thirty words per minute can be sent, scarcely at all augments the scientific interest of the invention or discovery. In fact, that is all centred in the doing of the thing once. The value of the invention to the world is quite another matter. Up-to-date telegraphy is good because it is accurate, and cheap, and rapid. Any system which is to take its place must be more rapid, or accurate, or cheaper, or all three. When someone directed Michael Angelo's attention to a certain picture which he was supposed to admire because the artist had painted it with his feet instead of his fingers, the great man only said, "Why did not the fool use his hands?" Our readers can apply the story without aid from us. The bare fact that any system of telegraphy, or electric lighting, or power transmission, is wonderful, signifies nothing. The world's work is not done by wonderful things because they are wonderful, but because they satisfy certain conditions. Unless new inventions or discoveries will do this a little better, they must remain marvellous. They will never find their way into such common use as to cease to be wonderful.—*The Engineer.*

THE YEAR'S WORK OF A LOCOMOTIVE.

THERE are 19,914 locomotives at work on the railways of the United Kingdom, and each of these on an average runs 19,096 miles in a year, and earns for this £4,573, so that each mile the locomotive runs its gross receipts are about 4s. 9d. Out of this the working expenses of stations, the upkeep of permanent way, and the cost of signalling, &c., as well as the drivers' wages and the coal burned, amounting in all to nearly 3s., have to be paid. Like the human factor in all industries, the locomotive to-day is doing less than that of ten years ago, for the 15,924 locomotives then on the railways each ran 19,035 miles, but unlike the human factor, the engines are now earning less—or £4,629 per annum. If, therefore, we take the cost of an average locomotive at £2,700, it is found that it earns in gross receipts her total cost in seven months; but net receipts are quite another matter, for, not only the expenses of the locomotive, but of the railway and all the extensive organisation, have to be met, and are payable from the receipts got directly from the locomotive's work. The Scotch locomotive seems to do the most work; that is only consistent with the chief characteristic of the hardy Northern. There they have one locomotive for every 1 mile 6 furlongs of railway open, whereas in England and Wales there is an engine for every seven furlongs or so; and although in the latter case there is £5,136 worth of traffic to be dealt with, against £3,010 in Scotland per mile of railway open, the number of locomotives is relatively less for the volume of traffic. Thus, a Scotch locomotive in a year travels 23,361 miles, against 18,591 miles in the case of the English locomotive; while the Scotch engine takes in gross receipts £4,855 and the English engine £4,544. In Ireland there is only one locomotive for every four miles of railway, the amount of traffic being £1,112 per mile of railway open, and thus the engines work more leisurely than the Scotch, running 20,911 miles and earning £4,416.—*Engineering.*

DID MAN ONCE POSSESS A THIRD EYE?

THIS query heads the following statement in a recent number of the *Evening Telegram* (American). Deep researches as to the structure of the human body have recently furnished some startling facts regarding changes which man is at present undergoing physically. It is believed that man was formerly endowed with more teeth than he possesses now. Abundant evidence exists that, ages and ages ago, human teeth were used as weapons of defence. Unintentionally, traces of such use are often revealed by a sneer. The teeth are sometimes bared, doglike, ready, as it were, for action. The practice of eating our food cooked and the disuse of teeth as weapons are said to be responsible for the degeneration that is going on. The wisdom teeth, in fact, are disappearing. Human jaws, found in reputed palæolithic deposits, have wisdom teeth with crowns as large as, if not larger than, the remaining molars. In ancient times a short-sighted soldier or hunter was almost an impossibility; to-day a whole nation is afflicted with defective vision. It is almost certain that man once possessed a third eye, by means of which he was enabled to see above his head. The human eyes formerly regarded the world from the two sides of the head. They are even now gradually shifting to a more forward position.

In the dim past the ear flap was of great service in ascertaining the direction of sounds, and operated largely in the play of the features. But the muscles of the ear have fallen into disuse, for the fear of surprise by enemies no longer exists. Again, our sense of smell is markedly inferior to that of savages. That it is still decreasing is evidenced by observations of the olfactory organ. But the nose still indicates a tendency to become more prominent.

USEFUL AND SCIENTIFIC NOTES.

THE calorific value of blast-furnace gas is on the average 1,000 calories per cubic mètre. In utilising the waste heat to generate power by steam-engines and boilers, the best one may hope to obtain is about 450I.H.P. from a 100-ton furnace.

A NEW YORK electrician has invented a new form of condenser. In its construction two conducting wires are wound on a bobbin, preferably arranged in alternate layers, one of the wires covered with thread, having a comparatively low specific inductive capacity, the several convolutions of which are separated from one another so as to leave open spaces between them; the other wire is bare. The ends of the covered conductor are connected to one terminal, and those of the bare wire to a second.

Tea and Rheumatism.—Dr. Kellogg says the habitual use of tea as a means of relieving headache is, without doubt, an efficient cause of rheumatism in numerous ways. The writer has met many persons who could not forego the morning cup of tea or coffee without suffering severely from headache and depression during the day. The thein or caffein of tea has precisely the same effect as uric acid, and hence has come to be a favourite domestic remedy for headache. When used habitually, however, as will readily appear, the effect must be to cause a storing up in the body of uric acid and urates, thus laying the foundation for chronic rheumatism and the various allied conditions which have their foundation in the so-called uric acid diathesis or lithemia.—*Popular Science, N.Y.*

The Electrical Engineer Institute.—The Electrical Engineer Institute of Correspondence Instruction of New York has issued the third edition of the Institute's catalogue, which shows the interest all classes of workers are taking in this new educational departure. The courses taught include all branches of electrical engineering—e.g., electric lighting, electric railways, electric mining, telephony, telegraphy, mechanical engineering, mechanical drawing, &c. A strong feature of the Institute's work lies in the fact that all its instruction-papers have been prepared by the most eminent specialists and authorities in their respective fields. A valuable feature of the new catalogue is a complete synopsis in detail of every topic in every course which the Institute teaches. Mr. Joseph Wetzler, M.E., E.E., is the president of the institute, and Mr. T. C. Martin, Editor of *The Electrical World and Engineer*, is vice-president. The Institute's catalogue will be sent free to anyone on application by addressing the main office, 120-122, Liberty-street, New York.

SCIENTIFIC NEWS.

A NEW comet (*e*, 1899) is reported to have been discovered by M. Giacobini, on Sept. 29. It was situated in the north-western part of Ophiuchus, and was moving in a south-easterly direction. Its position, 8h. Nice mean time, on Sept. 29, was R.A. 16h. 26m. 32s., S. Dec. 51° 10′. From Konigsberg its position is given on Oct. 1, 8h. 0·5min., R.A. 16h. 31m. 0·7s., S. Dec. 4° 39′ 50″. The comet is described as faint, and is "new" only in the sense of rediscovery, as it was observed in 1896 and in 1898.

It is stated that the observatory on the Schnee Koppe, in the Silesia Mountains, is now finished, and is the loftiest in Germany, being at an altitude of 5,216ft. It will be managed under the Prussian State.

Two new "variables" are announced by Dr. T. D. Anderson, of Edinburgh. A star in Hercules, position is (1855) R.A. 17h. 53m. 27s., N. Dec. 19° 30′. It has a variation of nearly a mag. as observed in August, and is about 2′ or 3′ *n.p.* B.D. + 19·34, 89°, which is of 9·2mag. Another is in (1855) R.A. 20h. 9m. 44s., N. Dec. 30° 37′, but when observed in September was rapidly diminishing in brightness. It is in Cygnus, and the variation is 8·5 to 9·2.

The Melbourne Observatory is open to visitors at certain times, and according to the report the great telescope and the south equatorial have been used during the year by 189 persons on Wednesday afternoons and by 195 visitors who observed at night.

The *Bulletin* of the Société Astronomique de France for October contains, amongst other interesting articles, one by M. Berthelot entitled "Sur les Miroirs de Verre doublé de Métal," and another by Ch. V. Zenger on "Le Centre du Monde," and the law of the movements of the Celestial Bodies. The illustrations of lightning flashes accompanying an article by M. Em. Touchet on "Les Orages d'Aout et Septembre, 1899," are specially interesting.

Prof. Andrew Gray, F.R.S., Professor of Physics in the University of North Wales, has been elected to succeed Lord Kelvin in the chair of natural philosophy in Glasgow University.

Major R. Ross, of the Indian Medical Service, has returned with other members of the Liverpool Tropical medical expedition to this country, and is reported to have stated that the authorities at Sierra Leone had, on the advice of the expedition, decided to use every means to exterminate the malaria-spreading mosquito. Other conditions in West Africa were favourable to health, there being a good water supply. He thought, however, that the white population were not careful enough, and that the houses were badly constructed, and compared unfavourably with the residences of whites in India, which were constructed on plans that gave the inhabitants every chance of health, despite the tropical climate. Major Ross attached great importance to this question of the construction and situation of the houses. Dr. Fielding Ould, a member of the expedition, remained behind to consult with the medical officers on the coast respecting measures to be taken for the extermination of the malarial mosquito in the neighbourhood of the principal towns. The opinion of the party was that these measures would decrease the danger of the spread of the disease.

The building for the Paris Institute of Biological Chemistry, towards which the Baroness Hirsch contributed £80,000 for erection and endowment, has been completed, so far as the erection is concerned; but it has now to be equipped, which will probably be done in a few months.

A special committee appointed to make representations to the London University Commission have presented an interim report, in which they recommend that there should be one faculty of science connected with the University, with adequate representation on the Senate and the Academic Council; that engineering should be a distinct branch of the one faculty of science and not a separate faculty, but degrees should be given in engineering bearing a distinctive name. The art or profession of teaching, the committee felt, should be a branch of the faculty of arts. The committee was also of opinion that the restriction of the amount of property to be held by the University to an annual value

of £10,000 should, if possible, be removed. In moving the adoption of the report Prof. Dyer pointed out that when the value of the London University property was compared with that of other universities, it was comparatively small. A proposal was made to institute a degree showing the merits of teachers. "Master of Education," it was contended, might clash with "Master of Engineering." So "Doctor of Pedagogy" was suggested. Eventually it was moved that the committee should reconsider their recommendation with regard to the faculty of teaching; but the motion was defeated and the report received.

In his address to the students of the Royal College of Science, Prof. Rücker said that the changes which loomed largest in the immediate future were the erection of new buildings and the creation of what would, in effect, be a new university. A university was a place where education was combined with the advancement of knowledge, and the teaching of a university was based on the principle that knowledge was desirable for the influence which knowledge and the search for knowledge exerted upon ourselves, and not merely for the power which it conferred of improving our external surroundings. The first of these characteristics distinguished it from a school; the second from a workshop or a college with purely technical aims. The Royal College of Science had not been unmindful of the fact that the duty of a university was to advance knowledge.

It is announced that Mr. Richard B. Westbrook, of Philadelphia, has left to the Wagner Institute of Science the sum of 10,000dol., which, after the death of his widow, is to be used as an endowment fund for a special lectureship to secure the full and fearless discussion of disputed questions in science, especially those relating to the theories of evolution.

The death is announced of Mr. John Donaldson, the partner of Mr. J. I. Thornycroft in torpedo-boat construction. He was born at Elgin, and was in his 58th year. The deceased gentleman was apprenticed to engineering, and went to Glasgow University. Subsequently he went out to India, where he did much good work, but, having married Miss F. S. Thornycroft, he joined his brother-in-law, and they produced for the Norwegian Government the first fast torpedo-boat ever built. Mr. Donaldson induced other foreign Governments to introduce torpedo-boats into their navies, and by his lectures to the Royal United Service Institution in 1877 and 1881 he helped to bring about their introduction into the British Navy. When Mr. Thornycroft produced his water-tube boiler, Mr. Donaldson at once saw the far-reaching consequences of that invention, and a year or two later, by accepting absolute responsibility on behalf of his firm for the boilers of H.M.S. *Speedy*, he gave the then First Lord, Lord George Hamilton, the opportunity of initiating his policy of water-tube boilers for the Navy.

Dr. C. Russ, an enthusiastic ornithologist, died on Sept. 29, at Berlin.

The death is also announced of Prof. Kowalowsky, professor of hygiene in the University of Warsaw.

The Corporation of Glasgow have appointed Dr. R. M. Buchanan bacteriologist to the city, and a laboratory has been assigned to him in the Sanitary Chambers. He is expected to devote the whole of his time to the work.

The degree of Doctor of Pharmacy has, for the first time, been conferred on M. Lacourt by the University of Paris.

The Hackney Vestry have issued a warning in connection with milk to housekeepers. They state that out of a hundred samples of milk examined by an "experienced biologist" twenty-two were infected with tubercle bacillus. They wisely advise the public to boil the milk before using it.

The tenth International Congress of Hygiene and Demography is to be held in Paris, from Aug. 9 to 17, 1900.

It is stated that Prof. A. E. Dolbear, of Tuft's College, Mass., the inventor of a telephone and the author of a work on the art of projection intends to seek an injunction (according to the Central News) to restrain Signor Marconi using wireless telegraphy in the United States. It is further stated that Prof. Dolbear patented a wireless telegraphing apparatus in 1886. There may be some interesting disclosures if the case comes before the courts, for it is certain that wireless telegraphy is not a new "discovery," for it was suggested by Steinheil about sixty years ago, and there are some records of experiments. Sig. Marconi has, however, demonstrated the utility of his arrangement.

The Senate of the Welsh University have just appointed Mr. W. Jenkyn Jones, B.A., lecturer in Philosophy in succession to Dr. McIntyre. Mr. Jones graduated B.A. in the University of London from Aberystwith, and in 1893 proceeded to Cambridge, where he gained a scholarship at Caius College. In 1895 he obtained first class in the Moral Science Tripos Part I., and 1897 first class in Part II. of the Paine Tripos. For the last two years he has filled the post of professor in Psychology at the Cambridge University Day Training College.

The iron sand found on the coast of New Zealand, which has puzzled so many exploiters, is not as valuable as some people seem to think. According to Sir George Whitmore, who lately gave an interview to a representative of *Commerce*, there is a good deal of misapprehension concerning the extent and the possible value of this sand. There are great quantities of it, but if the industry assumed anything like large proportions the sand would not last very many years. And, besides, these deposits are not unique. On the coast of Norway and Sweden there are already under treatment great breadths of this kind of sand, containing quantities far beyond anything that exists in New Zealand.

The Continuous Brakes return presented to Parliament for the half-year ending Dec. 31, 1898, shows that the number of vehicles complying with some or all of the conditions laid down in the Board of Trade circular amounted to 95 per cent. of the number in use, and that only 4 per cent. were fitted with pipes and connections only.

In June, 1900, there is to be an International Exhibition of Tramways and Light Railways at the Agricultural Hall. It has been arranged with the object of acquainting municipal and other local authorities, as well as the general public, with the latest apparatus designed for the equipment of mechanical tramways and light railways. The idea is good. It may hasten the progress of electric traction, and may possibly help to get rid of the present expensive practice of sending deputations to the Continent and America to inspect for the thousandth time the system in Buda-Pesth, Hamburg, or New York. The exhibits will comprise examples of every imaginable method of traction, and the auxiliaries and accessories of the newer systems.

Fifteen thousand eight hundred and fifty-two miles of railways in Russia are operated by the Government, and 9,114 miles by public companies.

Seven hundred and fifty-five locomotives were built at the Baldwin Locomotive Works last year, of which number 348 were exported. Two hundred and forty-two were compound engines and the rest single-expansion; of the compound locomotives, 235 were of the four-cylinder type and seven were of the two-cylinder type.

A highly satisfactory test of the new 6in. quick-firing gun, constructed for the American Navy by Messrs. Vickers, Sons, and Maxim, has been made at the Indian Head Proving Ground. The first shots were fired with cordite, which in each instance gave velocities of 2,700 foot-seconds. After a sufficient number of rounds to demonstrate the fact that the velocities would exceed what was expected of the gun, Admiral O'Neill, chief of the United States Artillery Department, determined to obtain a comparative result by using Navy smokeless powder. Accordingly, he had employed a charge that would give a chamber pressure not exceeding 17 tons per square inch, and the result obtained under these conditions was a velocity of 2,913 foot-seconds; such a muzzle energy with the pressure employed has never before been obtained. In England, with the use of cordite, this gun gave a velocity of 2,873 foot-seconds with a pressure of 17 tons. The projectiles fired weighed 100lb. A gas check was used, and to a considerable extent accounts for the high energies obtained, and prevents any abnormal wear due to the use of modern gun-cotton or nitro-glycerine explosives. The striking energy of the gun was no less than 5,724 foot-tons, which would perforate a thickness of steel amour of 17in. The energy obtained per ton of gun is 768·3 foot-tons, and as a rate of fire of ten rounds per minute for long series of rounds has been easily obtained, the gun is capable of doing work to no less extent than 57,240 foot-tons per minute.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, *332, Strand, W.C.*

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

THE ABSOLUTE ZERO OF TEMPERATURE AND METEORS.

[42911.]—In answer to "F. J. G.," according to the current theory, heat consists of motions of the particles of matter. The greater the velocity of these motions the larger is the quantity of heat and the higher the temperature. The two extremes are evidently that the velocity should become 0, and that it should become infinite. Both extremes are probably unattainable. But in measuring the relative quantities of heat contained in two bodies (or their respective temperature) it is convenient to start with an assumed position of molecular rest, and to estimate the quantity of heat by the excess of motion over this position. It is computed to be at −273° C. or thereabouts. As rest does not admit of degrees, when this position is attained no further cooling is possible. In fact, your correspondent seems to confound the popular ideas of heat and cold with the scientific. Popularly, a thing is said to be hot if it is above the ordinary temperature, and cold if below it. But scientifically, all known bodies are hot, and cold is the mere absence of heat. The heating of a body consists in increasing the heat, and the cooling of a body in diminishing it. There is probably a limit to the possible heating of bodies other than that of infinite molecular velocity. But we know nothing about this limit at present, and there seems reason to believe that every known substance is capable of being heated after it attains the gaseous state. Indeed, the gaseous condition itself may pass into another unknown condition when the temperature is sufficiently raised.

It is not of much consequence whether we can conceive an absolute zero or not. But if heat consists of molecular motion, so far is the absence of this motion from being inconceivable, that in reality it is only the scientific who conceive its presence. However, many of our supposed laws only hold good within certain limits, and fail when these are surpassed; and I confess that I do not in the least know what a body totally divested of heat might be like. I might form, not merely a conception, but a dozen conceptions, and they might all be egregiously wrong. As to Fahrenheit's zero, however, I believed he merely took the lowest temperature that had (to his knowledge) been actually observed.

May I add a remark as to meteors which are often supposed to reach us with "the cold of space," which, again, is supposed to be not very far from the absolute zero? Now, a meteor is exposed without an atmosphere to the heat of the sun until it gets into the shadow of the earth, and if we suppose it to be travelling at the rate of 1,000,000 miles per day (which is no doubt in excess of the truth), and to be moving almost directly towards the sun (the most unfavourable direction for the present purpose), the intensity of the sun's heat on the meteor ten days before impact will be four-fifths of its intensity at the earth, and this heat will gradually increase to equality as the meteor continues its approach. Now take a stone of about the supposed size of the meteor, and expose it for a few hours to a hot sun. What will the temperature be? A meteor will, I think, be highly heated when it enters the earth's shadow.

W. H. S. Monck.

METEOR.

[42912.]—A splendid meteor passed over here this evening (Sunday) exactly six o'clock, course S.W. to N.E., and exactly overhead, very slow, 8sec. to 9sec. passing over. Just after passing the zenith it emitted two sparks, apparently no noise, and in passing over it left a long train of light. I was fortunate enough to see the start and finish, and it started from one horizon to the other.

High-street, Epsom, Oct. 8. W. Nash.

[42913.]—A brilliant meteor was seen here this evening at 6.3 (Sunday). I happened to be looking at the part of the sky where it appeared, almost due S.W., at a height of about 30° above the horizon.

It passed almost directly overhead, and disappeared in the N.E. at about the same height of 30°. Colour, glistening primrose yellow, with a bright golden tail about 3° long. When overhead it threw off two small portions, which trailed behind and disappeared. Total length of time visible, about ten seconds. John H. Bateman.

1, York-road, West Norwood, Oct. 8.

EPSILON LYRÆ.

[42914.]—Adverting to Mr. Espin's remarks (letter 42873), and his reference to the correspondence which took place years ago in these columns and his doubt whether this group had ever been laid down in a diagram, I may be allowed to state that one was supplied at the time by the late Major T. A. Skelton, using a 15in. With mirror, which I think showed several more stars than Mr. Espin's sketch.

Southampton. A. H. S.

OBSERVATIONS OF THE PERSEIDS AND AQUARIDS, 1899.

[42915.]—The following is a synopsis of the watches kept for meteors:—

1899.	From.	To.	Number seen.	Number Regd.	Seeing.	Remarks.	Hours of Obs.
	h. m.	h. m.					h. m.
July 27	—	—	—	—	—	Unobservable	—
„ 28	10 15	13 0	15	13	3	Moon up during whole watch......	2 45
„ 29	10 30	12 30	9	8	3	Moon up during whole watch......	2 0
„ 30	10 20	12 45	20	17	2	Sky very clear, but moon up nearly the whole time	2 25
„ 31	10 30	12 0	18	15	1	Watch for Perseids	1 30
„ 31	12 0	12 45	8	7	1	Watch for Aquarids	0 45
Aug. 1	10 15	11 30	7	5	2	Watch for Perseids	1 15
	11 30	13 0	11	11	2	Watch for Aquarids	1 30
„ 2-7	—	—	—	—	—	Unobservable	—
„ 8	9 50	11 50	21	15	2	——	2 0
„ 9	9 50	13 5	55	47	2	——	3 15
„ 10	10 10	14 10	67	50	2	——	4 0
„ 11	10 25	14 0	84	50	2	——	3 35
„ 12	11 15	13 30	35	28	1	——	2 15
„ 13	10 30	12 30	25	20	1	——	2 0
„ 14	9 45	12 0	19	18	3	——	2 15

In the above table, under the heading "Seeing," 1 means excellent, 2 good, 3 fair.

Thus, during the period of observation—July 27 to August 14—observations were made on 12 nights. On three of these the seeing was 1, on six 2, and three 3. Seven nights were overcast.

The times spent in observing were distributed as follows:—

—	Number seen.	Number recorded.	Hours of obs.
Perseids	375	286	29h. 15m.
Aquarids	19	18	2h. 15m.
Totals......	394	384	31h. 30m.

RADIANTS OBTAINED.

No.	Radiant Point.	No. of Meteors	Nights of Observations, 1899.	Date of Max.	Remarks.	Name.
	α° δ°					
1	44½ + 57	7	Aug. 9	—	Swift; streaks	Perseids
2	45 + 57	29	Aug. 10	—	Very swift; streaks	Perseids
3	46 + 57	17	Aug. 11	—	Very swift; streaks	Perseids
4	48 + 58	7	Aug. 12	—	Very swift; streaks	Perseids
5	49 + 57	5	Aug. 13	—	Very swift; streaks	Perseids
6	49 + 58	8	Aug. 13, 14	Aug. 13	Very swift; streaks	Perseids
7	342 − 11	3	July 31, Aug. 1	Aug. 1	Bright; stellar; trained; slow	δ Aquarids
8	0 + 90 85 + 87	7	July 31, Aug. 9, 11, 13, 14	July 31	Rather swift; short	Polarids
9	2 + 48	13	July 28, 29, 31, Aug. 9, 13, 14	July 31, Aug. 9	—	α Cassiopeids
10	18 + 59	10	July 31, Aug. 1, 9, 11, 12, 13	Aug. 9, 11	Short; streaks	δ Cassiopeids
11	25 + 62½					
12	21 + 40	5	July 30, Aug. 11, 12, 14	—	Swift	γ Andromedids (1)
13	26 + 48½	12	Aug. 8, 10, 11, 14	Aug. 10	Swift; streaks (?)	γ Andromedids (2)
14	39 + 52	8	Aug. 8, 10, 11	Aug. 11	Very swift; streaks	θ Perseids
15	45 + 64½	4	Aug. 8, 9, 11	Aug. 11	Swift; streaks	Piazzi III. 94 Camelopardids
16	55 + 70	4	Aug. 9	—	Swift; streaks	γ Camelopardids
17	61 + 58	10	Aug. 9, 10, 11, 12, 13, 14	Aug. 12	Very swift; rather bright; streaks	P. III. 208 Camelopardids
18	325 + 9½	6	July 31, Aug. 1, 12	Aug. 1	Swift; white	ε Pegasids
19	340 + 32	4	July 29, 31, Aug. 1	Aug. 1	Swift	β Pegasids
20	341 + 46	4	Aug. 8, 10, 11, 14	—	Slowish; stellar; short	o Andromedids
21	354 + 50	5	Aug. 11, 13, &c.	—	Swift; streaks (?)	λ Andromedids
22	359 + 59	5	July 28, Aug. 9, 14	Aug. 14	Moderate	β Cassiopeids

In the above table the radiants are arranged in order of R.A. The column headed "Date of max." contains the date on which the largest number of meteors belonging to each shower was observed.

INFINITESIMAL ETHER—MICRATOMIC ETHER—CREATION OF MATTER—SOUND, LIGHT, AND HEAT—CHEMICAL AFFINITY—COHESION—GRAVITATION.

[42916.]—The object of this letter is to present to readers a line of thought which may perhaps help to simplify ideas as to the nature of the ether, of matter, and of the forces with which they have to do.

Reference is first made to "Lucretian's" letter (42770, page 68), headed "Micratomic Ether," in which the theory is advanced that atoms of matter are themselves composed of atoms of ether. Thus is the mystery connected with the genesis of matter turned into a mystery of the ether. But why stop at micratoms, "Lucretian"? If the human imagination, with its ever-widening scope, can conceive no bounds to the outer universe, why complicate matters by attempting to assign limits to its inward divisibility?

The following qualification of the micratomic theory is suggested:—Ether consists of a substance, infinitely divisible, allied with motion, occupying all space. There would, therefore, be no finite particles to deal with, for wherever there were space to be filled the ether would (by virtue of its separability) break up and (by virtue of its motion) extend itself to fill it. Nor could the objection raised to a "gaseous" form of ether be applicable here. In a gaseous ether, discrete particles transform the energy of translation into that of vibration, and vice versâ; whereas, in the case of an infinitesimal medium, the force acting will be of a simple kind throughout. And yet from this uniform substance "matter" has probably evolved. Exactly how it commenced to do so is a question which must be answered when those relating to the origin of ether, of motion, of life, and of intellect receive elucidation. A directive impulse, however, passing through a formless ocean of ether and inducing therein a state of momentary instability, would, the writer thinks, suffice to explain (so far as that be possible) the creation of matter. For, assume by some such means the motion to be abstracted from a portion of the ether, it would there close up or contract—forced together by the more energetic ether surrounding it, which latter would thus acquire the space the central mass had lost. What would happen during the process of contraction? According to Laplace's Nebular Hypothesis, the contraction of a gaseous body causes it to rotate. Similarly, in the case of the ether (if the analogy hold good), a resultant rotation would ensue, which would permanently isolate and differentiate the contracted portion from its surroundings, and an "atom" would be created.

If the stability of an ether constituted as aforesaid cannot be mathematically demonstrated, the writer would suggest as an alternative an *original* instability in the ether to result in the creation of atoms. Further, that these atoms, by ordering the etherial vibrations around definite centres, would produce the needful stability in a hitherto ungovernable medium. The writer is aware that in the modern vortex ring theory a construction is contemplated for the atom somewhat different to that above suggested. However, if our simpler rotating atom is able to satisfy all queries, the other need not be gone into. Otherwise, it should be observed that the two theories by no means appear to be antagonistic, for, to reconcile them, it is only necessary to show that a number of rotating atoms, if placed end to end around a circular core, would form a vortex ring.

In leaving this part of the subject, the attention of those who would speculate further as to the causes involved in the creation of matter is drawn to the enormous quantity dispersed throughout the universe—from the myriads of suns down to those smaller agglomerations rendered visible occasionally as meteors. From this it is evident that the amount of ether condensed and converted into matter formed at the outset no insignificant proportion of the whole, although it now occupies comparatively far less space.

Let us now proceed to investigate some of those properties and conditions of matter which it is sought by this theory to explain.

Etherial Resistance.—The first question likely to occur would be that of locomotion. Would not an atom, battered on all sides by a powerfully vibrating ether, be as much confined as is a prisoner in his cell? It is a part of the present theory that single atoms (at all events, in a normal state) would be so fixed. Contrive, however, to bring two or more atoms together—that is, inclose them in one and the same cell—and it will be evident that, while the wall of their prison has not increased in strength, their power to break it down has grown directly in proportion to their numbers. Thus, for bodies of atoms, and also for single atoms abnormally excited, the resistance of the ether becomes a negligible quantity.

Mechanical and Atomic Force.—Before proceeding further, it would be as well to state that the word "mechanical," as applied hereinafter to force or motion, is intended to define that condition of the atom, or bodies of atoms, in which etherial resistance to locomotion is overcome. To illustrate: the motion of a cricket ball sent flying through the air is mechanical. Water poured from a jug moves mechanically. The locomotion of the molecules of a gas is, by this definition, likewise mechanical.

On the other hand, "atomic" force or motion refers to that exerted by one atom or more, whereby the ether is strained only, and is not broken down nor rendered resistless. The straining of a dielectric, magnetic rotation, chemical affinity, vibrations originating heat and light, &c., are examples of atomic force.

Incompressibility of the Ether.—The distinction between mechanical and atomic force here made is of much importance in solving an apparent difficulty in the way of the present theory—viz., the supposed incompressibility of the ether. That you cannot charge a prescribed space with more ether than it already contains has been demonstrated by the ice-pail experiment of Faraday, the insulated sphere of Cavendish, and other tests.

Now, incompressibility may imply one of two things: (1) That there are no spaces between the particles to allow for any diminution in bulk, or (2)—and to this view the writer would beg the most careful attention—that the power of subdividing itself possessed by ether, coupled with its exceedingly rapid state of vibration, baffles all attempts to hold it—it slips, as it were, through the

fingers. To put the matter in other words, the force required to *appreciably* compress the ether is mechanical, being at least equal to the minimum amount needed to break the medium down; and the latter effect, therefore, occurs when that amount of force is used.

It may be urged as an objection to this view that, in the case of a dielectric charged with electricity—(i.e., with "ether," a process somewhat analogous to pumping water into an elastic bag) this breaking down does not occur, because, if it did, the dielectric could not be charged at all. The answer to this, of course, is that the process of charging a body with electricity is atomic, not mechanical. This is shown by the fact that where a charge is so powerful that the atoms composing the insulator are jogged into "mechanical" motion, the insulator itself at once breaks down, its cohesive power is lost, and equilibrium is restored.

Sound, Light, and Heat-Wave Propagation.—The word "appreciably" italicised above, is used because the writer does not deny—nay, he suggests, for reasons to be now stated, that the ether is capable of an "atomic" compression due to the atom's heat and light vibrations; and this slight change in bulk, being atomic, is obviously incapable of direct measurement.

We have now to account for the propagation of waves in the medium surmised, and, in doing so, to take into consideration the phenomenon of polarisation.

First, let it be said that the writer is not at present convinced that a medium, whose vibrations can fix an atom as before mentioned, would not be electrostatically rigid up to the limits of its power to resist being broken down, and, therefore, capable of a certain amount of shearing stress, such as is required in the creation of transverse waves. That water and gas (both molecularly constructed) assume this this state may, of course, be assigned to reasons more complicated—e.g., the attraction between their positive and negative elements. But, when the nature of these forces is made clearer, such a reason will have to give place to a simpler one, which will, perhaps, prove the analogy between a gas and the ether in this respect to be very close indeed.

Assuming, however, pure transverse motion to be inadmissible, the following argument in favour of the "sound" class of pulsation and criticism of its theory is put forward. Sound is propagated by reason of the medium becoming suddenly compressed in the direction in which the sound is about to travel, and then springing back to its original state, such compression and expansion being communicated onward at a certain speed depending upon the elasticity and density of the medium. Now, what the writer suggests is that in a compressible "sound" medium the impulse is not communicated directly forward. When the blow is given, the compression which follows tends to cause a lateral spreading out of the particles at right angles to the line of progression. This transverse expansion goes on until the limits of the medium's compressibility is reached, when reaction sets in and produces the amount of resistance necessary to send the impulse forward.

To make the matter more clear, let us take a mechanical illustration. When a gun is fired the gas evolved within expands all ways; but it is chiefly to the *lateral reaction* of its metal walls upon the gas that the necessary force of propulsion is due. Without this, the projectile would stand a poor chance of reaching its destination. In the same way, a sound impulse, without the lateral resistance of the surrounding molecules, would be deprived of the best part of its propelling force. If this be the correct view to take, then, as each longitudinal pulsation proceeds the lateral pulsation will proceed also, and the sound-wave works itself out as a sort of combined transverse-forward impulse, able, by proper means, to be polarised.

Chemical Affinity and Cohesion.—Having grasped the foregoing facts, the nature of chemical affinity will not be difficult to comprehend. Briefly, the process may be typified as follows: Two atoms are, by mechanical means, brought into contact—i.e., become inclosed in one etherial "cell." If equal as regards temperature and constitution (size and rotation velocity may possibly affect the latter) nothing particular happens; they are simply held together by the walls of their prison house. This is cohesion. But assume one to be a more energetic atom than the other. The former at once begins to equalise matters by jogging its weaker neighbour, and in this way transfers some of its own heat to the other. This causes the latter to expand abnormally and to become strong enough to break down the ether. It flies off into a state of momentary freedom, is relieved of its superfluous heat by radiation, and, finally, its initial motion carries it again into contact with another atom similar to the last, when the process is repeated. Thus it will be observed that chemical union is not an "attraction" properly so called. The atoms, having been brought into contact by some means, such as the mechanical intermingling of two fluids, are held together cohesively (as in a vice) until the action above described separates them with great force, and this force carries them into union with new partners.

Gravitation.—What, then, is gravitation? This question has been left until last, because its answer depends to a great extent on what has been already said. The force we have here to deal with is an exceedingly minute one compared to that of chemical affinity. The latter is (according to Dr. Oliver Lodge) ten thousand million billion billion times greater than that of gravitation acting at the same distance. It is not hard, therefore, to accept the statement that gravitation is only a residual pressure by the ether towards the atom. We have all noticed the effect of surface tension upon bubbles in a teacup. Etherial pressure can be shown to have a similar effect. It may be explained in this way: —Were the ether free of gross matter, the pressure exerted by the continual collisions among its parts would be no greater in one direction than another. Evolve an atom, however, and the case is different. As has been suggested previously, the atom, by virtue of its definite shape, tends to order the vibrations of the ether relatively to itself, just as, for instance, reflected sound-waves tend to assume the form of the object which reflects them. The vibrations, for this reason, practically resolve themselves into two sets—viz., those to and from the atom (that is, radially) and those at right angles thereto, which it will readily be seen extend round the atom in layers, or concentric spheres. The former may be disregarded because they act in straight lines, and their pressure is no greater inwards than outwards.

It is to the latter, therefore, that we must turn our attention. These "spheres" of vibrations are infinite in number, and enlarge, of course, directly as the square of their distances from the atom.

Now, it can be shown that forces acting round a curved surface and parallel thereto will have a resultant effect, not *round* the curve, but *inwards*, and the greater the curvature the stronger this effect. Consequently, by the same reasoning, collisions between the parts of a sphere will have a resultant pressure towards the centre, its strength depending upon the curvature or distance of the sphere. Hence, in the present case, the atom being in the centre of the vibrations, the phenomenon of gravitation is accounted for.

In conclusion, the writer is conscious of having attempted to condense into a small compass materials that would occupy a book, but trusts that the general idea will be grasped. If the inferences herein set forth find acceptation, he will be pleased; if refuted, then the knowledge gained thereby will amply compensate him for the trouble taken.

R. A. Kennedy.

THE LATE FLYING MACHINE ACCIDENT.

[42917.]—It is to be hoped that the late flying-machine accident in which the valuable life of Mr. Pilcher was lost, or, more properly speaking, thrown away, will be a warning to all such thoughtless persons that we hear of now and again who contemplate trying some wild plan such as that advocated by Mr. F. L. Davidson, and many others, among them Prof. Langley of America. Nothing but disaster can come of any of these wild plans, because they are not devised on the true principles of aërial flight, as shown us by nature in the mechanism and manner of the bird; Mr. Maxim has been able to foresee this, or why did he give up after getting the power to fly, as he actually did attain? The truth is, Mr. Maxim, fortunately for himself, could see clearly that though he had actually overcome one half of the difficulty—namely, the power to rise into and go forward through the air, there was not the slightest chance of his ever attaining the other and far more important half—the power to keep his machine safely balanced in the air—so like a man wise in time, he gave up while he had whole bones. I have said so many times, and I say it again, in no machine designed to travel fast can safety be attained, because you introduce the element of danger even before you get in the air. It would be with you every moment of time you were in the air; but the moment you tried to land it would be intensified a thousand times. The same will happen in the case of Prof. Langley, unless he uses balloons in conjunction with his flying-machine; in that case it will not be a flying-machine, but a mechanically-propelled balloon. The true flying will require no gas-bags to aid it; it would be a sorry machine if it did, and, as I say, would not deserve the name of flying-machine. But I suppose these lamentable accidents will take place now and again until men get to use a little common sense on this subject; even had Mr. Pilcher succeeded ever so, he could have taken us no further than Mr. Maxim had already taken us. Mr. Maxim actually proved it is possible to ply the air mechanically; but we knew all that before—the bird had shown us all that—and Mr. Maxim has not shown us how to do the work for the simple reason that he does not know himself. I do not here intend to go into the subject of the construction of a practical flying machine; my object is to point out the utter madness of trusting precious human life to such flimsy contrivances as those of Herr Lilienthall and Mr. Pilcher, neither of which deserved the name of flying machine one mite more than would a large paper kite. The machine intended to have the care of human life up in the air should be built upon a decided and well-defined mechanical principle; this same principle should be worked out into a perfect system; there should be no loop-hole for danger. We must not be left to suppose this or to suppose that. We must suppose nothing, but be sure of everything beforehand. Nothing must be left to chance. These, then, should be the rules in regard to any machine intended to take human life into mid-air. First, should be perfectly uncapsizable—that is, it should be safe under any condition of the atmosphere; second, there should be no possibility of the machine descending rapidly, no matter what happened. Now these two simple conditions are all that is required to make it as safe to go up into the air in a flying machine as it would be to go out on to the ocean in a steamboat, and can they not be gotten? Most decidedly they both can, and in a simple manner, but not in the manner that so many seem to think, not in a machine designed to rush through the air at something like a hundred miles per hour. All we want in a practical flying-machine is plenty of power applied in the proper manner. This has never yet been done; hence there is not yet such a thing as a flying-machine.

Thomas George Challis.

A FORMING-TOOL HOLDER.

[42918.]—The following description of a forming-tool holder which I found in a back number of the *American Machinist* may be of interest to some of your readers, so I send it over. The writer, who

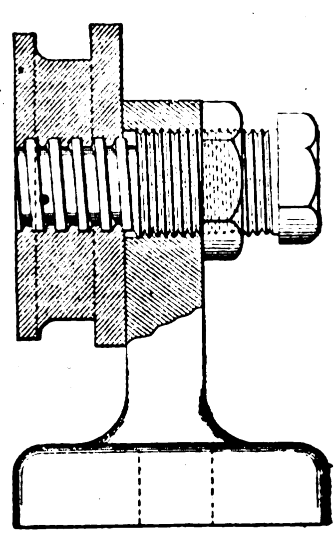


Fig. 1

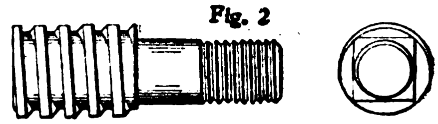
Fig. 2



merely signs "S. B.," says:—"Anyone who has tried to hold heavy circular forming tools in place by the usual means employed—viz., a flat-headed bolt through the former and holder, with a nut on the opposite end, will, I am sure, appreciate the simple device here shown, which will hold any circular former precisely in the position in which it is set.

In the old way the holding power depends upon the friction of the head of the bolt; and no matter how hard the nut is tightened, even if a piece of gas-pipe is used on the wrench, the former will slip at times, much to the annoyance of the operator, besides decreasing the output of the machine by the delays necessary for the readjustment.

Various means have been employed to overcome this difficulty, most of them too complicated and expensive to be practical. In endeavouring to find something to do away with this annoyance, I hit upon the idea here shown. So far it has proved a great success. The lock is positive, the adjustment simple and quickly made. Very little force is necessary to tighten the nut to hold the former against the heaviest cut.

"Fig. 1 shows the method of holding the former if a new holder is made. A square thread is cut in the former as it leaves an arbor for turning, milling, &c., without injuring the thread. A five or six-pitch thread is used, right or left hand, depend-

ing upon which side of the machine the former is set; the direction of the thread being such that the former will tighten by the force of the cut.

"To get any adjustment, the thread inside the holder must be of a finer pitch than that in the former, and run in the same direction. If desired to use the old holder, the bolt is made as in Fig. 2; the result is just as good. When once the square-threaded taps are made, the work upon the forming cutter is but little more than when making them the old way, while the result is a hundred times more satisfactory."

Criticism from your readers would be welcomed.

THUNDERSTORMS.

[42919.]—During a thunderstorm about three weeks ago I noticed the phenomenon mentioned by Mr. Monck in letter 42902, p. 185. I was watching a wind-vane when I noticed the dark thunder-clouds were approaching in a direction opposite to that indicated by the vane. The position of the vane was S.E., directly opposite to the clouds, which rapidly approached from the N.W. The vane veered round to N.W. in this case, however, long before the storm was over. From the speed at which these clouds moved, they must evidently be at a low altitude, and the cross-currents which must be flowing to produce the observed effects are not easy to account for. I was told by a friend who was standing near that he had noticed "that thunderstorms *always* came up against the wind." It was, however, the first occasion on which I remember noticing the phenomenon.

C. M. Dowse.

[42920.]—I watched closely the progress of the storm to which Mr. Monck refers (letter 42902), and saw exactly what he saw—that is, at first the smoke was blown in a direction opposite to the clouds, afterwards the smoke was blown in the same direction as the clouds, and then the storm ceased. I have noticed the same thing on many other occasions, and the explanation is easy. The wind all day had been blowing from the west, roughly speaking, and this was the direction in which the smoke was blown. The storm came from the east, also roughly speaking. While the lightning was still in the distance, the front of the storm-wave blew overhead, carrying clouds from the east; but did not disturb the ground current, which was from the west, as shown by the smoke. As the storm approached there was for a moment a calm, and then as it came closer it overpowered the westerly breeze, and smoke and clouds were blown in the same direction. The change of the wind thus denoted the moment when the storm passed overhead, and as it was moving rapidly it was soon gone inland out of hearing.

One night last year, while in the Queen's County, I observed a fierce display of lightning. On making inquiries I found that there was not any storm in Ireland in the direction of the lightning, but the "Mechanic" the week after gave an account of a heavy storm in Cheshire, I think, at the same hour. Is it possible to see the reflection of lightning at such a distance—about 200 miles? **Zeta.**

THE GREAT GLOBE AT SWANAGE.

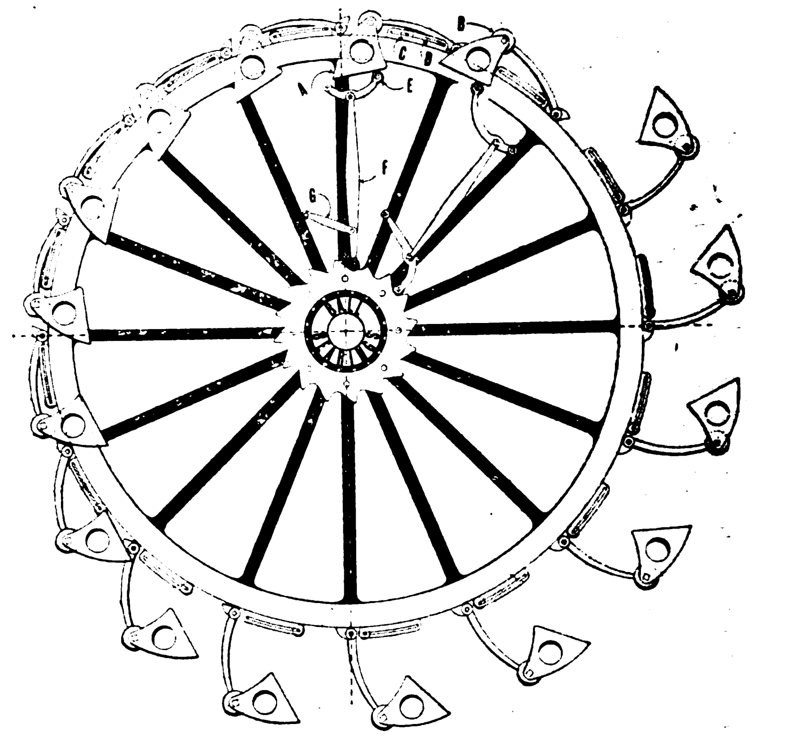
[42921.]—Having seen the great globe at Swanage several times while I was at Bournemouth, I can give "F.R.A.S." the information he wants about it. As far as I can make out it was placed there by a Mr. Burt, of the "Granite House," Swanage, who has in a great measure made Swanage what it is, I believe. I think the globe has been there about nine years. It is near the Tilly Whim caves, about a mile from Swanage. I do not know whether it is solid or not, but should fancy it was. The diameter is about 8ft., and I think it is constructed out of the Purbeck marble, but am not quite sure. I do not think it was made for any special purpose, beyond illustrating the earth as a globe, showing its rotundity, &c. The various Continents, &c., are marked out very distinctly, being in relief, while the chief mountain ranges are also marked out, slightly raised up. There are a good many names on it.

The data "F.R.A.S." alludes to as being cut on the wall in front of it refer to various facts relating to the earth, moon, sun, and stars, such as their size, mass, weight, distance, &c. This is doubtless for general information and edification. I believe a photograph and short explanation appeared in the *Strand Magazine* some time during 1896 or 1897 (or possibly 1895). **Ivo F. H. Carr Gregg.**

GILBERT'S NEW POWER MACHINE.

[42922.]—I beg to send you herewith outline drawings, blocks, and particulars of my machine, to enable you to ventilate through "Ours" this long-forsaken problem of perpetual motion. There is some friction in these two machines which I do not like; but still the principle is there, and in my drawings Nos. 3 and 4, with which I am now busy,

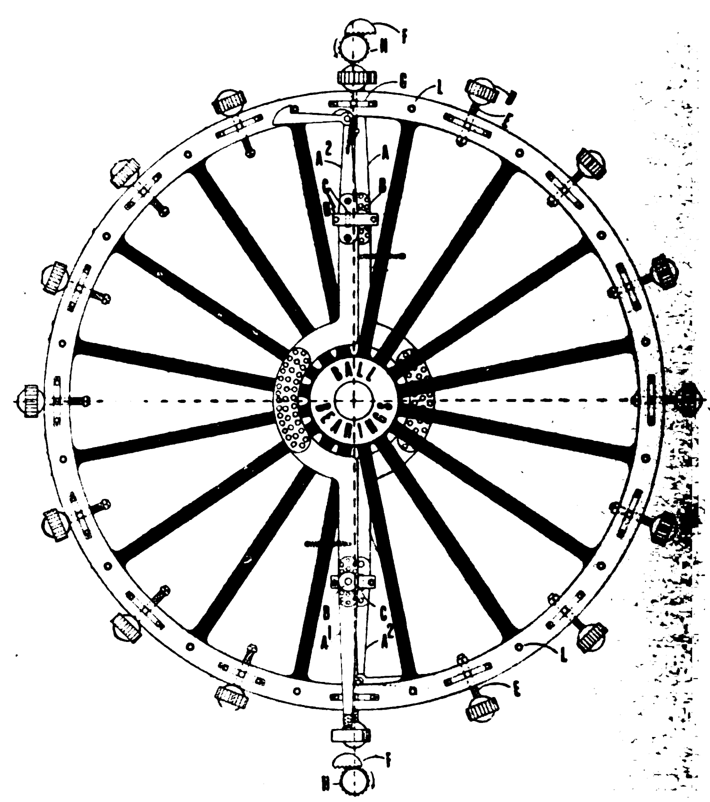
Fig. 1.



[Scale about $\frac{1}{8}$in. = 1ft.]

A, lug fixed to B; B, solid weight 2ft. diameter; C, check roller to hold up B as it is lifted; D, check roller slot; E, roller of lifting arm; F, main lifting bar; G, hinged guide. Wheel 50ft. diameter. E, F, and G, and those at right-hand are supported independently of wheel, and may be fitted at off-side in same manner. N.B.—Although the lugs and weights A B are all shown to be lifted at near-side, half may be lifted at off-side, and thus reduce the number of teeth to eight each side.

Fig. 2.



[Scale about $\frac{1}{8}$in. = 1ft.]

A, lever for increasing weight; A^1, lever for decreasing weight; A^2, impulse end of lever; B, pivot of lever; B^1, guide plates; C, roller; D, solid weight 2ft. diameter; E, thread; F, lifting comb; G, blade check spring to prevent weight D moving out or in by gravity; H, revolving cogwheel, part and parcel of D; L, pin roller. Wheel 50ft. diameter. N.B.—The two levers are supported, independently of wheel, at B; the combs F are a fixture on end of A, A^1.

I have, I think, entirely overcome friction, and fail to see why Nos. 3 and 4 (they will follow later on) should not revolve continuously or, if you exclude dust, say perpetually.

Although my drawings represent a 50ft. wheel, a 100ft. or larger would cause a steadier and more reliable action, and you would thus be able to increase the number of the propelling weights to double or treble that shown. I may mention that it is 20 years since I first took up perpetual motion

(I have had many tries in that time), but I could never get over certain points to my liking until now.

Arthur E. Gilbert, A.I.E.E.

23, King John-terrace, Heaton, Newcastle-on-Tyne.

THE STEREOSCOPE.

[42923.]—L. Paxton, in his letter (42893) with diagram, demonstrates clearly, that unaided eyes 2¼in. apart can unite, by gentle convergence of the optic axis, any stereoscopic pictures that are less than 2¼in. apart. But he does not show us how an average pair of eyes, say 2⅝in. apart, can perform the feat with average stereoscopic pictures set 2⅝in. and more apart. Will your correspondent explain, with another diagram, how that can be done without either looking cross-eyed as at Q in his diagram, or else stretching the eyes wider apart, which is what I meant in my last by outward squinting?

Leading opticians give me 2⅝in. as a rough average width between eyes, and any one who has a collection may see for himself that stereoscopic pictures are mostly set between 2⅝in. and 2¾in. apart. Here and there one may be found mounted at 2½in., but one of my best measures full 3in., and I saw to-day an American view on sale, that measured fully 3¼in. between corresponding points.

R. S. D.

THE MISTAKES OF AUTHORITIES A HINDRANCE TO PROGRESS — THE AURORA.

[42924.]—It is desirable to correct a misprint in letter 42895 (p. 163), headed as above, which alters the intended meaning. I wrote that the errors in the *Monthly Notices* relating to a class of ambiguous phenomena mentioned were *passively* sanctioned, meaning thereby that they were never challenged by the members, and the absence of any debate or criticism in reference to their value or accuracy was liable to misconstruction by the outside public. The explanation of responsibility given by one of the respected members of the R.A.S. (letter 42896, p. 184) is quite in accordance with my expectation; but I think their discussion by the members would be a decided advantage, instead of relegating them to obscurity unnoticed.

The example referred to is a calculation of the height and locality of a supposed auroral ray observed March 4, 1896, by Mr. T. W. Backhouse, Sunderland, founded on observations from three given places. An examination of the data supplied by them shows differences inconsistent with identity. If it be admitted that the results can be justified, then there can be produced observations of an opposite character, which will contradict those previously selected.

In answer to the concluding query, I was obviously dealing with auroral phenomena, and with certain advised methods of observing them by the same author as above.

Birmingham, Oct. 8. W. H. Wood.

IMPROVEMENTS IN ROTARY ENGINES.

[42925.]—In your issue of Sept. 29, p. 162, your correspondent "J. W." (letter 42891) makes reference to some practical experiments with rotary engines for steamship propulsion, which very much interest me. I assume from the names "Breynton" (not Brenton) and Wimshurst, these experiments took place about the late "Forties" or early "Fifties," as these gentlemen are credited in the Patent Office with patents No. 10786[45], 11541[47], and 13340[50] respectively. Would he kindly, if he can do so conveniently, amplify his remarks by any data concerning these trials, the chief drawbacks found in practice, and also say where any printed reference to these trials can be found, either in societies' *Transactions* or in published papers at that time, which, unhappily, were not very scientific?

I have the patents referred to, which confirm by the drawings attached "J. W.'s" general description. I quite agree with "J. W.'s" remarks as to modern men repeating the former failures; but surely it is worse to be permitted by the authorities to pay for a patent already three or four times, if not a dozen times, taken out for the same thing by others, which is notably the case with patents for rotary engines.

I am interested in a development of the form of rotary engine under discussion, which I think quite eliminates the causes of previous failure, and brings rotary engines up to what they should be—viz., an advance on reciprocating engines. Of the details of this engine, I shall be glad to forward details and photos., with notes of performance at an early date, for the benefit of "ours."

W. D. G.

MAGNETO IGNITION.

[42926.]—I should be glad if Mr. Bottone would give us his views as to whether it is better or not to use an induction coil with magneto dynamo for ignition for motors. In the Sims machine the bobbin oscillates between the poles of a permanent magnet, and sparking is advanced in ordinary manner by varying moment of drop in cam. This oscillating movement appears to me inferior to a rotary motion at high speed. A view of Sims' method is given in *Auto-Motor Journal* for August.

In another I have seen no coil is used at all, and armature is advanced or retarded by moving a sleeve which carries armature round at angle of 45°. To get best results for starting and running this works very well; but armature is about 6in. diam., and appears altogether too large for tricycle work. Only advantage appears, it will spark easily at a very low rate of speed, which is important where you have to start by pedalling, as on a tricycle.

What I want to know is whether it is possible, by using larger armature, to do away with coil, or if same is of advantage in starting at slow speeds? The coil itself weighs 5½lb., so if half this weight was saved and put into armature it would spark easily when running slowly. The weight of "Dion" dry battery and case is 17lb.—a considerable item. Perhaps in reply to a query this week you may give some information that will be of interest just now. I am convinced some form of magnet will eventually remain as a survival of fittest. Can you oblige us with sketch of one suitable? Monty.

WHEN WERE YOU BORN?

[42927.]—Many of these tricks have been published by the "E. M.," but I do not remember to have seen this: Tell a young lady, or any other person, that you are able to find out the very day of her birth, if only—

1. She writes down on a piece of paper (that she shall not let you see) the date of the month in which she was born.
2. Multiplies that number by 2.
3. Adds 4 to the product.
4. Multiplies again by 50.
5. Adds to this second product the number of the month (January = 1, February = 2, &c.)
6. Multiplies the sum by 100.
7. And finally subtracts from the product the exact number of years she was old last year, and gives you the result.

For instance, let us say that the young lady is born on the 3rd of September, 1880. She, therefore, writes 3; multiplies it by 2, and has 6; adds 4, which gives 10; multiplies again by 50, which makes 500; adds 9, and finds 509: multiplies a last time by 100, and has 50,900; subtracts 18, the accomplished years last year, and produces 50,882, a number which apparently is not to give you any information whatever upon the date of her birth. Well, take the paper anyhow, and feign to examine it with the greatest attention; meanwhile, add mentally 100 to the number produced, it gives 50,982; subtract from it 20,002, an operation easy to do, also without a pencil or a pen. What have you then? 30980; and you can tell the young lady that she was born on the 3rd day of the 9th month of the 80th year of the century.

As I am always happy to find and note tricks of this kind, I should be grateful if any of "ours" should, with the Editor's leave, let me know of others I may not be acquainted with.

Milano, Oct. 7th. Hunot.

An American statistician calculates that in Pittsburg, under normal conditions, pig-iron can be made at a cost of 9·53½dol.; England can only produce it at the minimum of 15·70½dol.; and Germany at 15·34½dol. The United States can therefore produce pig-iron 5·81dol. cheaper than Germany per ton, and 6·17dol. per ton cheaper than Great Britain.

Blue Prints and Photo-zincography.—C. Fleck, writing in the *Photographische Chronik* on the use of grained zinc plates for three-colour printing, gives the following formula for preparing a ferro-prussiate sensitising solution. The prints produced upon the zinc plates are only used as a guide by the artist, who makes three-colour drawings as in chromolithography. For the sensitising solution take: Distilled water, 100c.c.; alcohol, 15c.c.; ammonio-citrate of iron, 15grm.; ferricyanide of potassium, 10grm.; gum-arabic, 5grm.; honey or caramel, 2grm. The gum-arabic may be replaced by three times the quantity of albumen, or five times the quantity of fish-glue. The plates should be immersed before coating in dilute filtered gum-water, and to obtain an even film the plate should be twice coated with the sensitiser, starting each time from opposite corners. Equalise the film upon the whirler, and dry over a spirit-lamp. Print till the shadows are slightly bronzed. The printing must be done in sun or electric light. If over-printed, reduce with yellow prussiate of potash. The correctly exposed prints should be washed for ten minutes in water, and the image thus obtained is in Prussian blue. After drying, the drawing may be made over the print with Lemercier's chalk, No. 2.

REPLIES TO QUERIES.

⁂ In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.

[96555.]—**Equation.**—To "M.I.C.E."—The assumption referred to is surely sufficiently obvious from the symmetry and rotation of the coefficients, although, like most algebraical devices, it is merely a means to an end. As "M.I.C.E." so strongly objects to it, I am the more surprised he should have recourse himself to a similar non-algebraical supposition. When, for instance, a quadratic is presented for solution—say $x^2 + 3x = 5$—there is no implied condition that x shall be an exact integer or fraction, and unless the equation represent a set of conditions in which positive integers and fractions are the only admissible quantities, we have no right to import any such restrictions into the problem. Hence, one cannot accept the solution given by "M.I.C.E." on pp. 163 and 164 as orthodox, although we may admire its ingenuity. If we accept the premises that 34445·25 must be exactly divisible by x^2, and that the latter must also be an exact quantity, then the statement that ·25 and 2·25 are the only values which fulfil these conditions is certainly not accurate, for—

$$34445\tfrac{1}{4} \div x^2 = 137781 \div 4x^2 = (7 \times 3^9) \div 4x^2$$

where x may be $\frac{1}{2}$, $\frac{3}{2}$, $\frac{9}{2}$, $\frac{27}{2}$, $\frac{81}{2}$, or each of these multiplied by $\sqrt{3}$, $\sqrt{7}$, $\sqrt{21}$—i.e., twenty values in all. The particular values which satisfy the equations are therefore dependent, even on the false premises alluded to, upon twenty trials, and do not otherwise express certainties—i.e., the assumed x may not be the true x. The correct process of solution leads to the biquadratic.

$$m^4 - \tfrac{2240}{447} m^3 + \tfrac{1300}{149} m^2 - \tfrac{24125}{4023} m + \tfrac{5000}{4023} = 0$$

where $m = \frac{5}{3}$, $n = \frac{7}{3}$, $x = \pm \frac{3}{2}$, and the only values which satisfy the problem are $\pm (\frac{3}{2}, \frac{5}{2}, \frac{7}{2})$. The expression $\sqrt{9m^2 - 45}$ employed by "Ontario," or its simpler form $3\sqrt{m^2 - 5}$, may denote 2, 6, 22, &c., where $m = \frac{7}{3}$, 3, $7\frac{2}{3}$, and possibly some other values. So, likewise, $\sqrt{16m^2 - 351}$ may denote 7, 15, 57, &c., by putting $m = 5$, 6, 15, &c. Therefore the values $m = 3$, $x = 6$, as obtained by "Ontario," do not *necessarily* satisfy the equation. The only legitimate solution of "Ontario's" equation, like that of Mr. Harding's, is one involving a biquadratic, and if we attempt any alternative method it must involve assumptions and trials, or the "guesswork" complained of.

West Norwood. Henry T. Burgess.

[96588.]—**Wool Grease.**—If a "patent was taken out," as stated in the query, the particulars can, of course, be found in the specification. The query is rather funny, because readers are asked to give "common names in trade terms of the above." The "above" seems to be missing; but if the subject is a patent, full particulars can be obtained from the specification, or that is worthless and quashes the patent. R. S.

[96589.]—**The Keyword Interest.**—The "keyword" is simply some word known to those interested, and when known anything can be read by it, although to others it might appear to be mere "rubbish." To a 'cute man that would suggest something beneath. M. T.

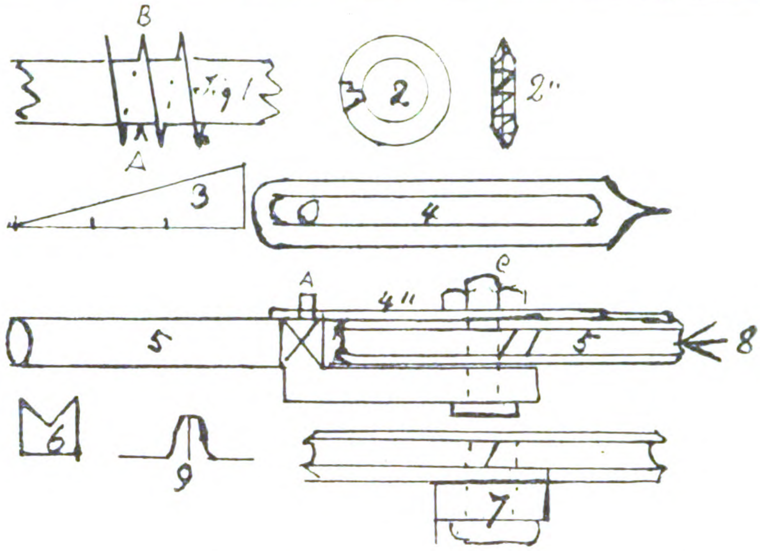
[96633.]—**Green Water.**—I have to thank "M. T." for kindly noticing my query. The water turns green without any bather entering it. I should be grateful if "M. T." would tell me where to send samples of the water for analysis, and for a sound opinion as to whether the greenness can be cured? Will he also kindly inform me what the cost of the analysis will be? Quex.

[96675.]—**Railway Lines.**—I have seen electric tram lines put down, but there was no welding of any kind. The connection between the rails was made in this way: A hole was bored in each rail near the end; one end of a copper rod was fixed into the hole in one rail, and the other end of the rod into the hole in the next rail. This rod was not straight, but somewhat bent—corrugated, as it were, and it got more or less bent according as the temperature tended to make it shorter or longer.

Trams.

[96680.]—**Temperature.**—Solution of the following will enable you to get 5° to 22° Fahr. of the heat of chamber. Inexpensive comparatively. Placed in a convenient vessel in room:—Calcium chloride, 20, magnesium chloride 20, sodium chloride 6, potassium chloride 13, water 41. If mixed with equal volumes of snow of 32° Fahr., freezing mixture of 5° to 4° Fahr. obtained. Ammonium nitrate 1, water 1, gives 5° Fahr. Ammonium nitrate 4, water 3, gives 13° Fahr., &c. Regent's Park.

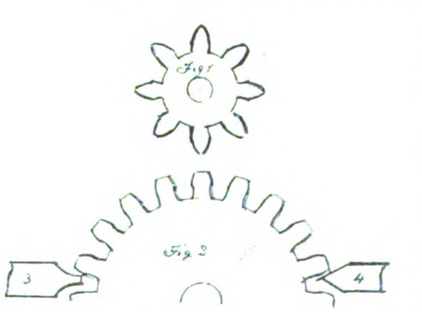
[96602.]—**Cutting a Worm-Wheel.**—You are not going to make a satisfactory job of it unless you go the proper way about it. Say Fig. 1 is the screw of the pitch you want to cut. Take the diameter from bottom to top of thread, as shown at B, and



plot out three times, as shown at Fig. 3, the base being, of course, the pitch. Now you have the angle for lining out face of wheel. Your hob section, shown at 2, step-toothed half the depth of thread and cutting clearance, only every other one into the bottom of hob—i.e., just below the others just to the bottom—and you will find it cut all right; 2 is the single disc-cutter to divide your wheel out, and cut out very near down to the depth (it cuts best if the teeth are zigzag from the centre); 4 is an index made out of a piece of saw-plate or sheet steel—the former best with the temper in it; 5 is the bar for placing the wheel on for cutting—may be made out of wrought iron or cast, of a pattern. A stud is placed upon it at A that just fits the slot in 4, and two flat sides are filed upon the bolt C that holds the wheel 5, to fit the same. The wheel should only embrace one-fifth of the circumference of the screw and the edges chamfered off, as shown, to depth of thread, and the face hollowed out very near same radius as the bottom of hob. The stalk of bar is round, and you will want a saddle-piece or vee-block to put it in, so that you can cast your job to the proper angle (see 6 and 7). The best section of thread for the teeth is wheel teeth or pitch, as shown at 9. Set your work central with centre of lathe (see 8). Divide your wheel out on the edge of chamfer, cut very near down to it with the single cutter, then finish with the hob, letting the wheel run loose upon the pin, not forgetting to set the top cheek of wheel level before performing the latter operation, and you will find it a beautiful job.

JACK OF ALL TRADES.

[96667.]—**Wheel-Cutting.**—You can do a lot of work with two cutters, only you must know how to use them, and they will work well enough for any ordinary purpose, and I have made one cutter do various jobs in that line; but it is in the one instance a cutter proper for every job that is done at once; then with the two cutters going over twice, then again with a single cutter going over the work three times. Just look up the sketch, and it will show you how it is done—rather stout for



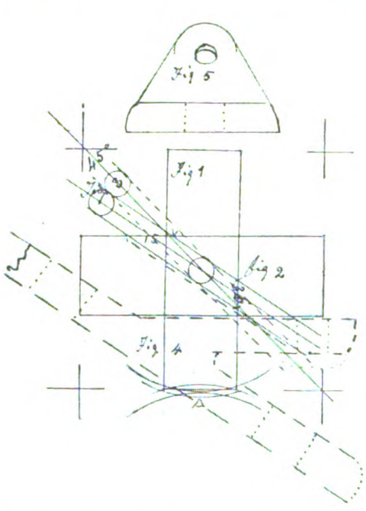
clock wheels. You should have given more particulars—i.e., diam. and pitch. Fig. 1 shows you pinion, and Fig. 2 a wheel. Now this is to illustrate the difference in shape of teeth. I have cut wheels from $\frac{5}{8}$ bevel or mitre top to close upon 3ft., and many I have done by the following dodges with fly-cutters. Where rose-cutters were not in stock, and time could not be spared to make them, or the job would not pay to do so, make either a cutter as 3, with a radius the same as the tooth, or a vee the same as 4, and raising your cutter above or below the centre of work, or applying it central and down to the pitch-line for your gauge, made them as near an approximate as no matter for practical working, and have had no fault found with them. Go thou and do likewise.

JACK OF ALL TRADES.

[96692.]—**Liquid Nitrogen.**—The question as put by "Pressure" cannot be answered without making various assumptions, and even then an exact solution would be a matter of some difficulty; and I cannot at present see how to solve it in a simple manner. However, "Justus's" remarks (p. 166) are certainly wide of the truth. Whether or not the liquid state persists above the critical temperature is still somewhat a moot point, owing chiefly to the fact that there appears to be no sharp line of demarcation between the liquid and gaseous states. This much is, however, certain—that it is impossible to convert by pressure a gas whose temperature is even slightly above the critical value into what is usually considered a liquid. "Pressure's" assumption is therefore correct.

Trin. Coll. Oxon. J. M. W.

[96711.]—**Spiral Gear-Wheels.**—The accompanying sketch will show you how to go about it. This shows you how to lay them out and how to go about cutting them. You will want two angle-plates made as shown in the bottom Fig. 4, which is the side view, and show you the lines to get them. Fig. 1 and Fig. 2 are the two wheels at right angles. They are $\frac{3}{8}$in. thick to $\frac{5}{8}$in. diameter, the one wheel marked off to 30 and the other 15, about $\frac{1}{4}$ pitch. The bottom shows you depth, and pitch line is $2\frac{1}{2}$. There is only one cutter wanted, a single point Vee with the point taken off, so as to make the bottom



$\frac{1}{16}$ wide, and the tops the same; top of between teeth $\frac{3}{16}$. I believe that they will run at that for what power is wanted for manipulating cams for gas-engines. If you are anything of a lathe man you can do the lot upon your lathe.

JACK OF ALL TRADES.

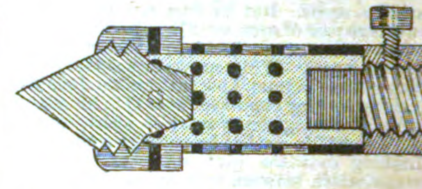
[96719.]—**Gauging Tanks.**—I am much obliged to "Regent's Park" for answer he has furnished; but the tanks may contain anything, from empty to full, and I wish to construct tables for various tanks, giving the contents for each inch of fluid in tank.

CHEMICAL.

[96729.]—**Grindstone.**—Possibly data might aid. Resistance to deflection from a direct line of motion offered by a body making one revolution in a minute in a circle of 1ft. radius is ·000341 of its own weight. This resistance varies directly as the radius of the circle, and as the square of the number of revolutions per minute. Thus, let A = radius of wheel in feet; R = revolutions per minute; C = constant ·000341. Then, $A \times R^2 \times C$ = centrifugal force of wheel in terms of its weight.

REGENT'S PARK.

[96738.]—**Gas-Heating Soldering-Iron.**—The blowpipe, Fig. 1, illustrated on p. 120 in



"Ours" of September 15 last, only needs a copper bit (as here shown) attached to meet "Bunson's" requirements.

161, Albion-road, N. A. CLARKE.

[96749.]—**Electro-Magnets in Series.**—The electro-magnet which will not work has probably got all or most of its turns short-circuited. This may be tested, if suitable apparatus is available, by measuring the resistance of the two coils, when the partially short-circuited one will be found to have the lower resistance; or a rough test may be made by connecting the two magnet coils in series across the battery, and then placing the wires from an electric bell across each coil separately, as if the coils were batteries. If one coil is badly short-circuited, the bell will ring only very feebly, or not at all, when placed across it, but will ring vigorously when placed across the good coil, if this has not too low a resistance. It is also possible that the coil of the magnet which will not work has been wound so that some of the turns are in opposition to the remainder; but this is not likely. In either case the only remedy (if no fault with the insulation can be seen on inspection) is to rewind the coil.

G. A. R.

[96756.]—**Ornamental Blocks.**—If you ever come across "Silk," by G. H. Hurst, of G. Bell and Co., London, you will see lustring is given to yarns by exposure to action of steam in oven, whilst stretched between two highly-polished revolving rollers of steel. Hanks are hung on rollers, oven closed, steam 5lb. to 10lb. pressure admitted, rollers revolve, at same time gently drawn apart, thus stretching and opening out silk yarn. The hanks obtain high lustre. Sometimes ovens are dispensed with; hollow rollers used heated with steam, but said not to be so good. Sometimes rollers are horizontal, sometimes vertically. However, this may not suit you, as you may want something in the nature of a size or starch. Possibly following may be worth a trial on small scale, and then if found adaptable done on the larger:—Lustrine Alsacienne (starch gloss): Borax, $2\frac{1}{2}$oz.; gum arabic, $2\frac{1}{2}$oz.; spermaceti, $2\frac{1}{2}$oz.; glycerine, $6\frac{3}{8}$oz.; distilled water, $2\frac{1}{4}$ pints; a few drops of some sweet-scented essence; add six spoonfuls lustrine to $6\frac{3}{8}$oz. of boiling starch.

REGENT'S PARK.

[96759.]—**Bikes and Prams.**—I am much obliged to your correspondents who have kindly noticed my query, but I want to know whether any court of law has decided the point. Let me put the case. A bicyclist out with his wife wheeled his bicycle and his wife's on to the pavement—say, in Bond-street—while she went into a shop. He was summoned and fined for having bicycles on the pavement (meaning the footpath or sidewalk); but perambulators are permitted. I happen to live in a place where perambulators are tolerated—in fact, we call it Perambulator Parade—and don't wish to say a word against the practice, because it is better that mothers should bring their children out than leave them at home to play with matches, &c.; but if perambulators are all right (legally) on the sidewalks, why should "bikes" be considered as offenders against the law? I have read of cases where a cyclist has been fined because he wheeled his machine on the sidewalk, when he could not wheel it on the road, as that was "up." Is there any "law"?

ROTA.

[96761.] — **Ginger-Beer Plant.**—I am much obliged to the gentlemen who have replied to my query, but I think Mrs. Harris does come into the question. The query originated in, or was based on, a statement that the ginger-beer plant was a "root" from Asia Minor, and that all that was necessary was to put it into water with sugar, and you obtained ginger-beer: hence the question—"Does it make ginger-beer without putting ginger into the sugar?"—"water" should have been appended. I think it may be stated definitely now that there is no such thing as a "ginger-beer" plant, but that there is a fungus which will produce carbonic acid; and if there is sugar and ginger (the ginger is the

point), in the water, it will produce ginger-beer. Hope the replies will be useful to some people.
ZINGIB.

[96763.]—**Salicin.**—Chemically it is $C_{13}H_{18}O_7$, a glucoside, obtained from most of the willow or salix order, used as a febrifuge and adulterant of quinine, soluble in about 28 times its weight of water or spirit at common temperatures, a white, shining, bitter crystal. See Attfield's "Chemistry" and Greenish's "Materia Medica," and others.
REGENT'S PARK.

[96776.] — **Wickless Paraffin Lamp.**—Most likely if you boiled the corroded part for a very short time in soda and water, or stronger alkali, you would cleanse. REGENT'S PARK.

[96777.]—**Balloon.**—A small model can either be made of gold-beaters' skin, cambric, or calico; the last two varnished with linseed oil, boiled. If querist could refer to back numbers, he will find all the information he seeks *re* lifting power of balloons, &c., together with practical information on the utter fallaciousness of aërial navigation by balloon or aërial vessels containing gaseous contents.
E. WILSON.

[96781.]—**Electric Lighting.**—To MR. BOTTONE.—There would be practically no use in employing a lamp in your case. The purpose that a pilot lamp serves, in a large installation, is to show at a glance, by a comparison between its brilliancy and that of the other lamps in the system, the potential at the terminals of the dynamo, as compared to that at the distant points. (2) If the shunt dynamo is correctly wound, with a fair proportion of wire on its F.M. coils, little or no difference would result. The lamps left on would probably "blink" momentarily; but the increased resistance caused by throwing two lamps out of circuit would quickly send up the voltage to the requisite point. (3) No. 18 platinoid wire, about five yards to the ohm. S. BOTTONE.

[96781.] — **Electric Lighting.** — A voltmeter would be better than a pilot lamp, since it would consume so much less current. Either piece of apparatus is simply for the purpose of ascertaining whether the dynamo is given the correct voltage. The result of suddenly switching in half the number of lamps would be a diminution of the voltage, partly on account of the increase in armature reaction, and possibly also owing to the slowing down of the engine under greater load. A variable resistance in series with the shunt-coils is a useful addition, as, by these means, the voltage can be varied at will within certain limits. For a 50v. 4a. dynamo a suitable resistance would be a number of 1-ohm coils (about 10), each consisting of 2ft. of No. 21 Reostene wire.
A. H. AVERY, A.Inst.E.E.
Falmen Works, Tunbridge Wells.

[96785.]—**Lamp for Firing Tube.**—As several ask questions on same, one answer will serve the lot. (1) Lamp will not do for paraffin, only benzoline or petrol, which will vaporise without heat; it makes a little noise, but only half the noise of Æ na. It, of course, must be used vertically, the loose pan first filled with methylated spirit to heat it. When spirit is just burnt out, turn on petrol, when it should burn with an intense blue flame. An air-pump is necessary on tank, same as Æ na lamp; but as tank should always be higher than lamp, not more than half a dozen strokes are ever necessary. The correct height of lamp is ⅞in. from under side of tube to top of lamp; it is held by a clip round the lower part of steel union. This is same pattern as used on Daimler cars. An outside lamp-case, made of sheet-iron, about 2in. square by about 8in. long is necessary, to prevent draught cooling tube. This latter is 1⅝in. long by 3/32in. diameter. The chief drawback to use of lamp is, it frequently blows out in wind, when it is a great trouble to relight, and it is impossible with it to vary the firing moment as with electric. They can be bought a great deal cheaper than it is possible to make one only—cost about 7s. The nipple, locks, central tube, and burner-chimney altogether is shown clearly in sketch given on p. 141. MONTY.

[96787.]—**Gas Battery.**—In 1843 Mr. Grove succeeded in constructing a novel battery in which the active elements were gases. It consisted of a series of 50 pairs of platinised plates, each about ¼in. wide, inclosed in tubes partially filled alternately with oxygen and hydrogen gases. The liquid in tubes was dilute sulphuric acid (sp.gr. 1·2), and the following effects were produced: (1) A shock was given which could be felt by five persons joining hands. (2) A brilliant spark visible in broad daylight was obtained between charcoal terminals.
A. HORSFIELD.

[96787.]—**Gas Battery.**—Consists essentially in two tubes of glass, closed at the top, but open at the bottom, plunged into a vessel containing dilute sulphuric acid. In these tubes are strips of platinum, the upper extremities of which pass through the top of the glass tubes, when they are sealed or otherwise closed. These tubes, before being placed in the containing vessel, are also filled with dilute sulphuric acid. If when the tubes are placed in the containing vessel, mouth downwards, oxygen gas is introduced in the one tube, and hydrogen in the other, the free ends of the platinums projecting from the tops of the tubes being connected together, a current flows from the platinum in the hydrogen tube to the one immersed in the oxygen through the acidulated water, thence back again through the connecting wire to the hydrogen platinum. If the gases are liberated in these two tubes by electrolysis, the effects are more powerful.
S. BOTTONE.

[96790.] — **Hot-Air Engine.** — According to Bryan Donkin, an expert engineer, they appear to be used only as stationary engines. You had much the best inquire about oil or naphtha. The Daimler Co. have an oil motor for boats. I saw something of the sort at Hurst and Lloyds, engineers, High Holborn, the other day. They were 6H.P., but no doubt 1 or 2H.P. (big enough for your purpose) is made by them. REGENT'S PARK.

[96791.]—**Dynamo.**—For an output of 15v. 5a. at 2,800 revs., wind your armature with 3oz. No. 20 S.W.G. If the armature were wound with wire of double the section (in conjunction with the same field winding), you would probably not get the machine to work at all, since you would only get about half the original volts generated in the armature, and these would be insufficient to force the requisite magnetising current round the field coils.
A. H. AVERY, A.Inst.E.E.
Falmen Works, Tunbridge Wells.

[96791.]—**Dynamo.**—There is some mistake in your query. It is impossible to wind a cogged drum armature as a Gramme ring. Please state exactly what your armature is, and I will advise.
S. BOTTONE.

[96792.]—**Dynamo and Engine.**—Knowing the proper revolution speed per minute required by the dynamo to enable it to give its normal output, take the speed per minute of the driving-wheel or shafting. Divide the former number by the latter, when the quotient will be the relative size (in diameter) which the driving-wheel or shafting should be to the pulley on dynamo. For instance, suppose the proper speed of dynamo to be 1,200 revolutions per minute, while that of the flywheel or shafting were 160revs. per minute. Then 160)1,200(7½, therefore the diameter of driving-wheel must be 7½ times that of the diameter of pulley on dynamo, or what amounts to the same thing, the pulley on the dynamo must be 7½ times smaller than the driver in diameter. 2nd. According to where it is purchased; our firm supplies this at about £35.
S. BOTTONE.

[96792.]—**Dynamo and Engine.**—Obtain from the makers the speed at which the dynamo is intended to run; then, knowing the speed of your engine and diam. of the flywheel, it is a very simple matter to calculate what size of pulley to put on the dynamo, for the speed is proportional to the diameters of driving and driven pulleys. For instance, if both engine and dynamo pulleys were of equal diameter, they naturally would both run at the some speed (quite irrespective of the length of the belting). If the dynamo pulley were now reduced to half its original diameter, it would run at twice the speed of engine flywheel; if reduced to a quarter its diam., at four times the speed, and so on. The rule is, when wishing to find the diam. of any pulley, to run at a given speed, multiply the diam. of flywheel or driver by the speed at which it runs, and divide by the required speed of the driven pulley. The result will give the diameter of the latter. For instance, if the engine flywheel is 36in. in diameter, running at 160 revs. per minute, and it is required to drive the dynamo at 1,600 revs. per minute by the above rule—

$$\frac{\text{Diam. of flywheel and revs. of flywheel}}{\text{Revs. of driven pulley}}$$

$= \text{diam. of driven pulley, or in figures } \frac{36 \times 160}{1,600}$

$= 3{\cdot}6$in. A 60-light (16c.p.) dynamo will cost £40.
A. H. AVERY, A.Inst.E.E.
Falmen Works, Tunbridge Wells.

[96792.] — **Dynamo and Engine.** — Your dynamo now apparently runs off your 4N.H.P. engine at 910 revs. per minute. Before we can give you the different sizes of pulleys to run your small dynamo off your larger engine you must give us the speed of it; but you can calculate for yourself thus: Multiply the diameter in inches of your flywheel by the revolutions per minute and divide by the revolutions your dynamo should run, and the product will be the diameter of your dynamo pulley. A thoroughly good, efficient, and reliable dynamo for fifty or sixty 16c.p. lamps will cost you from £35 to £40. If for 8c.p. lamps (you do not say whether 8c.p. or 16c.p.), £18 to £20.
WEBSTER MICHELSON AND CO.
Dudley. Electrical Engineers.

[96793.]—**Speed.**—It appears to me that any guess of speed of an engine is a rough one. If it is a gas-engine you want speed of, allow one of the valves to keep touching your hand. Count these for a minute and double the number. This will give the exact revolutions. If steam-engine, allow the crosshead pin or some other reciprocating part of the engine to touch the hand and count for a minute. WEBSTER MICHELSON.

[96793.]—**Speed.**—Hold a watch having seconds hand in your left hand, while you hold your right hand in such a position over the head of the piston rod, so that it just touches it as it rises at each revolution of the flywheel. Keeping your eye on the watch for, say, 15sec., count how may blows you receive, multiply by four, and this will give you, roughly, revolutions per minute. S. BOTTONE.

[96793.]—**Speed.**—You will get useful general hints in W. S. Hutton's "Works Manager's Handbook." Piston-speed governs mainly, and may be found by multiplying twice the length of stroke in feet by number of revolutions per minute of crank-shaft. Piston - speeds vary as you know in different types from 250 to 1,200ft. per minute. Stationary and non-condensing range from 250 to 300ft. per minute. Average of modern stationary non - condensing simple engines is 260ft. per minute. Piston-speed of engines with high rates of expansion should be not less than 420ft. per minute, but rather 500ft. per minute. The length of stroke in engines of strong construction is usually = diameter of cylinder multiplied by 2. Engines of light construction have generally a length of stroke = diameter of cylinder multiplied by 1·5, &c. REGENT'S PARK.

[96793.]—**Speed.**—Fix a sheet of white paper to the flywheel, not too far from the centre, and, watch in hand, count how often the paper passes a certain fixed point in any given time, say 60sec. With a little practice, it is quite easy to follow the paper accurately up to about 300revs. per minute. With more practice 1,000revs. per minute can be counted with a fair amount of accuracy.
A. H. AVERY, A.Inst.E.E.
Falmen Works, Tunbridge Wells.

[96794.]—**Bluing.**—Perhaps this requires a little time; black takes about a half-hour's immersion; steel-grey less; uniform light blue less; to light brown least of all. Hot solution: Lead acetate 50 grains, sodium thiosulphate 50 grains, water 5 fluid oz. See "Hiorns." REGENT'S PARK.

[96798.]—**Gelatine.**—F. H. Storer gives thus of it:—Gelatin, $C_{13}H_{20}N_4O_5$, permanent. It swells up in cold water, but does not dissolve therein. Soluble in warm water, insoluble in alcohol, soluble in acetic acid, decomposed by boiling in alkaline solutions. Soluble with decomposition in cold concentrated sulphuric acid, also soluble with partial decomposition in nitric acid. Soluble in cold concentrated chlorhydric acid. Slowly and partially dissolved by solutions of the caustic alkalies. Have a look at Watts's Dictionary of Chemistry under "Proteids," to see whether you get extra hints, page 339. REGENT'S PARK.

[96799.]—**Acetylene Gas.**—A five-gallon tank would hold ⅘c.ft. of gas, and one pound of the best carbide would give off probably 4½ft. of acetylene at most in the hands of the amateur. In any case, carbide varies from 3c.ft. to 5c.ft. per lb. according to quality. "Cape Colonist" had better be persuaded not to experiment with any acetylene apparatus till he knows a little more about gases.
W. D.

[96800.]—**Acetylene Carriage Lamps.**—It is so easy to make a lamp that will be dangerous that until R. Colin H. knows enough about acetylene not to require any help on this subject, he had better be content to buy one. A thoroughly successful carriage lamp would certainly be the subject of a patent. W. D.

[96801.]—**Pump.**—You would find an ordinary deep-well lift-pump the best fixed within a few feet of the water. We should be glad to send you one on knowing how you propose to work it—whether by manual labour or power.
Dudley. WEBSTER MICHELSON AND CO.

[96804.]—**Hertzian Waves.**—Premising that unless you have a fair knowledge of electricity and magnetism, and also of the cognate phenomena of light and sound, you will find even the simplest book on this subject by no means easy, I should recommend you to read "Electric Waves," by Dr. Heinrich Hertz, translated by D. E. Jones, 10s. 6d. net. S. BOTTONE.

[96806.]—**Rain Supply.**—I expect J. Blake, of Accrington, whose advertisement you may see in the BUILDING NEWS, is second to none for these goods. He would send illustrated list free, if asked. REGENT'S PARK.

[96808.]—**Dynamo Switchboard.**—You will find full description of the mode of using the switchboard, connecting-up to dynamo, accumulators, and to lamps in the book you mention, "How to Manage the Dynamo," at p. 36 *et seq* Sect. 19. S. BOTTONE.

[96809.]—**Bacilli.**—The symbol μ, which is sometimes termed micron when used to express the measurements of bacteria, denotes the one-

thousandth part of a millimètre. The other expressions referred to in the query relate to the specific rotatory power of solutions under two different conditions. Solutions of various substances in water are capable of rotating a ray of polarised light, to which the terms dextro- or lævo-rotatory are applied, according as the rotation is towards the right hand or the left. The terms dextro- and lævo-rotatory are very often expressed by the signs + and −. Now, the specific rotatory power (S.R.P.) of a substance is defined as that rotation which is given to a ray of polarised light when passed through a length of one mètre of a solution of the substance containing 10 grains of substance in 100c.c. of solution. Some polariscopes use yellow sodium light, obtained by placing a small quantity of salt in a Bunsen flame. The S.R.P. of a substance under these conditions is denoted by the symbol $[a]_D$. Other polariscopes use light of a pale rose-violet tint, which is secured by an optical arrangement of plates of quartz, to which the term "transition" is applied. The S.R.P. with light of this refrangibility is expressed by $[a]_j$. The connection between the two is $[a]_j = [a]_D \times 1{\cdot}108$, which is easily seen to hold between the two figures quoted in the query. A. Price, B.Sc.

[96812.]—**Winding ¼H.P. Motor.**—To Mr Bottone.—Wind the armature with 2lb. No. 26 silk-covered wire, as carefully as you would a coil, shellacing each layer as you put it on. Wind the field-magnets with 4lb. No. 24 cotton-covered wire, and connect up in series. The motor will take about 4amp., and will develop, if well made, about ¼H.P. With regard to your dynamo, it is rather small to get 10amp. or 12amp. out of, at 15volts. I should certainly wind two coils of wire in each slot, one on each side of the spindle. If you can get a little over two yards of No. 18 d.c.c. in each complete coil, or say about 6oz. in all, and wind the fields with 2lb. of No. 20, connected in series, you will probably get the desired results. S. Bottone.

[96813]. — **Oxidised Steel and Iron.**—Grey colour on iron. A good and uniform dark-grey colour can be imparted to iron and steel by first depositing a coat of copper on article and then immersing in the following solution:—Ammonium sulphide solution 1 fluid oz., water 6 fluid oz. Well to repeat immersion once or twice to get good colour. Potassium or sodium sulphide may be used in place of ammonium sulphide. A light grey colour may be imparted to iron and steel by means of a solution of antimony chloride. The article is first coppered as before, then immersed in solution of antimony chloride 30 grains, water 1½ fluid oz , hydrochloric acid to make solution clear. A deposit of antimony may be obtained on plain steel without previous coppering, but appearance not so good. A good grey colour can be obtained by immersion in hot solution of arsenious oxide 50 grains, hydrochloric acid 90 grains; to dissolve above, water 1 fluid oz. No effect is produced upon either plain or coppered steel in a cold solution. Puscher works by lead acetate and sodium thiosulphate: Lead acetate 50 grains, sodium thiosulphate 50 grains, water 5 fluid oz.; solution used hot: 1 light brown colour, 2 darker, 3 purple and blue mixed, 4 purple and blue (paler), 5 light blue, 6 steel grey, 7 black after half-an-hour; time of immersion various for tints. Black colour:—Sodium thiosulphate 50 grains, water 5 fluid oz. Blue-black produced has warm coppery tints, &c. Regent's Park.

[96814.]—**Acetylene.**—A burner passing one-third of a cubic foot per hour will give about 8c.p. actual, and require 1½oz. to 2oz. of carbide per hour. I have never experimented with a solution of acetylene in alcohol; but would advise caution both in making and using. It would be very awkward to use in a lamp, and certainly dangerous. W. D.

[96815.]—**Malleable Castings.**—Pig-iron preferably used is a white charcoal pig, melted in cupolas, or in a reverberatory furnace. Mostly green sand used, from metallic patterns to insure constancy of shape and smoothness of surface. Castings as brittle as glass; then put into tumblers, or revolving cylinders of cast iron with ribs inside, in which article is deprived of adhering sand, and becomes polished by mutual friction. The clean castings, intended for conversion into malleable iron, next packed close, with alternate layers of powdered iron-scale from rolling mills into rectangular cast-iron boxes, which become of an elliptic shape after length of use, and which can be placed one on another, if need be, and closed at top by mixture of sand and clay, which prevents contact with air, and follows settling of the mass. Then into the annealing furnace, which resembles those used for making bone black of sugar refineries; leaving aside time necessary for raising temperature and cooling off, articles are subjected for about a week to a white heat—not sufficient, however, to melt what may still remain of cast-iron. After proper annealing, castings are covered with a film of oxide of iridescent colours. Any adherent oxide is removed by another passage through tumblers, and the process of malleable-iron making is finished, &c., &c. See "Moulder's and Founder's Guide," by J. Overman, M.A., Sampson Low and Co., London. Regent's Park.

[96819.]—**Coil, Transmitter, &c.**—To Mr. Bottone.—Either your tapping key does not make contact, or your jars are defective. To test the former, detach the jars, put a wire at a fair sparking distance across the terminals of your coil, and give a spark tap with the key, the battery and key being, of course, in circuit with the primary of coil. If you get no spark between the coil terminals, the key is at fault; but if you get a spark there, then there is something wrong with the jars. One may be cracked, or they are not of insulating glass, and will not retain a charge; or else the knobs of the transmitter are too far apart to allow the discharge to pass. Provided the vertical wire make good electrical contact with one side of transmitter, it does not matter about its being close to it. S. Bottone.

[96823.]—**Wimshurst.**—Rub the surface of your plates lightly over with a thick cream made of water and carbonate of magnesia. When quite dry, rub it all off again with a warm dry piece of flannel. Polish the balls, dry the glass-work with a hot flannel, and see that the brushes stand at 5min. to 5 on each plate, and that they really touch the plates. Your machine will then work. S. Bottone.

[96825.]—**Meteorites.**—Records of meteoric falls in the British Isles are few. In 1695 a "shower of unknown matter" fell in Ireland. This is apparently the earliest. I believe nearly all the remaining instances are given in the catalogues in "An Introduction to the Study of Meteorites," issued from the British Museum (Natural History), to which I presume the querist refers. A search for others might, however, be made in Arago's "Astronomie Populaire," tome IV. pp. 184-204 (French edition), where a list of 273 aërolitic falls will be found. The Reports of the British Association from 1860 to 1880 also contain notices of such fall (see reports of the Luminous Meteor Committee in those volumes, especially for the years 1860, 1867, and 1870 where general catalogues are given). Walter E. Besley.

[96826.]—**Polishing Oak Floor.**—You may have to scrape it level and sandpaper it. A good scouring mixture I suppose you know of, if not, clean sand 12 parts, soft soap 8 parts, lime 4 parts. Use scrubbing-brush, and rinse. Allow to dry thoroughly, and then polish with Ronuk, sold by oilmen in many places, or wax polish with pure beeswax and oil in proportions of 1¼lb. wax, ½lb. linseed-oil. Melt together, remove from fire, and when mixture is cooled a little add 1 quart turpentine and mix well. Use felt rubbers 4in. by 2in. square, or 6in. by 3½in. Avoid signs of tackiness. Avoid doing where you have to walk immediately, and therefore do not begin at door. If your door is S.E., begin on N.W., so as to get most light. Avoid dust entering. For large surfaces felt rubbers 8in. or 9in. long 6in. wide, glued on a piece of hard flat wood with centre arm fixed on upper side, two weights of ¼cwt. or less each placed on each side of upright arm, and another long arm be hinged to short arm on block. After applying the wax, draw and push weighted rubber backwards and forwards until the desired effect is produced. Wainscot work: Take beeswax as required, place in glazed pan, add q s. of 90 per cent. alcohol to cover, and let dissolve without heat. Make consistency of butter. Well rub mixture into grain of wood, clean off with clean linen, &c. Regent's Park.

[96827.]—**Trepanning Bar.**—The term is new to me. Fettlers knock out cores by means of a common round bar about 1in. in diameter, driven by hand, and operating like a tamping bar. J. H.

[96828.]—**Rontgen Rays.**—Better experiment for yourself. Get a one-pound coffee-tin. Throw away the lid. Cut a hole in the bottom of tin of sufficient diameter to allow it to slide over the top of the chimney of your paraffin lamp when the tin is inverted over it. The mouth of tin should reach to reservoir of lamp. Now put the lighted lamp covered by its tinned iron cap in a tall wood box having air-holes beneath, and an exit for hot air above. Put a "journal" or a newspaper in the box, close up, and see what you can read. Please report results for benefit of other readers. S. Bottone.

Four hundred and nine locomotives have been shipped abroad from the Baldwin Locomotive Works during the year ending August 1st last.

The Japanese are making progress in the ship-building industry. At Nagasaki there is now being constructed a vessel of 6,000 tons, similar to that built for the National Mail Steamship Company last year. Greater rapidity has characterised the building of the second than that of the first vessel, the latter having occupied fully eighteen months, while, from the laying of the keel to the launching of the second, not more than thirteen months will elapse.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered, are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[96829.]—**Women as Inventors.**—Is it true that women have never invented anything? Can any readers give instances of inventions accomplished by women? An arrogant dinner-party of the superior sex sat on me last night by unanimously declaring that the total lack of invention in women proved the inferiority of the sex, and I had little to say; but I do not believe it, and I appeal to "Ours" for instances. — A Woman Reader of "Ours."

[96830.] — **To Practical Electricians.** — Our people intend building a factory, and propose lighting it with electricity. We require about 30H.P. for driving other machinery, and propose getting boiler and engine big enough to drive dynamo for 500 lights 16c.p. at 110v. Can we work dynamo at full speed, having only half the quantity of lamps on, sending surplus electricity into accumulators for use when engine is stopped. If we charge accumulators at 110v., what can be drawn out of it? How many cells would be required, and what sort would answer best in use? Can you give name of any work likely to be useful to novice, or outline a system likely to be successful? What is leakage in using accumulators, and what is the probable cost of battery? Would it be best to have smaller dynamo at a higher voltage for charging battery, say 130v., to insure getting 110v. back? H. Richards.

[96831.]—**To Mr. Bottone.**—I am constructing an intensity coil, and would like to know if cotton-covered wire would do for the secondary coil, as I have a quantity of No. 36 cotton-covered wire.—New Reader.

[96832.]—**Electro-Plating.**—Is there any simple process by which small articles, cast in alloy of lead and antimony, can be plated with thin coat just for appearance, and without a battery?—J. B. C.

[96833.]—**Wimshurst.**—Will Mr. Bottone please favour me with the following particulars for making a 12-plate Wimshurst for X-ray work, with plates 3ft. in diameter, cut from 21oz. glass? (1) The size of the base so as to case the machine in glass. (2) Size and number of sectors for each plate. (3) Size of hubs. (4) Diameter of steel spindle on which the plates revolve. (5) Size of discharging balls. (6) Size of long dumb-bell-shaped conductors to which the combs are fixed. (7) Fastest rate at which plates may be safely revolved. What lengths of spark may I expect to get?—Amateur.

[96834.]—**Transit Instrument.**—Can anyone tell me how to light up the interior of a transit instrument for night work? The diameter of the hole in the axis being only ⅜in., I find great difficulty in getting sufficient light down it.—R. A.

[96835.]—**Motor for Phonograph.**—Will some reader please describe how to make a clockwork motor suitable to drive an Edison style of phonograph?—R. W. A.

[96836.]—**Microphone.**—Will some of "ours" kindly explain the construction of a Hunnings microphone? Will ordinary gas carbon do for the granules, or must it be prepared in any way? Is there any reason why an amateur should not succeed in making one. What will probably be his difficulties?—Sarum.

[96837.]—**Phonograph.**—Would "F. F." kindly give some explanation of a "Bettine reproducer to show the difference between it and the ordinary glass diaphragm reproducer? Is there any superiority of the phonograph over the graphophone or vice versa? As far as I have found, the graphophone records seem louder than those made for the phonograph. Any hints as to the above would be extremely gratefully received.—C. E. O., Thaso.

[96838.]—**Chords of a Circle.** — What formula multiplied by the diameter gives the chord 1/18 of the circle? How is this formula obtained? What is a good book on the subject?—F. G. M.

[96839.]—**Spark Coil.**—Would Mr. Bottone please say if there is any difference in using thick tinfoil, the silvering kind. for condenser? I have made mine with very thin bright foil, bought as tin; but on testing get quite a flaming spark from the primary, much more than without c. in circuit b tween the brake, and only 1/32in. spark from secondary; ½lb. as yet of 32 d.s.c., have not made contact-braker yet, and same result with secondary

away, and also with another condenser instead, six sheets 24 by 12 between sheet glasses. My core is slightly altered, being 7¾in. by $1^1/_{16}$in. dia., and four layers 18 d.s.c., 1lb. full; ebonite tube, ¼ thick, equals 2¼ outside; battery 4v. accumulator, 8 amps. normal.—SPARK COIL.

[96840.]—**Microscope.**—I have seven lenses taken from an old telescope, with the following diameters:—Two of ⅞in., two of $^{11}/_{16}$in., one of ¾in., one of ⅝in., one of 1in. Can I use any of these to make a microscope? Kindly say length and diameter of eye and power tubes. Also distance between eye and field lens.—MICRO. AMATEUR.

[96841.]—**Decomposition of Mercury.**—Will any readers answer the following? (1) If a current of electricity is passed through a body of mercury, will it decompose it? (2) If the mercury is in a limited space, will the gases of the decomposed mercury gather, and in time explode?—F. E. N.

[96842.]—**Motor Tricycle.**—Can any reader tell me if I can obtain the complete component parts of motor tricycle, finished, but not enamelled or plated? I wish to make motor tricycles as cheaply as possible. Any particulars as to cost will be gratefully received. Is 1½H.P. sufficient, or 2¼ advisable? Should be glad of explanation of magneto ignition.—DAMON.

[96843.]—**Motor-Car.**—Could any of your contributors give me a little help in making a small motor-car? I intend buying a motor similar to those fitted to the Beeston tricycle, 1¾H.P. I propose making it after the style of a dogcart. My intention is to connect the motor by a strap to a fast and loose pulley running on a shaft 18in. from the motor, and at the end of the shaft, which will project through the side of car to have a eight-tooth bicycle cog, and connect this cog by a bicycle chain to a similar cog on one of the rear wheels of car. The motor runs at about 700 revolutions per minute. To stop car I should shift belt on to loose pulley. Will this work satisfactorily? What size pulleys should I use on motor and shaft to make car travel about 8 to 10 miles per hour? The car will have 28in. bicycle wheels.—IVANHOE.

[96844.]—**Arc Lamps not Burning.**—Can any of your correspondents say how to get over the following difficulty with the Crompton-Pochin arc lamp? The lamps are used outside, and in wet weather moisture gets on the rubber tubing, causing it to grip on the brake wheel, and thus stopping the feed of the carbons. The covers are whole, also a rubber washer around the joint at top of lamp, and the tubes on top of lamp, where leads come through, have been made secure against any rain getting through.—A. M. O. K.

[96845.]—**Water Motor.**—Will someone kindly tell me how I can make a ¼H.P. water motor from a ⅝in. main? The pressure is about 40lb. or 50lb. to the inch. I should like to have the dimensions for one this size. I do not want it to be too complicated, as I have not a very large selection of tools.—J. RIVER.

[96846.]—**Voltaic Cell.**—I should be extremely obliged for information, as I thought of making a voltaic cell. Which would be the best chemicals to use in the porous cell? If so, how should they be mixed? Would zinc in outside cell and carbon in porous cell act?—R. P. L.

[96847.]—**Motor Cycle.**—(1) Would "The Writer of the Articles" kindly state the length of the "life" of the De Dion dry battery which is mentioned in the articles as being sold at £1 15s.? (2) At what rate per hour would cycle travel on a fairly level road with motor working at normal speed (1,000 revs.) and carrying two persons? (3) Would travelling speed be doubled at 2,000 revs.? (4) Would motor be powerful enough to carry three persons if cycle was so arranged?—ANXIOUS.

[96848.]—**Failure of Dynamo.**—I have in our factory a dynamo 60 volt. 15 amp., which is supposed to run 15c.p. lamps, which I have in different parts of the premises; the machine is a compound, and well built. The difficulty is this: every light that is switched on appears to lower the voltage of the remainder, so that if I have an 8 or 9 lamp, I get practically no light at all. I have plenty of power, so that is not the reason. I am running the dynamo at 2,000 revs. per minute. Will someone kindly help me, as I naturally imagine I ought to get 15 good lights from machine? I may say I have been obliged to use 10-volt. lamps in order to keep six lights going. Any information relating to failure will be esteemed.—BREWED GINGER.

[96849.]—**Board of Trade Exam.**—I wish to sit for the Board of Trade exam. for marine engineer. I have served five years in the drawing office, and eighteen months in the fitting-shop at a large steel works. Will any kind reader inform me as to the best course to take?—NO NAME.

[96850.]—**Leaven.**—What is leaven? Does it differ from yeast? How is it made when there is none to begin with? Does it cause bread to taste sour?—S. A. M.

[96851.]—**Colouring Photographs.**—Can any reader inform me how the photographs to be seen in railway carriages are coloured? The colours appear to be laid on the face of the print. What paints are used, and is any preparation of the surface of the ordinary gelatino chloride paper required?—CURIOUS.

[96852.]—**Bicycle Rim.**—Is it possible to make a bicycle rim of any of the white metals (Kronand, Peerless, Hecnum, or other) strong enough to bear the unrestricted use of a Bowden or other rim-brake? Or can a steel rim be coated with one of these metals?—BENVENUTO.

[96853.]—**Heat-Absorbing Power of Alum in Solution.**—I think it has lately been shown that the supposed power of a solution of alum to absorb heat rays to a considerably greater extent than pure water is a mistaken idea, the difference being immaterial. Is this so? Where are the experiments described? How can they be easily repeated, and what was the exact result?—GLATTON.

[96854.]—**Rolled Paper Pipes.**—Would some kind reader inform me how machines are constructed for making rolled paper pipes about 3ft. long, 1½in. to 3in. diam.? How are the rolling mandrels made to be easily withdrawn from the pipes? If pitch be used for adhesion, how can it be sawn or cut without the pitch or tar adhering to the saw?—J. E.

[96855.]—**Aluminium for Electric-Lighting Cables.**—I read in a paper, the other day, that the lighting of the town of Northallerton, in Yorkshire, by electricity, is done by twelve arc lamps, each 2,000c.p., up to the present. The most novel feature of the installation is that an aluminium cable is used instead of copper, and is said to be the first in this country. The charge for the light is at the rate of 6d. per unit. Can anyone tell me what advantage is obtained by the use of aluminium for leads?—E. G.

[96856.]—**Emery-Wheels.**—In a comment on the report of the committee on Dangerous Trades (I think), it is stated that: "This is another very hard rock (from Smyrna or the Isle of Naxos), ground into the finest powder, and then made into wheels by the addition of some substance like shellac or indiarubber, and then made into wheels under hydraulic pressure. Corundum (an oxide of aluminium, which comes from Canada) is used as a substitute for emery. In the use of these wheels, owing to the great speed at which they are driven—a 3in. wheel will be driven at 7,400 revolutions a minute, and a 3ft. wheel at 600—there is great danger of centrifugal breakage, besides the injuries caused by the dust given off in their use. The committee recommend that all such wheels should be provided with protecting guards and with suction-pipes, and a fan to carry away the dust from the workman's face." I thought that emery-wheels were made with something similar to Portland cement, and were moulded under great pressure. It seems to me that both shellac and indiarubber would be rather dangerous substances to use as the cementing agents, on account of the heat engendered by friction. What is the truth?—J. M. T.

[96857.]—**Test for a Diamond.**—In a London evening paper it is given as a test for the genuineness of a diamond that you are to make a small dot on a piece of paper with a lead-pencil, and look at it through the diamond. If the "dot" shows only a single spot, the diamond is genuine. Please explain the reason.—DUBITANS.

[96858.]—**Doublets.**—In the trade imitation stones (imitations of precious stones) are known as "doublets." Can any reader tell me how these are to be detected?—X

[96859.]—**The Peculiarities of Precious Stones.**—Can any reader tell me what amount of truth there may be in this paragraph? "Diamonds are said to be as much alive as a starfish, or any other semi-vital inhabitant of the sea (remarks a writer in *Success*). A stone may appear flawless when brought fresh from the mine, but not unlikely before many hours are passed it will have burst. It may swell and develop flaws, and in a short time crumble to pieces and be useless. The turquoise is another stone which suffers bad health. The blue has infrequently been known to change to a pure white, and, of course, lose its value. In most instances, however, it can be made to regain its normal condition. The influence of cold upon jewels of various kinds is great, and capable of turning the colour in a short time." What is a "semi-vital" inhabitant of the sea or anything else?—Q. X.

[96860.]—**Companion to Aldebaran.**—Would "F.R.A.S." be kind enough to state the latest and most reliable measurement of the magnitude of the companion to Aldebaran? Also the minimum aperture that would fairly and doubtlessly show it on a dark, clear night? And, if possible, the present distance from Aldebaran? "F.R.A.S.'s" own measurements would be deemed a great favour.—C. H. STIBLOW.

[96861.]—**Shortness of Breath.**—I have for years suffered from shortness of breath; at the least damp I find it difficult to walk a few hundred yards even. If I stoop it takes some time to get over it. I am quite well otherwise. The doctors I have had do not seem to understand it. Can any reader help, or know of a remedy that will ease the choking?—BREATH.

[96862.]—**Fret-Saw Machine.**—Would a kind reader please give me a design for top work of above? I have good stand, treadle, and flywheel. I have used hand-saw frame with success, and, being a little ambitious, should like to make my own machine in preference to buying. I am only a young subscriber, so cannot refer to back vols.—TERF-WAS.

[96863.]—**Sticking Solution.**—Can any of "ours" help me with the following job? I have to split some ordinary sole leather $^1/_{16}$in. from the top surface for ⅝in. from the edge, and that has to be turned back when it is wet, and when dry it has to be stitched and then turned down again. I want something that I could put on when it is back which will stick the two substances together again when it is turned down. Is there anything that will stick without water taking effect on it, as I have to wet the leather again to turn it down?—SNOB.

[96864.]—**Knocking in Gas-Engine.**—I have a gas-engine that knocks through the hole in piston end of connecting-rod being worn, and there is no adjustment, the diameter of hole is ¾in., and diameter of boss is 1¼in.; leaving ⅜in. thickness of metal. Is there enough thickness to allow the hole to be bushed? If so, how large can I make it (with safety), and which is the best way to enlarge it? The rod is too long to swing in the gap of lathe. Connecting-rod is of mild steel.—CRACKPOT.

[96865.]—**To Mr. Bottone.**—I have a laminated drum armature 3in. diam., 4in. long. Would it be possible to wind it to give 50v. 20a., using cast-iron F.M.'s of Manchester pattern? Also, gauge and quantity of wire to wind A. and F.M. to be a shunt-wound machine for lighting purposes.—J. ELLIS.

[96866.]—**Wireless Telegraphy.**—(1) I should like to know if, in using a vertical wire 40ft. long, it should be perfectly vertical? (2) What is the box arrangement near the top of the long wire that Marconi uses? Does it make the apparatus more sensitive to the rays? (3) Is there any need, when using long vertical wires, to tune the transmitter and the receiver to each other, and if so, how is it done? (4) How to make Marconi's latest coherer? What is the size of silver discs, and the proportion of silver and nickel filings, and how fine should they be?—CARLIOL.

[96867.]—**Silencer for Oil-Engine.**—Please give the size of an exhaust silencer for a ¾H.P. oil-engine. The engine is to drive a lathe, and the exhaust annoys the neighbours.—W. TEAGO.

[96868.]—**To Mr. Bottone.**—Having purchased a ¾B.H.P. oil-engine, a 50v. 4a. dynamo, also a quantity of 7/22 cable and $^1/_{20}$ wire, (1) could I have engine and dynamo fixed in a shed about 50yds. away from where the lights are required, using 7/22 cable in casing running through outbuilding for about 46yds., the remainder across an open space in a tube of some kind? (2) Would the dynamo have to be running at a higher speed than 1,800 revs. per minute to allow for loss in mains to properly light the 50-volt 16c.p. and 18c.p. lamps that are required? (3) What difference in the voltage and ampères would there be if the dynamo was running at 2,000 revs. or more, dynamo being shunt-wound, with drum armature, undertype pattern?—W. P.

[96869.]—**Cycle Lamp Wicks.**—What can I put in sperm or colza oil to prevent it carbonising the wick in cycle lamp? The lamp goes out after burning two hours. How can I filter it?—C. W. STEPHENSON.

[96870.]—**To Perambulator-Makers and Dealers.**—I have an appliance that I wish to reach from the oil-valve of one wheel across to that on the other side (the larger pair of wheels I refer to). Will someone be kind enough to give me the different widths that I should have to make my appliance? Also, if possible, which width is most general in use?—LUBRICATOR.

[96871.]—**Image in Mirror.**—Where is the image, as seen in a mirror, formed? I have read several books on optics, and am rather puzzled to know how my image, which I see in a mirror five or six yards away from me, can be formed the same distance behind the mirror, remembering that there is a brick wall behind it.—THES. TOMPSON.

[96872.]—**Telephone Wire.**—Will galvanised iron wire do for a short telephone line—about 300 yards? Is the iron wire as durable as the bronze wire used by the telephone companies? What is the advantage of the latter wire?—TELEPHONE.

[96873.]—**Whole-Meal Bread.**—My wife has many times essayed the making of this, but has only once succeeded. We find it impossible in our suburb to get a good quality, and I should feel grateful to any reader who would give exact instructions as to proportions of yeast and meal, method of mixing, temperature of water used, temperature for rising, temperature of oven, kind of yeast, &c. In Devonshire, some years ago, I obtained some delicious whole-meal bread, and happening to meet the miller, was told by him that he had found by experiment that it was necessary to mix the Canadian red wheat with the home-grown product to obtain his present excellent quality of bread.—D. W. A.

[96874.]—**Prussic Acid for Fumigating Trees.**—The following paragraph is going the rounds, but can anyone tell me whether there is not some risk in using prussic (hydrocyanic) acid for the purpose:—"The fumigation of trees for the destruction of insect pests is soon to come into use in New South Wales. Successful experiments have already been carried out. The tree to be treated is completely covered with a tent, and is subjected for nearly an hour to the fumes of hydrocyanic acid, produced by the combination of sulphuric acid and potassium cyanide. The number of men generally employed in a fumigating gang is four or five, according to the size of the trees. One man introduces the chemicals, another looks after the generator and measures the acid, and two or three handle the tents. Such a gang can handle from thirty to forty medium-sized tents, and cover from four to six acres of orchard in a night."—HORTUS.

[96875.]—**Armour Plating.**—Can any reader tell me what is the maximum thickness of armour-plating on modern warships? I read in a technical paper that "the Krupp armour plates 1½ mètres in thickness, destined for the Russian ironclad now being built in Cramp's shipbuilding yard, have just been tested at Indian Head, in the presence of the American Admiral O'Neill and several Russian officers. It is reported that the tests proved that the Krupp plates are 50 per cent. stronger than the Harvey plates, and their success is expected to lead to their adoption in constructing new warships for the American navy." I suppose that by "1½ mètres" is meant a mètre and a half; but surely no ship floating can carry that weight of armour—plates a mètre and a half thick! There must be some mistake. If not, where are such plates rolled?—S. W.

THE State of Michigan contains large deposits of marl, which are about to be utilised for the manufacture of cement.

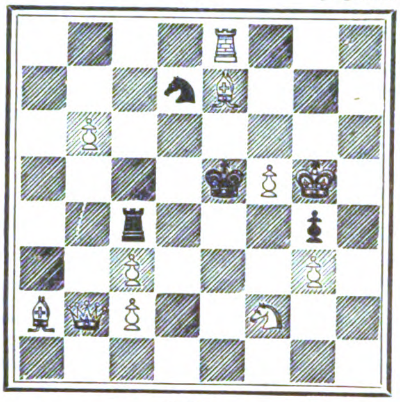
Railway Accidents in 1898.—The report on the railway accidents of last year contains some information which may be of use. The number of passengers killed in train accidents was 25, which is an increase on the previous year, in which the number was 18. These deaths were caused by eight collisions and two derailments of passenger trains. The total numbers of deaths and injuries to passengers from causes other than accidents to trains reported in 1898 were 128 killed and 1,238 injured, as against 115 killed and 1,315 injured in 1897. When all classes of accidents on railways are taken into account, however, only one passenger is killed in 6,947,131 passenger journeys, and only one in 568,402 is injured. Season ticket-holders' journeys are not included in these figures, because their number cannot be estimated. 1,283,045 season tickets were issued in 1898, and it is obvious that if an accurate estimate of the passenger journeys taken by the holders of such tickets could be made, a large increase in the number of passenger journeys would be shown, with a corresponding benefit to the passenger when calculating his risk of accident. During the year 504 servants were killed and 4,149 injured. These figures are irrespective of 38 killed and 8,830 injured in accidents in which the movement of vehicles was not concerned.

CHESS.

All communications for this column to be addressed to The Chess Editor, at the Office, 332, Strand.

PROBLEM No. 1696.—By F. G. Tucker.

Black. [4 pieces.



White. [11 pieces.

White to play and mate in two moves.

(Solutions should reach us not later than Oct. 23.)

Solution of Problem No. 1694.—By F. M. Teed.

Key-move, R-K 4.

NOTICES TO CORRESPONDENTS.

Problem No. 1694.—Correct solution has been received from E. C. Weatherley, P. Laubach ("Neat, but easy"), Rev. Dr. Quilter, J. E. Gore ("Neat and pretty"), G. W. U., Richard Inwards, A. Tupman, and Whin Hurst, Geo. Christie, F. B. (Oldham), T. Clark, Quizco.

Chalk, A. B. T., C. F., A. E. Stokes.—Only solution as above.

Of the 245,238 miles of railways in use in the United States in 1898, 220,803 miles had steel rails and 24,435 miles of iron rails.

Fuel made from compressed peat is being successfully manufactured at Stratford, Ontario. The peat is obtained from a swamp 40,000 acres in area, which varies from 1ft. to 20ft. in thickness. It is cut and air-dried, then pulverised, passed through a picker and to a hopper, which automatically feeds into a 2in. steel tube 15in. long. The pulverised peat is forced through this tube by pressure and formed by dies into cylinders 3in. long, and almost as dense as anthracite coal. It weighs 83lb. per cubic foot, as compared with 73lb. for bituminous coal and 93lb. for anthracite. It has been tested in locomotives, showing a thermal value of 100lb. of peat, equal to 95·15lb. of coal.

Big Skulls and Weighty Brains.—Prof. Arthur Thomson, M.A., M.B., continues his instructive discourse "On the Treatment and Utilisation of Anthropological Data" in the current number of *Knowledge*. Dealing with the form of skulls and brain capacity, he says: "The average weight of man's brain is about 50oz., that of woman about 45oz. This difference between the sexes is less marked in savage than in civilised races, and is apparently explained by the fact that in the higher races more attention is paid to the education of the male than the female, and consequently the brain is stimulated to increased growth. . . . It is hardly necessary to point out that quantity is no criterion of quality, and though the brains of many distinguished men have weighed much above the average (that of Cuvier weighed 64oz.), there are abundant examples of equally weighty brains, the possessors of which were not characterised by wits above the common herd. . . . But apart from the mere size of the cranium we have to consider its shape. If a number of skulls be taken and placed on the floor so that we can look down upon them, we will at once realise that they display a great diversity of form, provided always that we are dealing with mixed groups; some are long and narrow, whilst others are broad and rounded. . . . For scientific purposes these differences in shape are recorded by the use of what is termed the cephalic index . . . In practice, the cephalic index is obtained by the following formula: $\frac{\text{Breadth} \times 100}{\text{Length}}$ = cephalic index. The results are grouped as follows:—Skulls with a proportionate width of 80 or over are termed *Brachycephalic*. This group includes, among others, some Mongolians, Burmese, American Indians, and Andamanese. Skulls of which the index lies between 75 and 80 are *Mesaticephalic*, comprise Europeans, Ancient Egyptians, Chinese, Japanese, Polynesians, Bushmen, &c. Whilst skulls with a proportionate width below 75 are *Dolichocephalic*, and are more or less typical of Veddahs, Eskimo, Australians, African Negroes, Kaffirs, Zulus, &c."

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries, put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Oct. 11, and unacknowledged elsewhere:—

Nerps.—E. H. Micklewood.—F. A. M.—Chuck.—J. L.—W. B.—H. F. Y.—W. Ewart Gibson.—S. Elliman.—L. B. Tappenden.—A Fellow of the Royal Astronomical Society.—Dr. R. J. Ryle.

Joseph Jennens, Nelson, N.Z.—The makers inform us that your goods left England a few days ago, and that the delay has been owing to press of business. They say they have written you explaining this.

H. M. Campbell.—Thanks, but hardly sufficiently successful to warrant publication.

Doubtful.—(1) The question has been frequently answered. See the index of Vol. LXVIII. as to rights of patentee. Anyone can make a patented article for the purpose of experiment, but not for beneficial user. (2) An article must not be stamped "patented" unless it is really the subject of a patent.

B. L. S.—Probably we have illustrated every promising rotary engine, but, as you say, "none come to stay." The theory is faulty; the construction is not to blame. Reuleaux, as has been pointed out several times, said: "The irresistible tendency towards the invention of 'rotary' steam-engines has contributed greatly to increase the number of these arrangements. This tendency has given us many useless, or apparently useless, machines, and has been the means of wasting much thought and capital. Would-be inventors have again and again been warned of it, but the warnings do not seem to have had any effect." The "rotary" motion is, on paper, much superior to the reciprocatory; but it is at present only with dynamos that it can be obtained satisfactorily.

F. W. Baker.—All we can do is to offer to illustrate and describe your device. We cannot act as go-between for the benefit of perpetual motion inventors and capitalists. There is another Richmond in the field this week. Has he anticipated you?

G. Paget.—Cannot say who supplies them here, or if they are made for sale. Any ordinary electrician ought to be able to devise a pair for you, however, from the description we gave on p. 155.

D. G. Taylor.—Thanks; we have sent your letter and catalogues on to the writer of the articles.

H. R. Bone.—For the electric engraving machine, see pp. 120, 140, 163, 258, Vol. LXVI. Illustrations in No. 1701, Oct. 29, 1897. See also the indices of other volumes.

Learner, S.G.—Any bookseller can supply you with the works required; but if you are not within reach of a library, you could procure Lukin's "Lathe and its Uses" (Trübner), 16s. As to oil-engines, see recent volumes. Donkin's work, published by Griffin and Co., contains much information. See the articles on "Motor Cycles" in last volume.

L. Panton.—We have sent the photos on to "F.R.A.S." We fear we are unable to reproduce them satisfactorily.

Amongst the timbers of Tasmania, beech, or "myrtle," grows in immense forests, the largest trees having a trunk of 40ft. to the first limb, and a diameter of from 2ft. to 6ft. It is somewhat like the European beech in working, but tougher and rather heavier. It is a capital wood for all inside work, cask-making, tools, floors, and furniture; it wears to a smooth surface, and stands well if cut in the winter. There are two varieties of this timber—viz., the red and the white.

A town in Pennsylvania has an electric supply station, which, until recently, had been driven by a steam plant, the boilers being fired by natural gas. The boilers are now given up, and the gas is used directly in gas-engines, three of 125H P., and one 200H.P. The Westinghouse Company, which has supplied the engines, guarantees the consumption of gas not to exceed 13c.ft. per brake horse-power per hour, as compared with about 52c.ft. on the former system. An air compressor, driven by a small gas-engine, charges air reservoirs placed below the engine-room, which furnish the compressed air for starting the larger gas-engines.

NOTICE TO SUBSCRIBERS.

Home Subscribers receiving their copies direct from the Office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a Pink Wrapper, as an intimation that a fresh remittance is necessary if it is desired to continue their subscription.

Foreign Subscribers will have the Pink Wrapper sent One Month before expiration, in order to give them time to forward fresh remittance before subscription expires.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, post free to any part of the United Kingdom. For the United States, 13s., or 3dol. 25c. gold; to France or Belgium, 13s. or 16f. 50c.; to India, New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-Office Order. Back numbers can also be sent out by the ordinary newspaper post at the rate of 3d. each.

Vols. XXIV., XXX., XXXII., XXXVI., XXXIX., XL., XLII., XLIII., XLIV., XLV., XLVI., XLVIII., L., LI., LII., LIII., LIV., LV., LVI., LVII., LVIII., LIX., LX., LXI., LXII., LXIII., LXIV., LXV., LXVI., LXVII., and LXVIII., bound in cloth, 7s. each. Post free, 7s. 7d.

Indexes to Vol. LI., and to subsequent Vols., except Vols. LIII., LV., LVI., LVII., LIX., LXI., 3d. each, or post free 3½d. Cases for binding 1s. 6d. each.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each post free from the office (except index numbers, which are 3d. each, or post free 3½d.)

ADVERTISEMENT CHARGES.

The Charge for Advertisements in the Columns headed:—

For Exchange.
For Sale.
Wanted.
Addresses.
Situations.

is Sixpence for the first Sixteen Words, and Sixpence for every succeeding Eight or part of Eight, which must be prepaid. No reduction on repeated insertions. Advertisers should state under which heading they wish their announcements to appear.

The address is included as part of the Advertisement and charged for. No displayed Advertisements can appear in above columns. Rates for Displayed Advertisements are as follows:—

For advertisements on inside pages, except page facing leader, for less than a quarter-page; per inch single column—

1	6	13	26	52 insertions.
7s. 0d.	6s. 6d.	6s. 0d.	5s. 6d.	5s. 0d. each.

Per Column.—

1	6	13	26	52 insertions.
£3 0s.	£2 15s.	£2 10s.	£2 5s.	£2 0s. each.

	1	6	13	26	52 insertions.

Per Page	8 8	7 0	6 0	5 5	5 0	each.
Half-page	4 10	3 15	3 10	3 0	2 10	"
Quarter-page	2 10	2 5	2 0	1 15	1 10	"

Back Page, £10 10s. A few dates open during 1899.

ORDINARY ADVERTISEMENTS.

	£ s.
Thirty Words	2 6
Every Additional Eight Words	0 6

Front Page, Five Shillings for the first 40 words, afterwards 9d. per line. Displayed Advertisements, 10s. 6d. per inch. Paragraph Advertisements, One Shilling per line. No Front Page or Paragraph Advertisement inserted for less than Five Shillings.

All Advertisements must be prepaid, and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.'s.

Advertisements *must* reach the Office by 1 p.m. on Wednesday to insure insertion in the following Friday's number.

For the convenience of advertisers, replies to advertisements (except those in the Exchange and Sale Columns) may be addressed to "———," care of the English Mechanic Office, and will be forwarded by post to the advertiser, for an extra fee of Sixpence per insertion over and above the cost of the advertisement.

All Cheques and Post-Office Orders to be made payable to The Strand Newspaper Company, Limited, and all communications respecting Advertisements should be distinctly addressed to:—

THE PUBLISHER.
THE "ENGLISH MECHANIC,"
332, STRAND, LONDON, W.C.

This is necessary, as there are several papers published at the same address, and unless letters are fully directed, it is impossible to tell for which paper they are intended.

The English Mechanic

AND WORLD OF SCIENCE AND ART.

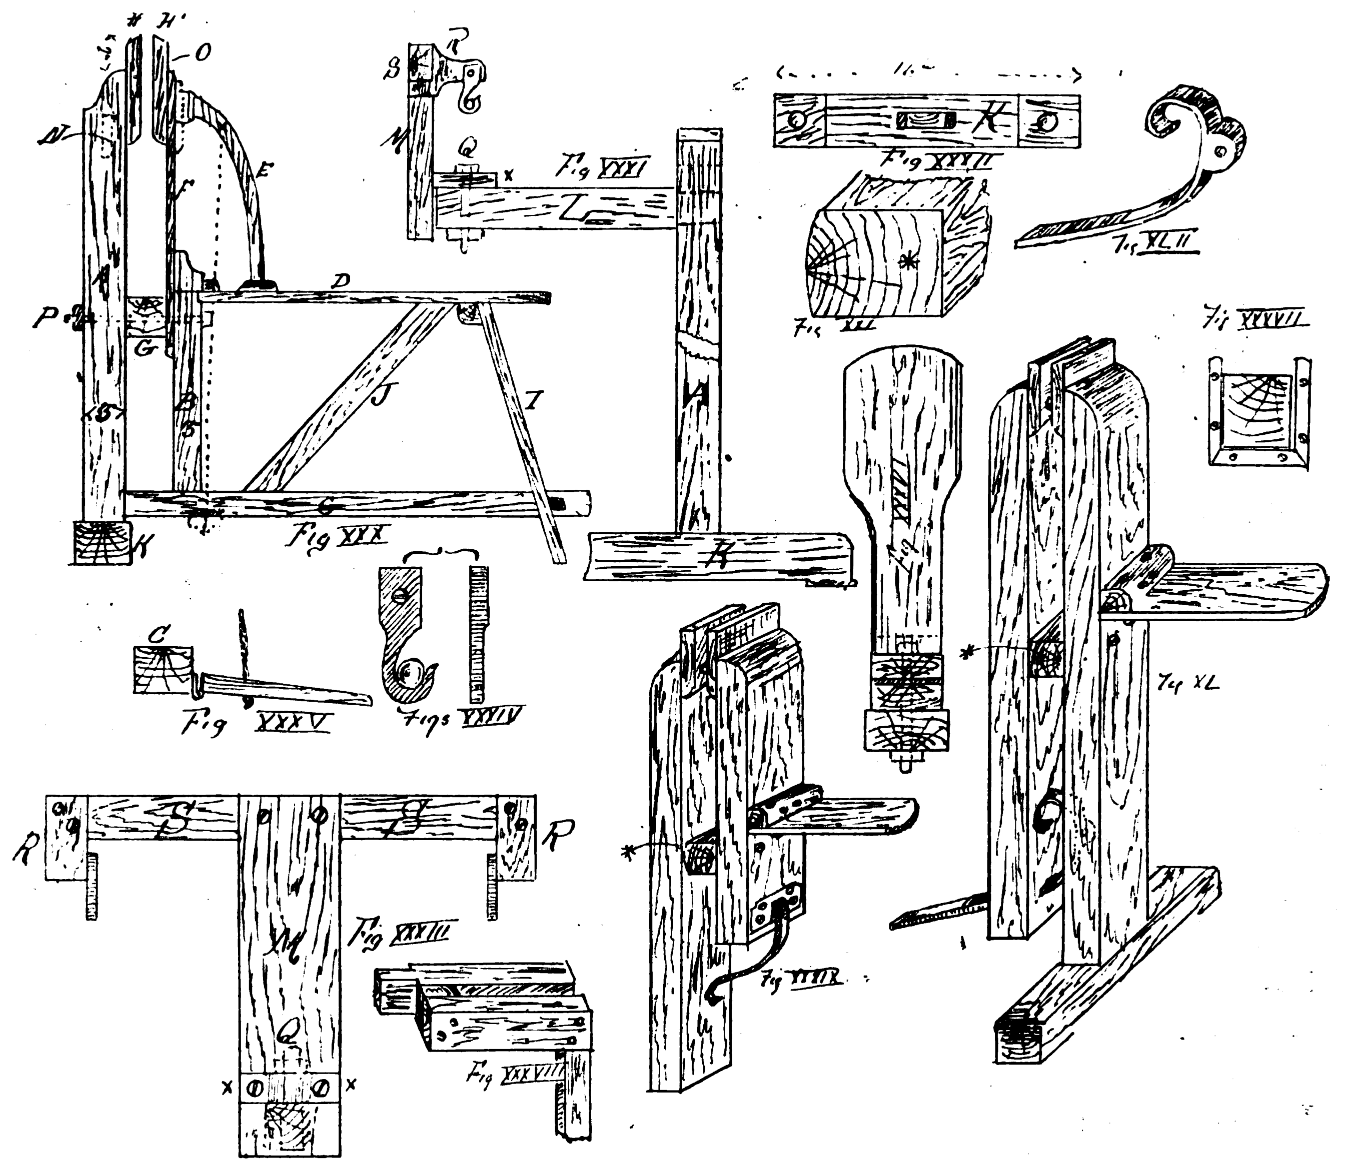
FRIDAY, OCTOBER 20, 1899.

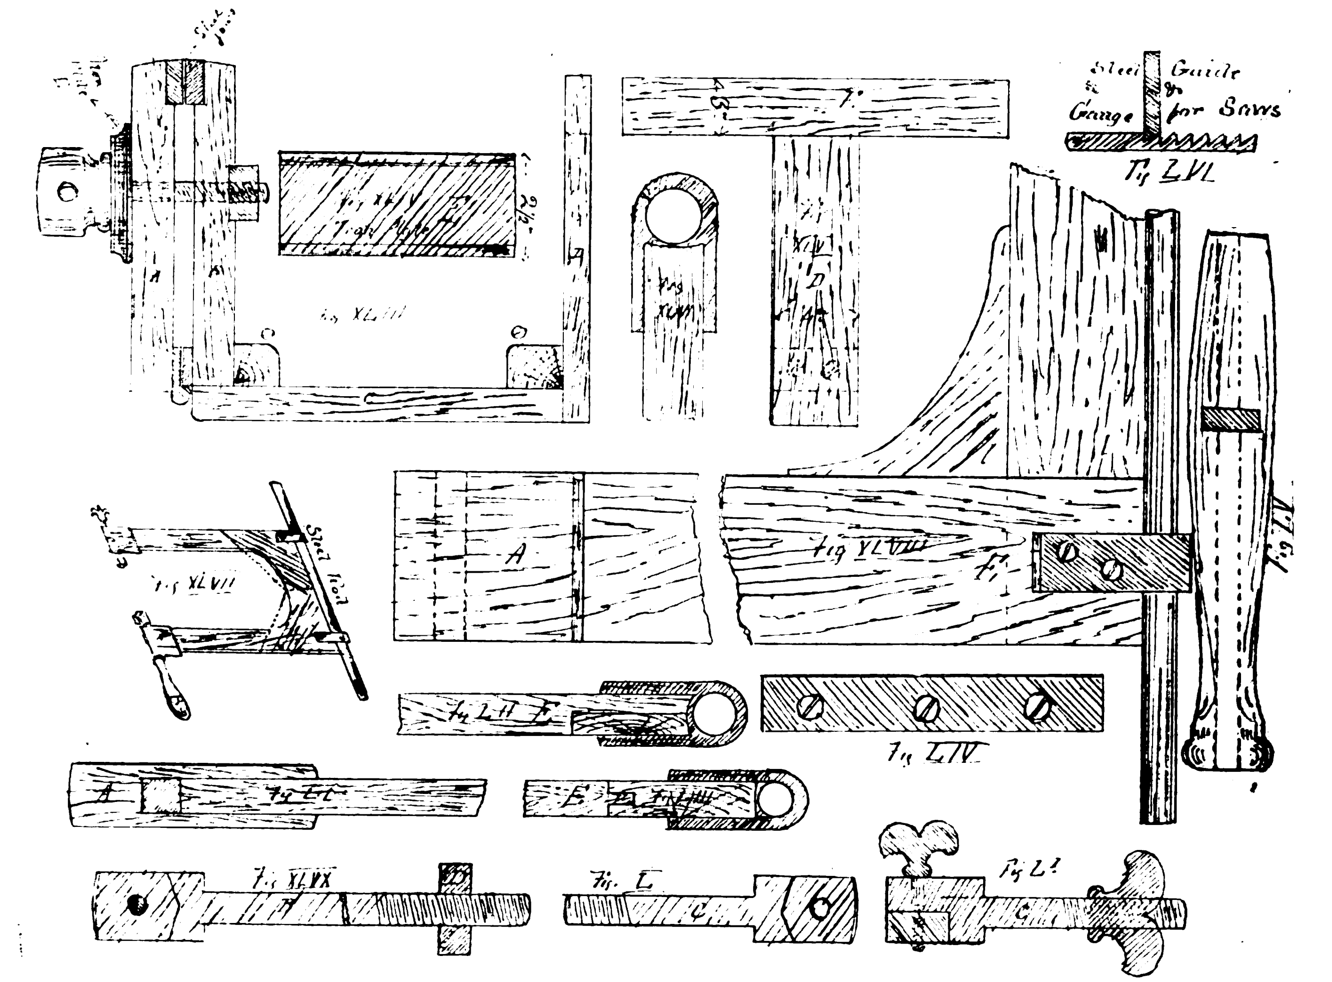
INLAYING.—II.

WE shall require a special appliance, first of all though of simple form. It can be made of deal, pine, or of more expensive material if desired. A slight knowledge of carpentry should produce a serviceable article of deal. It is termed a "donkey." The method of putting together is fully demonstrated in Fig. 30. The drawing shows the parallel frame as behind Fig. 30, the actual position being as at Fig. 31 viewing the standard A from the outside; consequently the guide frame is to the right of the sitter while at work. The standard or back-jaw should be stiff and about 4in. by 3in. in substance. From 30in. to 33in. will be about the average height to top of H H¹. For a shorter seated person much lower will do, even as low as 27in. As a better guide we may assume the position of saw-frame handle to be 3in. or 4in. below the chin. The exact height cannot be given, because we have to work at the medium, not too low for the eyes, causing a strain to them, or too high to tire the arms. An easy method to get at the working height is to seat oneself on an 18in. chair, and then measure off on a rod in front the height best suited to the individual use. The front standard B should be 3in. by 3in., and in height to extend above the seat board D about 3in. or 4in. To the inner face is glued and screwed the spring-jaw E, allowing clearance for the bolt P, central. The space between back-jaw and spring ditto is governed by the thickness of the hardwood clamps H and H¹. If they are of ½in. stuff, and the opening between ¾in., the block G must be 1¾in. thick, the length to be the width of standard A, and the height anything between 3in. and 5in. When bolted together, as shown in sketch, this should be very solid and firm. If the space is 1¾in., then our mortise hole should commence at 1¾in. in the stretcher rail C. The standard is tenoned at the bottom to fit the mortise in the foot. (See Fig. 32.)

Viewing the foot from underneath, the stretcher is tenoned into the standard just above the foot (about 1in.), and the shorter standard is tenoned into the stretcher at the dimensions given, 1¾in. The seat-board and leg are of 1in. stuff. The former is fitted into a shallow groove in short standard and blocked (glued and screwed); the latter splays out, and can be sunk into the seat-board if thought desirable, or only blocked, as per sketch, and glued and screwed firmly. On the leg end of stretcher is cut a long tenon with canted shoulders to follow the splay of the leg. A short mortise hole is cut in the tenon of stretcher, and is for the purpose of receiving a short wedge. The stay-piece J needs only fitting fairly between seat-board and stretcher to be glued and screwed. The lever E can be cut out of a piece of 1in. beech or birch, or a piece of bent shaft can be brought into use. Its use is to tighten or close together the jaws H and H¹ by means of the cords, which being attached to the pedals, the cords are drawn downwards when pressure is put upon the pedal by means of our heels, the toes meanwhile resting on the foot.

A better view is given of pedal and stretcher at Fig. 35. The upper jaws H and H¹ should be of very hard wood, preferably rosewood or Spanish mahogany, and about ½in. thick, and should project as at O, 2in. or thereabouts. Upon the other side, as seen in present view of standard, should be cut the mortise to receive the tenon of base L—about 3in. by 3in. is heavy enough. A bolt-hole is bored in the other end to receive the bolt Q, which passes through bracket X into and through the base L, and is fastened with a nut beneath. Its use is obvious: by slackening the bolt the frame can be twisted into position until the cut made with the saw is truly at right angles to our work. The upright M carries the cross-rail S S, to the ends of which are glued and screwed the wood brackets R R. The gunmetal sockets (see Fig. 34) are bolted to the brackets R R, as per sketch, and are for the purpose of receiving the steel rod of saw-frame (to be explained further on). The arm L should be bolted to the standard, and *not* glued, if to be portable. It remains now to glue and screw the bead pieces on seat-board to retain the lever E in position, no further





fixing being necessary on the seat, but at the top (as dotted) are glued and screwed two slips on to the spring, to prevent any sideslip of lever E, the bottom of which is rounded a trifle. The two circular holes of foot, Fig. 37, are to receive 1in. corks, so that when the donkey is in use it will not have any tendency to slip. Reducing the seat to give knee-room concludes the making of our donkey (see small sketch, Fig. 36 plan). At Fig. 37 is sketched the position or, rather, method of beading the lever F; Fig. 38 shows the double bed, where considerable length is required, as for cutting panels and table tops, and to be so made that the back tenon should fit the mortise hole of standard.

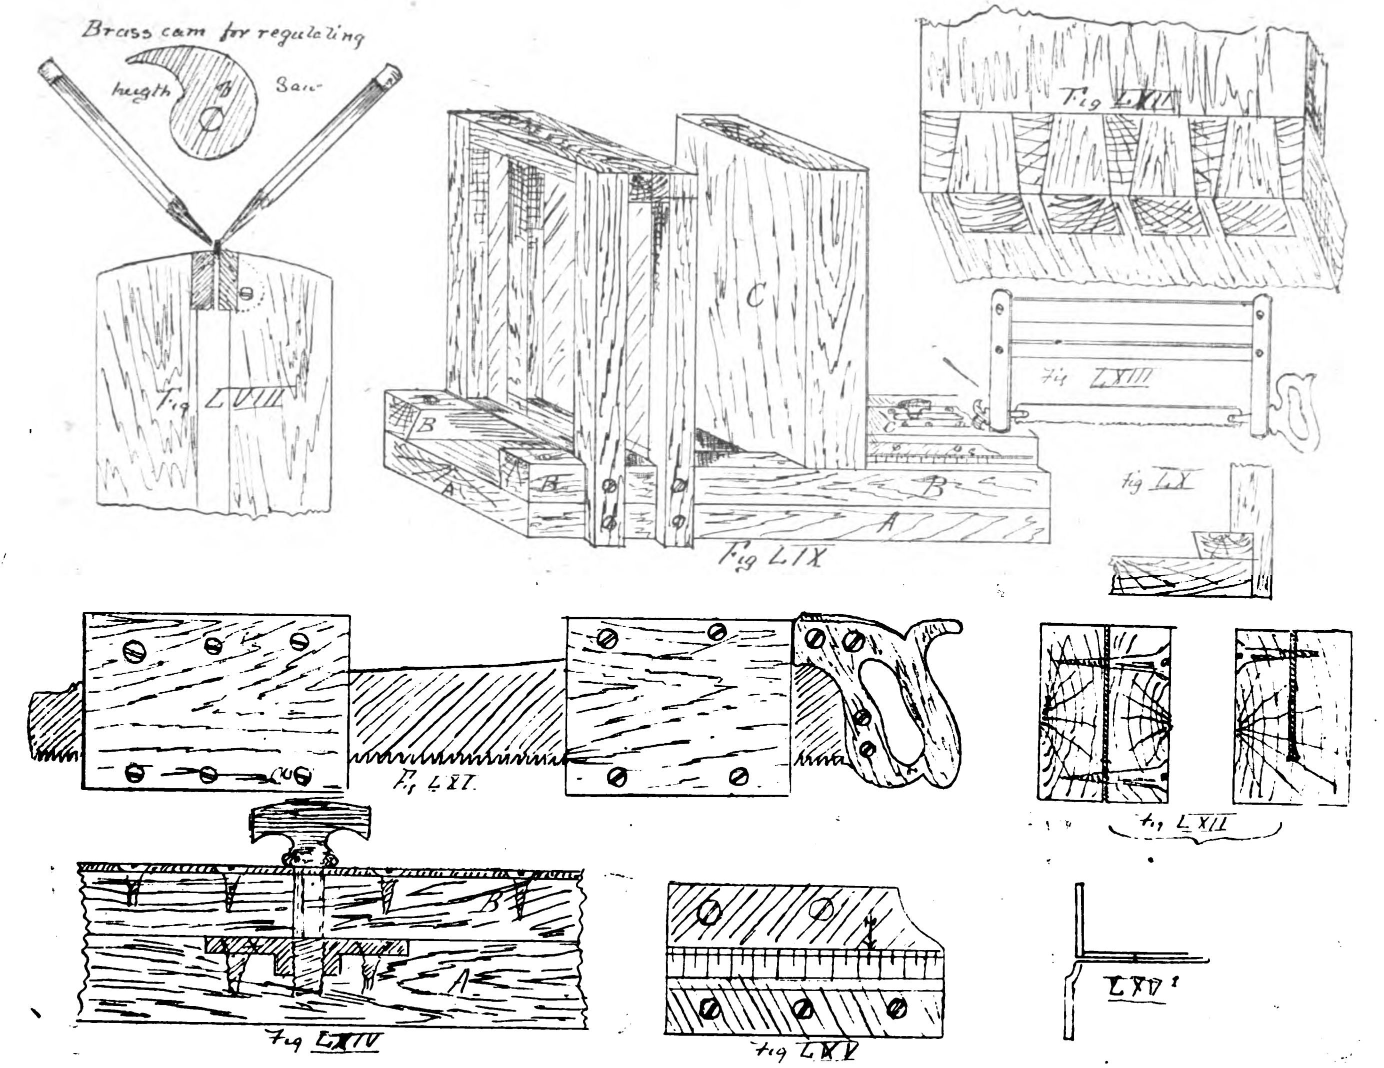
Figs. 39 and 40 show two simple contrivances that are easily fixed or removed at will. A parallel guide frame can be fitted to either, and little skill is required to bring ttem into use as duplicate machines. Fig. 42 shows the scroll iron entire, and in position in Fig. 40. The back standard will require a space cut out of such sufficiency as to permit of the scroll iron turning freely upon its centre. Fig. 41 shows the rounded block used at * in lieu of iron hinge. A good light is requisite. If the donkey is placed so that a ray of light is secured on the work over the left shoulder, no better position will be needed.

The next article required is the saw-frame (see perspective sketch Fig. 47). At Fig. 48 is shown the frame (one angle only with bracket in position). The angle joint can be either lapped (as at Fig 52) or tongued together (as at Fig. 53). The latter method will require a thin slab of wood 1/16in. thick glued both sides, when angle bracket is in position, and is to resist the strain put upon the frame when drawn together to gain the tension of saw necessary for cutting. Each side of the frame has two pieces of thin wood glued, the joint coming about the centre of cross-rail, as dotted in at Fig. 47 (small sketch). The two shoes, as at A, Fig. 51, are made to slip on to the sides of saw-frame, leaving a square hole just the size of the square part of steel clamps, Figs. 49 and 50 (B and C), which, by the way, show how to make them if not procurable at tool-shops. If a saw-frame is preferably purchased, a very good set of fret-cutting appliances are sold at cheap rates; but the frame, being invariably of metal, would require a slight modification to take the steel rod used in conjunction with the parallel guide frame. Upon reference to Figs. 49 and 50, it will be seen that the pinching jaws are so fashioned that the upper jaw, as at C, is solid with the shaft. The V-shaped joint is to prevent the loose jaw from turning round while in the act of tightening the saw-blade. The shorter clamp has a flying nut, and the longer a square nut, as at D, Fig. 49, which should fit tightly in the solid or rounded portion of handle. It follows that the handle is bored the entire length to receive the shaft of clamp. The inner portion of frame at the top can be rounded or hollowed out when the brackets and veneers are dry. The frame should be ¼in. wider at the mouth than at the top end, so that when pressed together they come about equal in width. Fig. 52 shows the lapped joint, with metal straps which secure the steel rod to the frame. As regards the measurements, these are not absolutely fixed sizes; the frame can be 18in. in length by 7in. or 8in. in width, the sliding shoes are about 2in. or 3in. long, glued and screwed as at A, Fig. 51. Fig. 46 gives a method of hollowing out the top of saw-frame to take the steel rod, which, of course, entails a little more labour, but looks well when done.

The vice for making and sharpening our saws can be made next. Two pieces of dry beech or birch, 5in. to 6in. wide, and the back B about 6in. high, the front one 5in. or 5½in., and of 1¼in. substance. The upper part of front and back jaws are rebated to receive two pieces of hardened steel accurately fitted, so that when the jaws are pinched together by means of the saw, the saw-blade is held perfectly rigid the *entire length*. It must be so, otherwise it will be a difficult task to put the necessary set on the saw that is requisite. The base-piece C is of such length as will permit the saw-frame resting on the upright D; about 14in. to 18in. will be ample (from front of jaw A to outside of rest D). The base-piece should be dovetailed at either or both ends to obtain a strong job. Reference to Fig. 62 will help you over the dovetailing. To make a secure and firm job, the blocks as at ⊖ should be glued and screwed; the upright D can be either mortised into or screwed bodily on to the cross-rail E in Fig. 45; the iron plate is to help in getting an even pressure over the front jaw E E. The steel jaw is shown at Fig. 64, and means of fixing by the countersunk holes. Fig. 65 is an enlarged sketch of handle with nut in position.

The means employed to set our saws is shown at Fig. 58. By striking the punch gently we shall be able to throw over slightly each alternate tooth. The aim should be to retain the punch in as near the one angle as possible, so that one tooth does not predominate over another.

The last contrivance is for the purpose of cutting small pieces of rich woods that otherwise would be cast aside. The capacity of our little machine will take in blocks of 2in. or more (according to the length of base) in thickness and of 4in. square measurements; a very useful size when we take into consideration that much of our ornaments will rarely exceed 2in. to 3in. in length. It is shown at Fig. 59. The base A, of 1in. stuff, has screwed and glued to its upper face two runners, dovetailed, as shown at B, glued and screwed. The frames are made of equal size, either by means of lapping or mortising, so that when half the substance is cut, as at Fig. 60, and fixed to both base and runner, a clear space of ⅞in. should be left. The opening space forms a guide for the saw with its long blocks, as at Fig. 61. The blocks are again shown at Fig. 62,



either as a pair screwed together, or one block with the kerf sufficiently deep to admit of fixing tightly by means of the screw shown. A simple saw-frame could be knocked up as shown at Fig. 63, only care must be bestowed to make all of the exact same thickness—viz., ⅞in. The index plates, as at 65, 65¹, should be of brass, when screwed in position, and with the upper plate marked with an index-point or line. The bottom plate is scored in this way: Assuming a block has been glued with a piece of paper intervening, so as not to injure the face of the sliding-carrier C, with the saw in position for cutting, a test cut is taken off the entire face. The saw is raised to clear the block, and the carrier is moved forward that amount, so that when the second cut is taken the substance of a veneer only projects beyond the saw. A mark is then made on the bottom plate, and a plate then has a series of marks of equal space marked on it the whole length.

If the saw is kept in good condition, the result should be a number of thin slices of exact equal thickness. The measurements can be varied to suit the maker. Solidity must be studied, and will prove of sterling value if due care is bestowed on the making. The manner of fixing is on the enlarged drawing Fig. 64. Into the base is sunk a socket-plate *, the T screw passing through a long slot, which is protected with a corresponding brass slot-plate and fixed on top of carrier base, engages in the socket-plate, and thus holds secure, whether the thickness be of one, two, or more veneers in substance. It will be seen then that we are not confined to a given substance, but can cut off, say, 1/16in., ⅛in., 3/16in., or ¼in., and that with precision.

A 28in. blade, with blocks of 8in. in length, will give us a clear run of 10in. to 12in., and plenty of bearing surface on the blocks.

How to make and sharpen the saws for marqueterie cutting will conclude this chapter. Very thin strips of steel ribbon can be purchased at most clockmakers' material warehouses, also the three-square piercing saw-file used to cut the teeth. A length of steel is broken off, long enough to be pinched in the steel jaws when the frame is pressed together. Although the saw-blade is shown having a hole in the end, that only applies to the larger or fret-cutting saws, that are generally purchased ready made. Having the blade ready in the frame, it is lowered down into the vice about half its width. The brass cam, which is fixed at each side of the vice, is to rest the blade on, and should be raised until they permit of only half of the blade projecting, as before stated. If the steel jaws are a good close fit, all along the blade will be securely held; but if, by chance, any portion does not grip, the higher parts must be planed or filed down until a perfect joint is obtained. A steel guide is required, especially by those who have not had any experience in saw-making.

About ¾in. from the end, measuring from clamp at the left hand, make a nick with the saw-file, then cut down, using the guide as a gauge as to width. By placing the guide as shown in Fig. 56, a second cut can be given without encroaching on the first. The same system must be pursued the entire length of saw. The main object should be to have all the teeth of as near equal space as possible, and all of one height. The setting can be done as before explained, by setting over every alternate tooth, working from back and front. If only one tooth should happen to be higher than the rest it will either cause the work to break away or the breaking of the saw.

Assuming all has been plain sailing up till now, it remains to prepare our cutting designs. If one only is wanted, or even two, a tracing can be made; but if several duplicate copies are wanted, then we must resort to a quick and ready method of preparing them. Pounced impressions are generally in vogue, and are prepared by placing the design proper on six or eight thicknesses of good substantial white paper—not necessarily thick, but should be tough and of close texture; the best white lining paper is in general use. Attach them by the four corners with either glue or gum. With a fine needle the whole of the design is pierced, forming a long line of minute holes, with the certainty of the whole six or eight being exactly coincident. Where a sewing-machine can be brought into operation, the task is rendered much easier, and a great deal quicker done. By raising the needle in the needle-bar, so that the needle, when at its lowest, just enters the piece of cork that is inserted in the little hole in the plate. It may be necessary to remove the pressure foot, but that will best be seen if found that the cork remains staple. Anyway, the use of the sewing-machine is of undoubted advantage, and better work can be done than by hand. The cutting up of the pattern and a few other matters will be treated later on, with designs that require separating, as for different-coloured woods, &c.

The object of piercing our patterns is to be able to drive some medium through them that can be fixed permanently upon another plain surface beneath. That most common is a dry, dark-powdered colour (a deep brown) and some resin powdered very fine. By mixing the two—say one-third resin to two-thirds colour will be about the proportion, because the resin, if in excess, will crack and fly off the paper beneath, and will not

require too much heat to cause the resin to melt, which it does when the pounced pattern or, rather, the printed result, is gently warmed, until the melting of the resin tends to combine with the colour, giving us an impression in minute coloured dots closely packed together. If the result has a tendency to wipe off, then a little more resin must be added. If they come off bodily, re-strain the resin until the happy medium is gained. Another plan is to pencil in the design with a lead of softer consistency; by rubbing a clean sheet of paper with an ivory or bone handle an impression will be got, only the reverse way; holding up to the light and tracing on a sheet of glass is also very handy, if, as we said before, only one or two impressions are wanted. There are a few more methods, but scarce worth while touching upon. A little ingenuity displayed by the student will soon overcome many obstacles that are sometimes in the way.

It is just possible at some time or other, a piece of work of great delicacy, requiring a lot of cutting, will demand a better impression; in that case, the dots will have to be connected up either with the pen and ink, or a lead pencil of hard texture. The retouching pencils, used in photographic purposes, will be found of great service.

Another method is to have a water-colour medium at hand to use in conjunction with what has already been cut. The method is thus:—Suppose we have a shield, crest-plate, or other ornament, which is singly, and not convenient to make a special drawing, we lay our piece of cutting on a slab with the colour spread upon the face, and transfer it to the paper on the ground work; the result will be a block impression of exactly the same particulars as piece of cutting. It remains when dry to cut the coloured portion out bodily. If the cutting has been fairly good an exact fit should result. There are one or two points that will require noting, not necessarily here (in case forgotten), but in that part that applies directly to whatever method will be employed other than what has been touched upon above. In cutting all pounced designs, endeavour to turn the work in such a manner as to keep the impression (dots) as intact as possible, otherwise great difficulty will be experienced in following the dotted design.

MILLWRIGHT'S WORK.—XIII.

THERE are several ways of erecting shafting. One is, to set out the position of the intended shafting on the underside of the beams. A chalk line is snapped, making a mark over the intended position of the shaft. Many have been

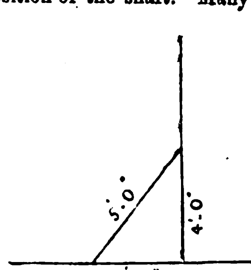


FIG. 78.

set in this manner, but it has the disadvantage that it becomes troublesome when several shafts have to be set up at right angles. Having the lines marked, the positions of the bearings in the vertical plane are obtained by a plumb-line. The device of a long parallel straightedge and level is adopted to secure alignment in the vertical direction, while for testing that in a lateral direction a straining cord will be used. The latter can be pulled taut along the edges of the open brasses, or at a little distance away therefrom, measurement being taken thence to the bearings, or to the shaft if the latter is in place.

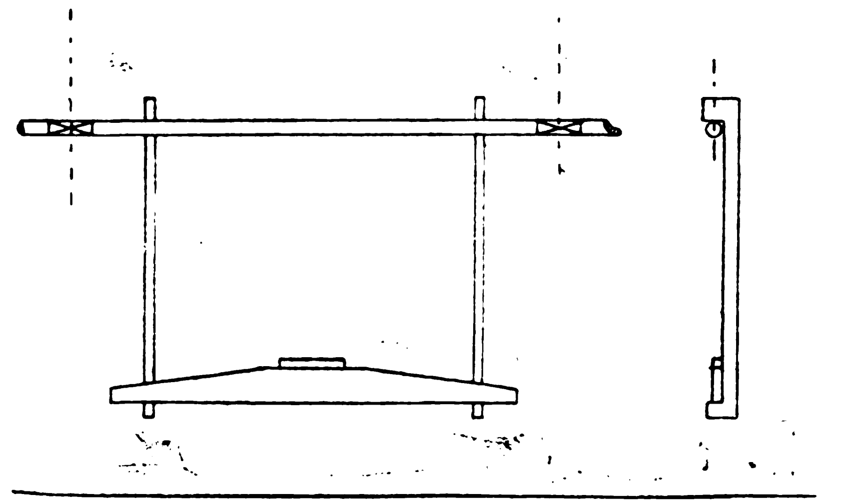

FIG. 80.

When machines already occupy the floor area, the bearings must be put up thus from above. But the best plan when the floor-space is available, as in putting in a plant in a new shop, is to lay down the positions of the shafts on the floor. Their centre lines are marked on the floor with a straining cord. Then this line is crossed at intervals with blocks of wood, which have to be all levelled exactly by means of a level and parallel straightedge. The straightedge being on the floor, set out also the positions of the bearings, and drive a nail in at the positions which correspond with the centre of each bearing. Plumb from these to the beams, and mark a centre on the latter exactly over the centre of each bearing. Make a templet to suit the bearings to be used, having a centre hole in it, and the bolt-holes drilled in the same positions as those in the bearing feet. Lay the templet under the beams with its centre hole over the

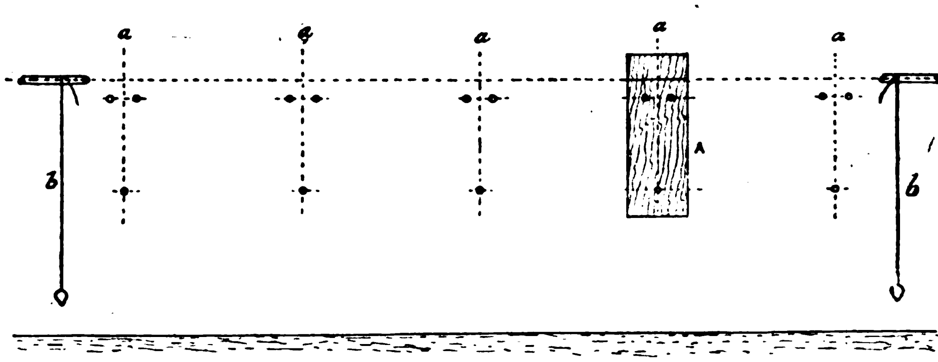

FIG. 81.

traversed from adjacent pairs of blocks, and shavings removed where necessary, until all are level: the result is a basis independent of the inequalities of the floor, from which basis the shaft can be levelled truly. Measurement is taken with a staff directly from the block in the first place to the bottom of the bearings, and afterwards to the under side of the shafting. Lateral adjustment, as before, is obtained with a straining line.

When bearings are fixed by lines laid down on the floor with a strained chalk line snapped carefully, then, as the chalk-marks will become obliterated, the end locations are fixed by driving in small nails. The positions of all shafts should be lined, and marked thus.

To strike lines at right angles with each other, a square is inadmissible because too short to give correct results. The rule "3, 4, 5," for obtaining a triangle is better; strips of wood, a long rule, or a trammel can be used for the purpose. Lay out 3ft. on the base-line, Fig. 78, from the point where one shaft is to intersect the other. Mark off a radius of 4ft. from the starting-point on the base, and 5ft. radius from the 3ft. point, to cut the 4ft. radius. The point of intersection will, when connected to the point of intersection of the shafts, be at right angles with the base-line.

Either of the geometrical methods of obtaining lines at right angles will also be suitable for adoption, provided radii of ample length are taken to eliminate error.

Lines at right angles on a floor to large dimensions may be drawn by a strip of wood having two nails in it. Fig. 79 shows the method. To bisect the line A B in C, set the rod alternately in A and B, and scribe arcs of circles on opposite sides of the line A B, as shown. A line drawn through the intersections will be square with A B.

Having the centre lines of shafting laid down centre plumbed on the beams, and mark off, and bore the bolt-holes. By these the bearings can be bolted in place.

The shafting will now be laid in the bearings, in readiness for final adjustments. The first setting will be that sideways; this will be set with a plumb-line over the floor. The line may either be looped over the shaft—in which case

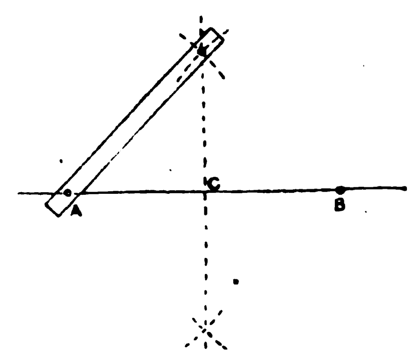

FIG. 79.

the centre of the shaft on the floor will be plumbed—or it may be set by one edge of the shaft, and then a line will have to be snapped on the floor for guidance at a distance of half a shaft diameter away from the centre line.

The vertical adjustment then follows. A couple of rods will be taken and notched to fit over the shafting, and to support a parallel straightedge below, Fig. 80. A start will be made from an end bearing, and each length corrected in succession by means of a level placed on the straightedge.

The risk of working with a spirit-level is that few shop levels are true. Sometimes a surveyor's level is used, and sights taken—a most accurate method, but one the use of which is as yet rather exceptional in millwright's work.

When a spirit-level is used, it should first of all be corrected by planing or filing the bottom if it has become worn by use. Then when employed in service it should be reversed, end for end, for every sight. Some millwrights set the level directly on the shaft; but this is not to be relied on unless the shafts are exceptionally true. If used in this way, the level should be laid upon a long parallel straightedge laid upon the shaft, by which device local inequalities will be merged in an average result. Levels, too, are often attached permanently to a long parallel strip, carefully corrected, which amounts to the same thing as interposing a temporary strip between the level and the work.

To lay down parallel shafts in adjacent shops, in which a dividing wall interferes with ordinary methods of measurement, a doorway may be utilised for the laying down of a line at right angles with the shaft in one room, and this line can then be made a base for obtaining another at right angles with that, and parallel with the one in the other shop. Even though geometrical methods are used, and the measurement made as large as possible, much care is necessary to insure complete parallelism by this method.

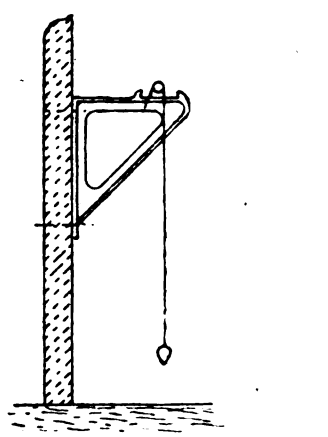

Fig. 82.

One way of erecting shafting is to locate the bearings from one end, working mainly in reference to a strained line, or to a wall or beams, but adjusting each separate bearing from that adjacent. Thus, the general positions of the bearings being indicated, an end one is bolted down, with the cap and top brass removed. The next one is set by a parallel straightedge laid in the hollow of its bottom brass, and extending to the same position in the first one. Lateral adjustment is effected by a straining line pulled taut along one edge of the brasses.

To fit wall-brackets, proceed as follows:—Mark the vertical lines Fig. 81, *a*, on the wall, which correspond with the centres of the brackets. These will be obtained with a plumb-line. The line will be chalked, and, when it is at rest, plumb,—the top and bottom will be held firmly, and the line snapped, transferring the chalk to the wall;—then chalk or scribe a line corresponding with the exact centre of the shaft, using a long straightedge and spirit-level for the purpose. Prepare a templet of wood or sheet-metal A, having holes bored in it to correspond with the holes in the foot of the bracket, and either with the top-edge or a centre line, coincident with the centre of the shafting. A vertical centre-line will be scribed and carried over the ends. The templet is laid against the wall, is set by the centre-lines, and the bolt-holes scribed off on the wall, and bored through. The next stage is bolting up the brackets. These may be all fastened before the shaft bearings are put in place, levelling and checking by the planed faces which receive the feet of the bearings. The latter are presumably bored and faced truly in the feet, and all of the same height. The first bracket is fixed by its holes and bolts, then the one adjacent is adjusted and fixed in reference to the first, using a parallel strip and spirit-level; thence adjustment is made to the third, and so on along the line.

The bearings can be now bolted in place, and the shaft inserted. Before finally inserting the wedge pieces at the ends of the bearing feet within the joggles, the truth of the shaft will be checked The horizontal accuracy will hardly be departed from at all; but a spirit-level can be tried upon it. The principal test, however, is that in the lateral direction. This is checked by dropping plumb lines over the shaft at the extreme ends, *b*, and Fig. 28, and at places intermediate, and sighting along them. Adjustment of the bearings by means of the end joggle-packings can be effected when all the bearings are in line.

J. H.

TRAFALGAR DAY.

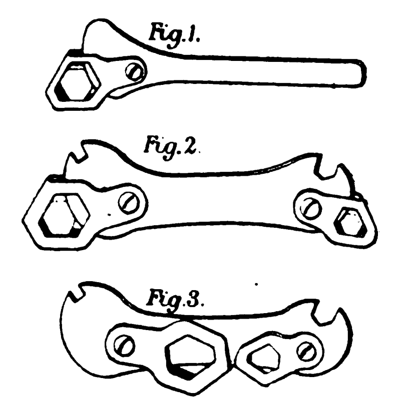
THE design selected by the Navy League for the decoration of the Nelson Column on Trafalgar Day, Oct. 21, is by Mr. George W. Bellgrove, F.R.H.S., outdoor manager of the Junior Army and Navy Stores Floral Department. The decoration combines floral and electrical effects, and bids fair to exceed anything ever attempted in this way before. The steeplejacks, Messrs. J. W. Gray and Co., commenced climbing the column on Friday, Oct. 13, and reached the capital on the following day—a record for this work. The laurel wreathing used is 3ft. wide, and encircles the column four times. The electric lamps, some 300 in number, are arranged to encircle the column between the wreathing. The four tablets—representing the Battles of the Nile, Copenhagen, Trafalgar, and St. Vincent—will be framed with laurel, and electric lamps and festoons of laurel garlanding will be hung from the top of the entablature to the lions' mouths, festooned over the four tablets, and then carried from lion to lion, entirely surrounding the column. Palms and foliage and flowering plants to the value of £1,000 will be grouped on the red baize covering the base.

ARCHITECTURAL PHOTOGRAPHY.

IN a paper read before the Photographic Club Mr. Henry W. Bennett said he would exclude from his lecture all those common or garden advices generally given to the same class of amateur, and confine himself principally to those matters on which differences of opinion might exist amongst experts. He first dwelt on the special difficulties encountered by the architectural photographers. The Scylla of limited space on the one hand, and the Charybdis of a too wide-angle lens on the other, were the two principal dangers encountered, which very frequently led to disaster. The judging of the length of exposure, too, is generally very difficult, and actinometers are of no value, whilst the so-called "intuitive" method of judging the exposure by the appearance of the picture on the ground glass must be altogether discarded. In fact, it is only by experience that one can hope to overcome this difficulty. The best atmospherical conditions will generally be those when light clouds are in the sky, especially when they are low down, as this illumination is best suited to reduce the harsh contrast frequently encountered in this kind of work. As already mentioned, the angle of the lens used is a most important feature, whilst it is generally impossible to work with long-focus lenses; wide-angle lenses frequently give monstrous results. Mr. Bennett found that a 7½in. lens on a whole-plate gave as a rule the best results. It is, however, necessary that the lens cover more than the plate, so as to allow the use of the rising front to its fullest extent. A flat field is, of course, very desirable, and Mr. Bennett is of opinion that the modern anastigmat is in this respect a great improvement on the older lenses. As to the position of the camera, it ought to be about 5ft. to 6ft. from the ground, as a higher elevation might very often be detrimental to the picture. Owing to the long exposures generally necessary, the absolute steadiness of the camera is of great importance, and, in order to secure this, Mr. Bennett recommended a tripod stay, one or two of which are on the market, although they are but seldom bought. In the absence of a proper tripod stay, a large rug will do good service. Mr. Bennett considers the backing of the plate essential. As to development, he invariably begins with what would be generally called a normal developer, and changes the same, as soon as the picture appears, according to requirements. He does not recommend (although this may appear safer at first sight) a diluted developer to begin with, as in this case it would be frequently very difficult to build up density afterwards. With regard to printing, very few negatives of this class can be printed without modifications of some sort. Mr. Bennett recommends covering the negative with tracing-paper; to cut out the highest lights and the deepest shadows with a second layer of tracing-paper. He protested against the word "faking" being applied to an operation of this sort, which is indispensable in order to get an harmonious picture. Touching upon the question of pictorial effect generally, Mr. Bennett was glad to notice that there was a growing tendency to consider this point more and more. Pictorial effect is, however, not inconsistent with sharpness throughout; and he protested strongly against that section of the photographic community which found salvation in "out-of-focus" effects. The suggestion of distance is just as important in a picture of this class as in landscape photography, and an otherwise satisfactory photograph might often be spoilt through its absence. There are photographs in the London exhibitions now which show this defect, and this is all the more regrettable in those cases where it might easily have been avoided, as, for instance, in photographs of church entrances, where the effect could have been obtained by opening the door instead of keeping it shut. Another defect which one frequently meets with (even in photographs that have passed the selection committees of our principal exhibitions) is the want of completeness. To be a success, the picture must be continuous; the principal object must not take too much space, or be only partially shown.

MEREDITH'S ADJUSTABLE SPANNERS.

THE illustrations show some patterns of adjustable spanners patented by Mr. J. E. Meredith, of Birmingham. A flat-section lever is provided at



one end with a metal loop formed of sheet metal folded centrally, thus forming a loop of two thicknesses of metal, which are arranged to embrace between them the end of the flat-section lever. The loop and lever are jointed together by a cross-rivet or pin, so that the loop can turn about the pin in a plane parallel with the face of the lever. The interior shape of the loop is hexagonal, or is a hole with two of its sides making an angle of 60 degrees, so as to suit hexagonal nuts. The end of the lever near which the looped part is jointed is so shaped and curved that when the looped part is turned in such a position as to project from the side of the lever, the latter does not protrude at all (or but very little) across the opening in the loop, and thus the latter will take a large nut, which will be pressed against the two inclined sides of the interior of the loop by the curved end of the lever acting like a cam when the lever is turned to turn the nut, thus securely holding the nut between the two inclined sides of the loop and the curved end of the lever. When the looped part is placed on a smaller nut, and the lever is turned to turn the nut, the curved end of the lever protrudes farther across the opening of the loop, thus diminishing said opening and pressing the nut against the two inclined sides of the loop as before. Thus the opening in the loop will suit various sizes of hexagonal nuts by merely turning the loop to such a position on the lever that the curved end of the lever fits against one of the flat sides of the nut and presses the nut against the two inclined sides of the loop. When the invention is applied to a double-ended spanner, Figs. 2 and 3, the lever is made curved at both ends, and each end is fitted with one of the said looped parts. When the spanner is not in use the looped part, or looped parts, can be turned and folded against the body of the lever so as to embrace the same, and thus occupy but little space.

DEEP PUMPING IN MINES.

DECIMAL twenty-two of a penny, or less than a farthing per ton of water raised, is not a bad performance for deep pumping in colliery operations. This is the record of the Commissioners appointed by Act of Parliament for the public drainage of the South Staffordshire coalfield, in respect of the past year's operations, and the

Commissioners may be fairly congratulated on the issue. The total amount of water raised has been the enormous aggregate of over seventeen million tons, of which more than thirteen and a half millions has been raised by the Commissioners' own engines, and the balance by private pumps and engines under agreement with the central authority. These facts came out at the annual meeting of this unique, and, in many respects, remarkable engineering body a few days ago, when also it was stated that the output of minerals in that portion of the drainage area where the big pumps are at work in the deep levels known as the Tipton district had been 680,000 tons, showing that twenty-five tons of water had been raised for every ton of mineral. Taking the entire coalfield over which the Commissioners operate, the mineral assessed for general drainage rates for the year aggregated somewhat over three and a quarter million tons, and, although the output in the Tipton district alone was an increase of 100,000 tons upon last year, what the pumping authorities want to make the district solvent, and to render the deep-pumping scheme all that can be required, is a further additional output of 200,000 or 300,000 tons, so that the output from the Tipton district alone may reach a million tons annually. With this object, the commissioners are doing all in their power to encourage the Staffordshire mine-owners to redouble productive efforts. A sum of £20,000 has been borrowed to improve the surface works by the laying down of a number of surface-pumps in various parts of the district, to prevent the water from going down into the deep. But for the starting of these light pumps the Commissioners are waiting the commencement of operations by a local electrical supply company, since the engines are to be worked by electric power. When these pumps get to work a considerable economy in the present cost of pumping will, it is believed, be effected. Mechanical and mining engineers alike the world over will wish for this dauntless mining body ultimate complete success.—*The Engineer*.

DETECTION OF BLOOD BY MEANS OF THE GUAIACUM REACTION.*

THE importance of a trustworthy means of identifying blood or blood constituents like hemoglobin, methemoglobin, and hematin in numerous judicial cases, and the value of a combination, on many rather difficult occasions, of the spectroscopic test and of the methods of preparing the characteristic crystals of hemin (as described by Teichmann, Hoppe-Seyler, Brucke, and Preyer), with the "ozone-transferring" action of the colouring matter of blood towards guaiacum, has induced me for many years to pay special attention to the last-named blood-test.

While others have mainly recommended to mix the blood solutions (obtained by extraction of a fresh or old bloodstain with small quantities of water (either alkaline or acidulated with acetic acid) under suitable conditions, first with an alcoholic guaiacum solution, and then with transferable oxygen in the form of hydric peroxide, or of the analogous compound contained in old and isolated turpentine oil (for instance, the liquid of Hunefeld, v. i.), and to observe the formation of the so-called "guaiacum blue," the method which I have proposed aims at the preparation of an intimate and durable mixture of the colouring matter of blood derived from the bloodstain with guaiacum resin. This mixture may be conserved for an indefinite time as a *corpus delicti*, and at every moment strikes a very intense blue colour by contact with one or another of the liquids containing loosely combined oxygen, provided that errors are cautiously avoided by check experiments. The proceeding, wanting but a short explanation in reference to the more explicit description in the paper quoted, chiefly consists in mixing the blood solution, obtained by extraction of bloodstains, with an alcoholic solution of guaiacum resin (or, as it has been lately proposed by O. Dobner, with a similar but weaker solution of guaiaconic acid). It is preferable, in this case, to use a solution of about 5 per cent. of resin instead of the alcoholic guaiacum tincture (1 to 2 per cent.) mentioned by Schonbein as the common reagent, in order to secure an easy secretion of resin in presence of small portions of blood. In this case a milky secretion results of the previously dissolved resin constituents, which, in these conditions, partly attract, fix, and precipitate at the same time the dissolved or suspended colouring matter of blood (either in the state of hemoglobin and methemoglobin or of hematin). In this way a mechanical combination of the secreted resin with the said blood constituents is formed, which process reminds us in some way of the well-known method by which some ferments, like pepsin, are secreted by means of an indifferent precipitate caused in the ferment solution and afterwards extracted. If, then, we separate the precipitated resin (or the above-mentioned constituent acting as reagent) by thoroughly dense filters (especially the newer "hardened filters" of commerce), the hematin compounds are fixed on the surface of the filter in extreme division together with the particles of resin. These filters, when well protected from light and air even during the filtration process and then cautiously dried in the exsiccator, may then be conserved for any length of time. But a small piece of them is wanted, to cause in a few moments an intense blue coloration in a porcelain dish or watch-glass on white paper, after it had been moistened with a little spirit of wine, and then a small quantity of Hunefeld's liquid (mixture of so-called "ozonised" turpentine-oil with alcohol, chloroform, and a little acetic acid) has been added. This process is equally applicable to bloodstains, and to the detection of blood in urine, and other similar objects, and may be used as well for the research of relatively fresh blood as for that of old dry stains, owing to the fact already observed by Schonbein—viz., that the colouring matter of blood altered by exsiccation even in higher temperatures still shows in unimpaired degree the different "ozone-transferring" properties, and even seems to act more intensely in some respects—for instance, towards a mixture of peroxide of hydrogen and cyanine.

Since the publication of this modification in the methods of detection of blood by means of guaiacum, some observations on different points of solubility of the red-coloured blood constituents, especially in dry blood, have taken place, which lead to new propositions concerning a reliable, very short, and direct way for the detection of blood, and therefore may be communicated in this *Journal*, after having been briefly related in the pharmaceutical section of the annual meeting of German naturalists at Brunswick in 1897. By occasion of former studies and experiments on the physical and chemical behaviour of chloryl hydrate, a special solvent power of highly concentrated—that is to say, 65 to 80 per cent.—aqueous solutions of the said compound has been observed, not only for several bodies already known, like starch, but also for very various different substances, like certain resins, colouring matter, stearoptenes, and also albuminous matters, especially the colouring matter of blood. In fact, experience showed that bloodstains which have become dry even for a long time on linen or other similar materials are extracted in a relatively short time by impregnation and contact with a chloral hydrate solution of about 70 per cent. and more thoroughly dissolved than by any other treatment. Even bloodstains many years old may, by this operation—after a somewhat longer contact with the solution—be removed to such a degree that their trace is but hardly discernible on the linen. It may be observed on this occasion that the solution of the blood constituents by aqueous chloral hydrate is much facilitated if the blood spots have been previously wetted with small quantities of concentrated acetic acid. The use of this acid is not only admissible for itself, as the guaiacum-blue is not affected by it, but even offers a certain advantage concerning a reaction of control to be mentioned later on.

Inasmuch as guaiacum resin, as well as the guaiaconic acid, specially concerned in the formation of "guaiacum blue," are both easily soluble in the concentrated chloral hydrate solution, a simple method may be devised for the extraction of bloodstains and the subsequent detection of the colouring matter of blood.

In fact, the guaiacum blood test can be prepared and managed on the simplest terms in this way, that first the coloured spots in question, after moistening with a little acetic acid, are extracted either with a 70 per cent. chloral hydrate solution or directly with a 1 per cent. solution of guaiacum in aqueous chloral hydrate, containing 70 to 75 per cent. of the latter. In regard to the fact that the resin constituents concerned in the subsequent reaction show a marked tendency for spontaneous oxidation—as is sufficiently proved by the well-known change of colour in the air and light—this latter method, on the whole, seems less preferable than the first named, which consists in first extracting the blood by means of chloral solution and then adding to the resulting blood solution about an equal volume of the guaiacum chloral solution. If in this process the bloodstain has been moistened with acetic acid previous to the treatment with chloral hydrate, the addition of guaiacum chloral solution to the chloralic extract of the stain to be tested for blood will permit a control reaction, inasmuch as the casual presence of nitrites (as, for instance, nitrite of ammonia) in the respective stain would at once cause a more or less intense blue colouration of the mixture owing to the decomposition of these salts by the acetic acid, the nitrous acid colouring guaiacum—viz., guaiaconic acid—blue even in high dilutions. Moreover, if the chloral extract of the stain contains only blood, the addition of the brownish-yellow guaiacum chloral solution to the pale red liquid derived from the stain will give a pale brown mixture exceedingly well adapted for a decisive zone reaction indicating the presence of hematin. To this blood guaiacum solution in aqueous chloral hydrate a stratum of the already mentioned turpentine solution of Hunefeld or of an adequate solution of hydric peroxide (the indifference of which towards guaiacum tincture being previously stated) is carefully added without mixing, then an intensely blue and rapidly-increasing zone appears, with extraordinary sensibility, in the place of contact and diffusion of the two solutions, while by sudden mixture a less pure blue colouration of the liquid results. The method may also, in suitable cases, be so modified that the blood solution is first mixed with Hunefeld's liquid and then added to the guaiacum solution. This process can just as well be conducted to obtain a zone reaction or also a capillary reaction.

In cases of extraordinarily small bloodstains, so as to necessitate, in a certain measure, a micro-chemical operation, or where the respective residue of blood has to be tested on its natural place, it is advisable to digest the stain on a flat porcelain dish with strong chloral solution (v. s.), having first moistened with a small drop of acetic acid, and, after an hour's contact, to pour on the digested spot first a corresponding small quantity of guaiacum chloral solution, and then, after having thoroughly mixed, a few drops of the one or other liquid containing the peroxide. With this method also a more or less intense blue coloration is seen to appear on the light-coloured underground. Experience has shown me that even very old bloodstains and exceedingly small parts of such may be identified in this manner, provided a sensible guaiacum chloral solution, prepared with quite fresh resin, and at the same time a liquid of Hunefeld or hydric peroxide solution of right composition and controlled in regard to their activity, are used. A solution of Hunefeld suitable for the purpose may easily be prepared, mixing f. i. 15c.c. of turpentine oil, exposed to light and air for a certain time (but which ought not to change directly blue in the guaiacum tincture), or 15c.c. of a 3 to 5 per cent. hydric peroxide solution, free from acids, with 25c.c. of alcohol, 5c.c. of chloroform, and 1·5c.c. of glacial acetic acid. The zone reaction surpasses the other older methods of testing by special purity of the blue colour resulting from the formation of the so-called "guaiacum blue"; besides that this purer colour is more durable, according to the fact that in the measure of progressive mixation of the active substances of the two layers (hematin as the oxygen-transferring body, hydric peroxide or essential oil as the source of oxygen and guaiaconic acid as the oxidable compound) small quantities of the intensely blue coloured oxidation product are formed gradually. It is true, however, that the "guaiacum blue," especially in the presence of organic reducing agents, is not very stable, inasmuch as this compound, to use an expression of its first investigator, C. F. Schonbein, contains loosely combined, movable and active oxygen in the ozonide state.

The foregoing shows, as it seems, the usefulness of the modified guaiacum blood-test when cautiously applied; on the other hand, it cannot be denied that the reaction is liable to certain misinterpretations, in cases where some other organic or inorganic substances are present, instead of blood. It is scarcely necessary to mention in this place the numerous compounds which, as, for instance, nitrous acid, free chlorine, bromine and iodine, chromic anhydride permanganic acid, peroxide of lead, the ferric and cupric salts, quinone, &c., directly colour blue the guaiacum resin; because first of all, many of these bodies are exempted à priori in the majority of materials submitted to the blood-tests, and secondly, because in their presence the liquid extract of a stain to be tested for blood would at once strike a blue colour when mixed with a little guaiacum tincture before the addition of Hunefeld's peroxide solution. In regard to these facts, the somewhat superficial notice of some text-books—viz., that the guaiacum blood-test is not reliable, "because many substances change guaiacum for themselves," cannot be taken as a warning against the use of the said method, since, certainly, no careful analyst will ever neglect to avoid mistakes by availing himself of the control-reactions indicated in each case! Yet, such substances of inorganic or organic origin, as share the "ozone-transferring" quality with the contents of the blood cells—viz., the colouring matter of blood, might in some single cases lead to a false interpretation of the guaiacum-blue-reaction. Among organic vegetable substances, bodies of the class of ferments may be named, as well as hydrolytic ferments (enzymes in the stricter sense of the word) chiefly so-called oxidising ferments, as they occur in numerous parts of plants, especially in mushrooms and plant seeds, while among animal substances in the first line saliva, extracts of some organs, the contents of white blood cells and pus cells, &c., show analogous properties. These albuminous substances of the character of ferments, existing in vegetable and animal cells, and exerting in a more or less manifest degree a catalytic and at the same time "oxygen-transferring" action towards hydric peroxide, strictly differ from the colouring matter of blood in that the last-named action is cancelled, or at least most strikingly weakened by heating to 100° C., or also by contact

* By Dr. Edw. Schaer, Strasburg Pharmaceutical Institute University.

with diluted hydrocyanic acid. In case the extract of a pretended bloodstain contains such a substance of the class of ferments, instead of ingredients of blood, it will cease to show the guaiacum reaction, even after a shorter digestion at the temperature of the water-bath; and also a control experiment with addition of hydrocyanic acid during the extraction of the stain will give essentially negative results.

However, the avoiding of all possible mistakes becomes rather difficult in such cases, where the presence of even the smallest quantities of ferrous oxide or other ferrous compounds can occur, as, for instance, in the testing of suspected stains on rusty iron materials. If the rust, even in the absence of blood, contains small portions of certain ferrous compounds—viz., ferrous carbonate or other ferrous salts—they could, by extraction, be introduced into the filtered solution, even in case the latter had not taken up any ferric hydrate or basic ferric salt; yet such an extract of a stain, even with the slightest trace of ferrous oxide, would cause the guaiacum-blue reaction after subsequent addition of guaiacum resin and hydric peroxide. A strict distinction of ferrous oxide and of the colouring matter of blood is not very easy in such cases, because the first-named compound manifests, even in the smallest quantities, the same intense "ozone-transferring" power as hemoglobin or hematin, which also contain iron. It will, therefore, form the object of further experiments to find out how the mentioned casual mistaking in the guaiacum-blood reaction may be eliminated. On occasion of such further researches concerning the reaction discussed in this paper, the question would have to be treated whether blood, which, after drying up in slow decomposition on certain materials, like stone, clay, or rough metallic surfaces, and after disappearance of the organic substance by the action of air and water, leaves but rusty spots, can generate in these conditions seizable quantities of ferrous compounds.

The above-described method of extraction of bloodstains with concentrated solutions of chloral hydrate, which, as is well known by this time, are also good solvents for resins, has induced some experiments in order to ascertain whether, by using the process mentioned in the first part of this essay, chloral solutions containing blood and guaiacum may, by precipitation with water and subsequent filtration, give a resinous secretion containing blood constituents, showing the mentioned behaviour and applicable to the guaiacum-blood reaction after any time of conservation. It may here be stated, by the way, that the trials performed in this manner have but led to a moderately satisfactory result, probably because even a diluted chloral solution still acts as a solvent on the resin in a low, but perceivable, degree, and besides, as I am induced to believe, because the colouring matter of blood is less easily precipitated by the secreting resin from a chloral-blood solution than from a chiefly aqueous liquid. But, notwithstanding the loss of material caused in that way, by the use of this method resin-covered filters can be obtained possessing the properties quoted in the beginning of this paper.

Lastly, it may be mentioned that—as it could be expected—the guaiacum blood-test executed with chloral solution is thoroughly applicable to a control-reaction—viz., to the chemical identification of the hemin-crystals, which are of high importance in judicial cases. A specially pure blue colouration is obtained when, instead of the ordinary guaiacum solution of guaiaconic acid in 200 to 500 parts of chloral-solution (v. s.) is used, and the reaction is observed in a glass tube as a zone-reaction. The guaiaconic acid, proposed as a substitute for the natural resin by O. Doebner in his interesting essay on guaiacum resin and "guaiacum-blue," is just as well liable to spontaneous oxidation in light and air with changes of colour; and, according to my observations, its use is more convenient for the described zone-reactions than for experiments in watch-glasses or dishes, where greater surfaces get into action. It is, moreover, obvious that this special experience cannot interfere with the certainly desirable use of the guaiaconic acid, as being the active constituent of the resin, in the numerous other guaiacum reactions. I cannot but feel convinced that the reactions with guaiacum resin have not, in all respects, met with the consideration they deserve, neither in general nor in medical and pharmaceutical chemistry, so I thought it advisable to publish this little contribution to the question in this convenient place.—*American Journal Pharmacy.*

ROLLER BEARINGS.

ROLLER bearings are preferred to ball bearings by many machinists, and one especially adapted for bicycles and machinery has been invented by Mr. St. Louis, of Carmel, Wisconsin, which, it is claimed, besides being cheap in construction, cannot bind or become disarranged. In Fig. 1 the bearing is shown applied to a bicycle, and in sectional side elevation. Concentric tracks are employed, secured to the axle of the bicycle-wheel, between which tracks is a bearing-ring formed or fastened on a cap attached to the hub of the wheel. Two sets of flanged rollers are employed, lying between the bearing-ring and the concentric tracks. The flanges of one set of rollers roll upon the flanges of the other set, the concentric tracks being grooved alongside their bearing-surfaces to receive the flanges, but without contacting with their peripheries. When the axle of the wheel is turned, the sets of rollers, being in contact with the inner and outer surfaces of the rotating bearing-ring, are made to turn in opposite directions, and roll upon the fixed concentric tracks. The flanges, besides separating the rollers, cause them to turn in unison. By arranging the parts in this manner the bearing-ring is placed between two sets of bearing-rollers, thereby forming double bearing-surfaces sustaining the weight equally. The load is directed against the outer set of rollers at the bottom, and bears against the inner set at the top, thus reducing the friction to a minimum, so far as the vertical stress is concerned.

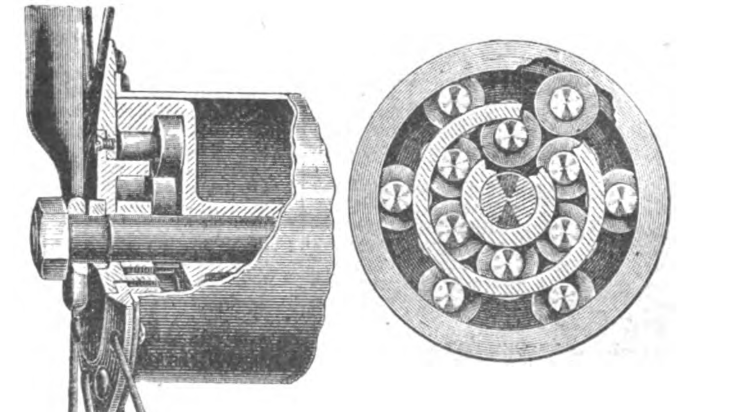


Fig. 1

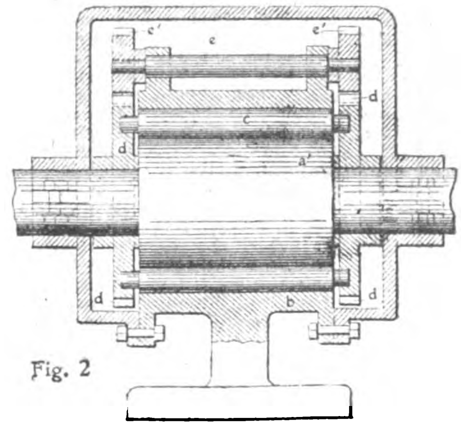

Fig. 2

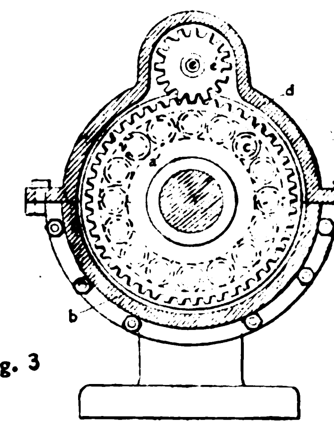

Fig. 3

In Figs. 2 and 3 a roller bearing patented by Mr. Horace Brown, of Reading, Massachusetts, is shown—a device which is said to be practically perfect. In Fig. 2, *a* is the journal, *b* the bearing-surface, and *c c* the rollers, which project over each end of the journal, and their projecting portions are turned to a smaller diameter, and fit so as to turn freely in holes in revolving rings *d* at each end of the journal. The holes in the rings are so spaced as to place the rollers as near as possible to each other round the journal without their actually touching. These several parts being in their correct positions and relations to each other, it is only necessary for the correct working of the system that both rings should revolve in unison, and that neither should ever be the least behind or in advance of the other. The edges of both rings are provided with gear-teeth, and these teeth are in mesh with two pinions *e'*, secured to each end of the shaft *e*. This, of course, insures the uniform rotation of the rings, and the correct action of the entire system. The trunnions on the ends of the rollers are intended to bottom in the holes in the rings, so that the larger shoulders do not touch the inner surfaces of the rings. The outer casing may have an oil-pocket which will carry oil at such a height as to insure lubrication of the roller trunnions and other parts that may require it.

THE FIRE-WALK BY EUROPEANS.

THE fire-walking "test" amongst savage nations has always been a performance that has puzzled experts, and the following notes in the *Athenæum* by Mr. Andrew Lang will be interesting:—Some weeks ago I condensed in the *Athenæum* a description of the Fijian fire-walker (Umu Ti), written by Dr. Hocken, F.L.S. Mr. Tregear, the well-known author of a Maori dictionary, now sends me Col. Gudgeon's account of his own adventure as a fire-walker. In the *Journal* of the Polynesian Society (Vol. II., p. 105) Miss Teuira Henry described the rite as practised at Raiatea in Society group, adding the ritual song chanted, and a photograph (not published) of the performance. In No. 1, Vol. VIII., p. 58 (March, 1899), of the *Journal*, Col. Gudgeon, British resident at Rarotonga, late a judge in the native Land Court, and an accomplished student of the Maori speech, records his own experience. A Raiatea man, young, but of the fire-walking clan, officiated. (This clan is analogous to that of the fire-walking Hirpi of Mount Soracte.) The date was January 20, 1899. As usual, a large fire had been blazing on a foundation of stones; the burning logs were hooked out, and at 2 p.m. Col. Gudgeon found the glowing stones ready for the ceremony. The officiating Raiatea man pointed out to his native pupil that two stones were not hot, they having been taken from a *marae* or sacred place. Nothing was done by way of magic except that the Raiatean spoke a few words (not reported), while he and his *tauira*, or pupil, thrice struck the edge of the oven with witch branches of the *ti* (Dracæna). "Then they walked slowly and deliberately over the two fathoms of hot stones." The pupil handed his branch to Mr. Goodwin (on whose land the performance took place) and said, "I give my *mana* over to you: lead your friends across." The word *mana* means a kind of "magnetic" or magical force which individuals are supposed to possess in differing proportions. Mr. Gladstone had plenty of *mana* from a non-Polynesian point of view. So, in a more absolutely Polynesian sense, had D. D. Home, the "medium." Perhaps "power" is the best English equivalent for *mana*.

Col. Gudgeon, before these performances, had asked that the glowing stones "should be levelled down a bit," as his feet "were naturally tender," and so the stones were "levelled flat." In walking across three white men accompanied him—Dr. W. Craig, Dr. George Craig, and Mr. Goodwin. Col. Gudgeon "got across unscathed." He says:—

"I knew quite well I was walking on red-hot stones, and could feel the heat, yet I was not burned. I felt something resembling slight electric shocks, both at the time and afterwards, but that is all."

As to the heat, the oven is made for the purpose of cooking the *ti*, which is put in after the rite. Half an hour after that performance a green branch

thrown into the oven blazed in a quarter of a minute. The *ti* (*teste* Col. Gudgeon, who ate his share) was well cooked. He walked "with deliberation," and "the very tender skin of my feet was not even hardened by the fire." He offers no explanatory hypothesis. The ceremony is not now practised in New Zealand; but when Col. Gudgeon's paper was read to some old chiefs of the Urewera tribe they said that their ancestors could also perform the ceremony.

In this case (1) no preparation of any kind was applied to the feet; (2) they were not hardened by walking unshod; (3) no abnormal psychical condition was involved. Three stock explanations were therefore put out of court. I have none to offer; but the facts appear to illustrate the mediæval ordeal, as well as certain other curious phenomena handed down from of old.

THE ACTION OF HEAT ON INDIA-RUBBER.

FROM more than one point of view, a consideration of the alteration which indiarubber, both pure and vulcanised, undergoes on exposure to temperature above the normal, is of interest and importance, for not only are some of the statements on this head to be found in textbooks erroneous and misleading, but practical questions of great import are involved in the use of indiarubber valves, hose-pipes, &c., in connection with high-pressure steam. An apology, therefore, is hardly needed for referring at some length to the subject in order to correct some misapprehension arising from failure on the part of certain authors to interpret properly the results of experiments, even though the matter may not, perhaps, be of so much importance to the general engineer as to the rubber manufacturer, or to the compiler of textbooks on physics. Without saying more by way of introduction, but to dive at once *in medias res*, the following statement appears in one of the books just referred to:— "Indiarubber, unlike the great majority of substances, contracts when it is heated." Now this, in itself, does not represent the whole truth, for an important word is left out — viz., "stretched," because, indeed, rubber in a normal condition expands on heating, and it is only when it has been subjected to tension that it acts in the opposite manner. We are not suggesting that there is anything new in this announcement, for, of course, there is not; but there is plenty of evidence to the effect that the facts of the case are not clearly grasped by many of those who have had a good deal to do with rubber, to say nothing of those whose general acquaintance with rubber and its manufacture is but superficial. The literature at our disposal in connection with this matter is scanty. About forty years ago Lord Kelvin suggested to Joule that he should examine the curious fact that indiarubber, when stretched, gave out heat instead of becoming colder, as all metals do. Joule experimented on the subject, and his results are to be found in the *Philosophical Magazine* for 1857. We have also the well-known experiment described by Tyndall in his "Heat a Mode of Motion," in which it is shown that a tube of vulcanised rubber, stretched to three times its length, contracts considerably when it is heated. The experiment is simplicity itself, and depends entirely for its result on stretched rubber being used, and it is the overlooking of this detail that has given rise to the statement to which we have just made an objection.

It is generally known that sound Pará rubber is very elastic. This is easily seen by cutting a strip from the raw rubber in the crude state in which it arrives in this country, and pulling it out; moreover, the thread produced will remain in the elongated condition for any length of time, provided the temperature is not raised. If such a thread, however, to be exposed to heat, even to that of the hand, it will be observed to instantly curl up and resume its original dimensions. If, now, heat be again applied, it may be observed to expand, not to any great extent, but still perceptibly. In connection with making experiments of this sort, it is most important that the condition of the rubber experimented on be fully known. Perhaps the best-known form of pure manufactured unvulcanised rubber that comes in the way of workers in a physical laboratory, is the fine cut or spread sheet, to use the technical terms applied to them: and we may point out that most of this sheet is to a greater or less degree under tension. This is due, in the one case, to the action of the machine which cuts the sheets from the solid block of rubber; it follows, therefore, from what we have already said, that such sheet rubber, if heated, will contract—a proceeding which it is easy to see might lead to false deductions. This action is well-known to the manufacturers of goods from cut sheet rubber, and they will take care to get the rubber in a normal condition before cutting it up. To do this, they simply expose it for a certain length of time on a steam-chest, though the term "shrinking," which is usually applied to the process, is not a particularly happy one. The writer being somewhat sceptical as to the amount of shrinkage which resulted, made some careful experiments, the result of which showed that there was a decided gain in superficies, this arising at the cost of the thickness. With regard to spread sheet, that is, sheet rubber which is made by dissolving the rubber in naphtha and then spreading the mass out on a length of cloth, and allowing the solvent to evaporate; this is also frequently found under tension, the elongation being given in the process of stripping the rubber from the cloth on which it has been spread. If further proof were required of the expansion of rubber under heat, we have it in the overflow which always takes place at the junction of the two sections of the mould when a moulded article is being vulcanised. Conversely, we have the well-known fact of the contraction that takes place when a block of rubber is immersed in a freezing mixture. These facts tell their own tale, and there is no need to bring further argument to bear upon a statement which it is apparent has arisen from a misconception, and which we hardly suppose will find any champion.

Turning now to the chemical aspect of the action of heat on rubber. This is well known to be injurious, and if the heat [temperature] is at all high, or if the time of exposure be long, the rubber is quickly destroyed. That the action is some form of oxidation is taken for granted, though there is plenty of room for research on the matter. Rubber cannot be heated above 240° Fahr. without decomposition setting in, and even if this is not at once visible it shows itself in a few days' time or on exposure to air and light. That pure rubber is hardened by cold and softened by heat is, of course, well known, and, as far as the engineer is concerned, pure rubber hardly comes under his cognisance, the vulcanised rubber being always used by him. Now, in observing the action of heat on vulcanised rubber, the important factor of the sulphur has to be considered. The free sulphur, which is always present in mechanical rubber goods, is liable to oxidation into that destructive body, sulphuric acid, and this acts injuriously upon the rubber when it is heated, hence it is difficult to apportion the blame properly in cases of decay. In practice the destruction of vulcanised rubber by heat, notably in the case of packings for steam joints, must be attributed to over-vulcanisation, due to an excess of sulphur. It would be better if such goods were made without this excess of free sulphur; and, no doubt, the low limit of sulphur stipulated for in our Admiralty contracts has been fixed with the object of avoiding the injurious action of an excess of this element. The higher the temperature to which the rubber is exposed, the more injurious will be the action of the free sulphur, and as the tendency of the day is to use steam of higher and higher pressure, this defect in the rubber joint-rings, &c., is likely to be more and more serious. At the same time, it must be confessed that there is a tendency to expect too much from rubber. The manufacturer is always getting complaints as to failure of hose, as engineers seem to think that there is no limit to what rubber should be able to do. Take, for instance, the modern practice of heating railway carriages by steam from the engine; complaints are rife that the rubber does not last long. Well, it is difficult to see how it should do, especially as the steam from the engine is not regularly passed through a reducing valve. The convenience of rubber hose as regards bending gives it a great superiority over flexible copper piping for this purpose, though the latter has now had an extended trial. Probably rubber will continue in use, but those who buy it must be prepared to find that it has only a limited life. Various modifications of rubber hose have been introduced of late years to meet the demand for a reliable high-pressure steam article, but the modification of the old rubber hose consists chiefly in introducing other bodies to replace the rubber. This is the only course, indeed, in which success is to be looked for, until the long-sought-for elixir, which is to preserve rubber against the ravages of heat, has been found.

The temperatures to which vulcanised rubber is exposed in practice do not reach that of destructive distillation, a chemical reaction which converts the solid hydrocarbon into a number of isomeric liquid hydrocarbons. This distillation process cannot be said to have any practical interest, for though these oils have been, at one time and another, used in small quantities for certain purposes, they have now in all cases been superseded by something cheaper. It has been mentioned that vulcanised rubber is less susceptible to heat than is pure rubber, though it would not be superfluous to add "properly" as a qualifying term; for if the rubber be not properly vulcanised, that is neither underdone nor overdone, its ability to stand heat is much reduced. It is not always easy to hit the proper mark, and though it is not difficult for a buyer of rubber goods to see whether such are under-vulcanised, it is quite the reverse to say with certainty that they are over-vulcanised. There is still a good deal of difference in opinion as to the desirability of giving a short time at a high heat or a long time at a low heat, though for certain classes of goods one process is more suitable than the other. The ordinary temperature is from 265° Fahr. to 280° Fahr., 275° Fahr. being the most usual figure. Quite recently it has been suggested that, instead of using the above temperatures with times of one to three hours, a much higher temperature should be used for a very few minutes. This process has been practically tried on the Continent and seems to have answered expectations; but the goods will require the test of time before the practicability of the method can be considered as demonstrated, and cautious people will wait for this test before attaching too much credence to what they hear on the matter. One thing is quite certain: the work will have to be carried out by reliable workmen, as any excess of time at the temperature proposed must prove fatal to the goods.

It is now a long time since Goodyear observed the change which sheets of rubber undergo on exposure to sunlight, and it cannot be said that his prognostications as to the employment of the sun to effect this change, to which he gave the name of "solarisation," have been fulfilled; in fact, the light of experience tended to show that this change produced by the sun was but the beginning of decay, and any such exposure had better be avoided. This can easily be seen by anyone for himself, if he take two pieces of rubber and expose them to the rays of the noontide sun, after covering one piece with a protective coat of paint or varnish. Seeing that exposure to heat is injurious, the fact that elastic rubber goods give out heat when they are extended is not without some significance as a possible factor in cases of early decay. Take, for instance, elastic thread. If a piece is stretched quickly over the bulb of a delicate thermometer, a rise of temperature may be noted; and if we imagine this alternate heating and cooling action continually taking place, it is quite within the confines of plausible conjecture to imagine that such physical change may be answerable for certain obscure cases of deterioration. At any rate, the point is one which seems worthy of further attention, especially in connection with elastic thread—a substance which in many of its applications very quickly loses its title to the adjective by which alone it is generally known to the public.

It may be further mentioned that, as in the case of the cotton manufacture, atmospheric conditions play a not unimportant part in the rubber manufacture, or, at least, in connection with the preparation of fine sheets from solid blocks of rubber. Where the heat is at all excessive, the rubber becomes too soft to be cut, a fact which certain Continental works, which endeavoured to compete with the English, found out to their cost. The freezing of the blocks of rubber in a mixture of ice and salt was not found a complete panacea, and one English firm of recent years decided to convert the whole workroom into a refrigerating chamber, and thus be able to work without stoppage through any spell of Tropical weather that might arise. It was in connection with this that an investigation into the specific heat of rubber was carried out by Gee and Terry, and the account of their experiments is to be found in the *Transactions* of the Manchester Literary and Philosophical Society for 1891. The figure found as the mean of a number of experiments was ·48, identical with that for turpentine. The knowledge of this constant may not be of the greatest importance, but the reference to it here may be useful, as the figure has not, to the best of the writer's knowledge, yet been included in any table of specific heats.

In conclusion, some apology may be considered due for the lack of continuity with which our subject has been handled; but it was thought, on consideration, that it would prove of more general interest to touch lightly on various issues of practical importance, rather than to attempt any exhaustive treatment of a particular point, or to indulge in the somewhat risky procedure of theorising on a subject of which so little is, as yet, known with certainty.—*Engineering.*

PLATING AND COLOURING ALUMINIUM.

METHODS of plating and colouring aluminium have been recently patented by M. B. Ryan, of Catford, Kent, and, according to specification, the invention relates to the electro-deposition of metals on aluminium and its alloys, and comprises a process for fixing on the surface of the alluminium a metallic amalgam, whereby a base is provided on which the "striking" solution may act positively, the amalgam base so intimately adhering to the surface of the aluminium that, after passing through the striking solutions, the metal may be rolled, drawn, or otherwise handled without causing any separation of the deposited metal film. The process to which the aluminium is subjected, preparatory to the application of the amalgam, is designed to be of such a nature as to preclude the formation of metallic salts between the surface of the article and

the metal deposited thereon. The claims are, the method of treating aluminium and its alloys preparatory to the electro-deposition of the final coating thereon, consisting of the alternate immersion in alkaline and acid solutions as follows: Whale oil soap, muriatic acid, cyanide of potassium, phosphoric acid, and the solution containing a muriatic salt, whereby the surface of the aluminium has fixed thereon an amalgam of mercury before being immersed in an electrically-operated solution. The process of electrically-depositing metals on aluminium and its alloys, consisting in cleaning the surface, then dipping it (1) in a muriatic acid solution having a gravity of substantially 15° Baumé, (2) in a cyanide of potassium solution having a gravity of substantially 20° Baumé, (3) in a phosphoric acid solution having a gravity of substantially 50° Baumé, (4) in a solution containing bichloride of mercury, and (5) then into an alkaline solution, (6) passing it through suitable electrically-operated striking solutions, and from thence (7) into the electrically-operated solutions for depositing thereon the final coating of metal. The process of plating aluminium comprising the following steps—after suitably cleansing it—(1) dipping in muriatic-acid solution having a gravity of substantially 15° Baumé, (2) dipping in cyanide of potassium solution having a gravity of substantially 20° Baumé, (3) dipping in a phosphoric acid solution having a gravity of substantially 50° Baumé, (4) dipping in a solution comprising one gallon of water, 2lb. of salammoniac, and 1oz. of bichloride of mercury, then (5) dipping in an alkaline solution as caustic potash, (6) and thence through the electrically-connected whitening or striking solutions, and then (7) into the electrically-connected solutions containing the metal to be deposited. The method of preparing aluminium for deposition of the final metallic coating thereon consisting in chemically cleaning the surface, applying an amalgam of mercury to the surface, and then passing the metal through electrically-operated and progressively-graded whitening solutions, whereby it is adapted to receive a final electrically-deposited coating of any suitable metal.

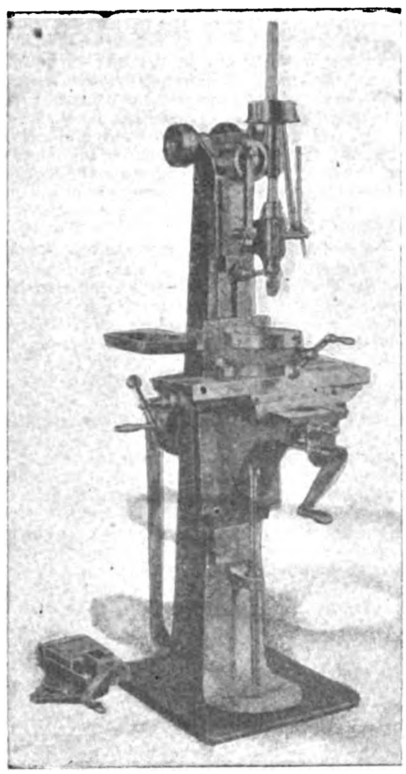

Fig. 1.

spindle is run in a taper bearing at the lower end, 5in. long and 1¼in. and 1⅜in. diameter respectively at the ends. The upper part of the spindle is ⅞in. The spindle has a taper hole with thread at the bottom for drawing in arbors solid. The sleeve for the spindle is operated by rack and pinion, with a movement of 4in., and is instantly clamped by a lever at the side for milling. The sliding-head, which is solid and stiff, has a vertical adjustment of 12in.

To this machine has now been added a slotting attachment, the details of which will be readily understood by reference to Fig. 2. A box 5in. long is attached to a wing of the sliding head; the vertical slide, square jibbed, is 8¼in. long and 3in. wide. The box is adjustable 5° each way from the vertical. The slide has a stroke of 2in., which may be made more or less if necessary. The tool-post takes ½ by ⅝in. steel, and has a spring-actuated relief motion on the up stroke. On the crank-shaft, which runs in an eccentric sleeve, is a bronze worm gear of forty-four teeth, which meshes into a quadruple thread worm of hardened tool steel on the milling spindle, thus giving a movement of 1 to 11. The eccentric sleeve is turned by a short handle at the back end of it for throwing the worm gear in or out of mesh with the worm. The normal speeds of the milling spindle are 300, 600, and 1,200 per minute, and the strokes of the slotter, therefore, 27, 55, and 109 per minute. The tool cuts ½in. in width easily. The back of the column of the machine is open, and can be used as a closet for tools and small parts. A swivel vice is furnished with the machine. It is built by R. M. Clough, Tollond, Conn.—*American Machinist.*

PHOTOGRAPHY APPLIED TO TEXTILE DESIGNS.

In the course of his introductory address at the opening of the twenty-sixth session of the evening classes at the Textile Department of the Yorkshire College, Prof. Beaumont gave an account of the new photographic method of preparing textile designs, invented by Jan Szczepanik, which he had recently been studying in Paris. The object of the appliances, it was explained, was by mechanical means to enlarge the artistic sketches of the designer, and to transfer the design to ruled or point paper, marked with millions of dots arranged in the order proper for the development of the

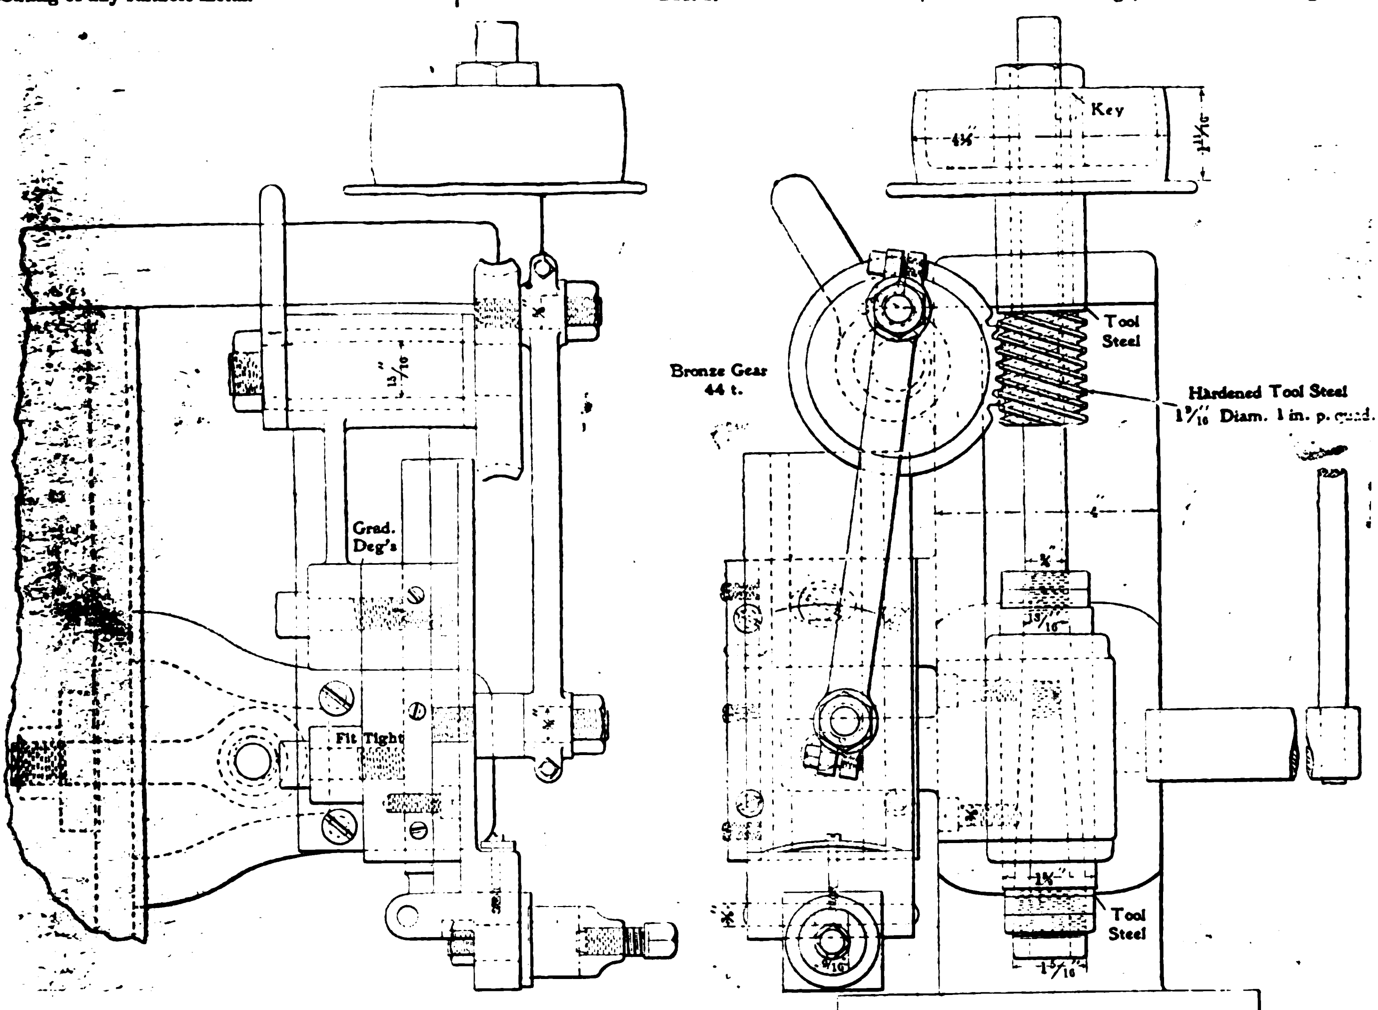

Fig. 2

COMBINED MILLING, DRILLING, AND SLOTTING MACHINE.

The beautiful little machine shown in the half-tone is almost an ideal machine for a fine tool-room, for the little shop where small experimental and model work is done, or for the high-toned amateur machinist. The machine is normally a vertical milling or profiling machine, and therefore also a driller, and as such has been made and sold. The machine, as will be seen, has a table similar to that of a universal milling machine. It is 20in. long, 7in. wide, with ⅜in. T-slot, and a movement lengthwise of 12in., crosswise 6in., and 18in. vertically. Adjustments of a thousandth of an inch are readily obtained by either screw. The milling

pattern in the weaves. Szczepanik printed the design by a photographic process on sensitised paper, and by his method the process of applying the weaves was governed, not by the skill of the artist or his assistants, but by natural laws. Inaccuracies in shading were thus made impossible, for the change in the weave is absolutely identical with the toning of the negative. Designs which now took weeks, and even months, to prepare for the loom, would by this new method be mechanically worked out in a few hours. For instance, in six hours a design in silk tapestry, 176 square centimètres, or about 35sq.in., in extent had been prepared. It might be imagined that this ingenious and novel invention was calculated to have an important influence upon the branches of the weaving industry, relating to the manufacture of all elaborately figured fabrics, especially if the designs worked out photographically were legible for all practical purposes. It was recognised, of course, that there must be limitations to its utility, as there were to all mechanical and automatic appliances. Yet, if it could be employed in accelerating the process of designing large patterns, it should have the serious attention of all who desired the further development of the weaving industries. It was a mistake to think that, if the invention became commercially useful, the sphere of the designer would be considerably restricted. In the long run, innovations of this kind, though at first they might dislocate certain branches of employment, enriched the industry in whose interests they had been introduced. The place of the designer, the brain-worker in textile factories, could not be assailed by inventions of this kind. The chair at the lecture was occupied by Mr. G. H. Nussey, vice-chairman of the Textile Industries Committee, and over 500 manufacturers were present from all parts of the country.

OLDEST ELECTRIC STREET RAILWAY IN EUROPE.

UNITED STATES Consul Hugh Pitcairn, who is stationed at Hamburg, Germany, describes in a late Consular report the electric street railway system of that city, which is the oldest and most complete in Europe. The road was built by the Hamburger Strasseneisenbahn Gesselischaft, with a capital of 21,000,000 marks, or 4,904,000dol. It is of the overhead trolley type, and operates 500 motor-cars and 400 "smoking-cars," or trailers. On account of the narrow streets, poles were prohibited in many places, and the span-wires supporting the conductors are anchored to the houses. For this accommodation the company paid the houseowners the cost price of the poles avoided, 11dol. 20 cents for a one-wire anchor, and 15dol. for a two-wire anchor. Where poles are used they are neat in appearance, and also serve as electric-light posts. Where the street was too narrow for two tracks only one was laid: but to avoid loss of current a double-contact wire was suspended.

The smoking-cars referred to are simply the old horse-cars utilised as trailers, and about every third trolley-car has one of these trailers attached to it. It should be stated that about ten years ago, and before trolley-cars were thought of, the Hamburg Electricity Works obtained a concession from the State for a monopoly in supplying "electric currents" and appliances on the public highways. While this was intended only to apply to electric lights, it was not so specified, and the railway company had to arrange with the old company accordingly, and the latter enlarged its plant so as to supply the current necessary. The Hamburg Electricity Works pays to the State of Hamburg 20 per cent. of its gross income for the monopoly, and the electric works charges the street railway company 12½ pfennigs, or 2·97½ cents per K-W. hour for electric power furnished. The State of Hamburg refunds to the railway company 20 per cent. of this price, leaving the net cost 2·38 cents per K-W. hour.

As compensation for the use of the streets the railway company pays the State 1 pfennig, or 0·238 of a cent for each passenger carried. As the average fare for each person is 2·74 cents, the State receives 8·7 per cent. of the gross income of the railway company. In addition to this, the railway company must keep up the paving between its rails, and for about 12in. outside of each track. The company is not at liberty to fix its own fares, but must forward passengers according to a tariff fixed by the Board of Public Tariff and approved by the Senate. All lines are divided into zones of 2,000 mètres, or 1·24 miles each; for the first two zones, or 2·48 miles, the fare is 2·38 cents; but for each two zones, or parts thereof, it is 1·19 cents, or 10 and 5 pfennigs in the two cases. The tickets issued differ in colour, according to the zones to be travelled over, and in price they run up to 20 pfennigs, or 4·76 cents, for a six-zone distance. The zones are numbered on the sides of the ticket, and the proper number is torn out by the conductor as a check on the distance paid f... as a check on the honesty or carefulness of the conductor, a "controller" is liable to board the car anywhere and count the passengers, and compare them with the list of tickets sold, which the conductor must fill out at the end of every two zones. If there is a discrepancy, the passengers must show their tickets, and the passenger having no ticket must pay again, whether he says he has or not, and the conductor is fined 1 mark, or 24 cents, for the first offence, 3 marks for the second, and for the third offence he is at once discharged.

A peculiar commutation-ticket system is in operation. As many people use the cars several times a day, these tickets are divided into two classes. The first class entitles the holder to use any one line in both directions as many times as he pleases, including Sundays. The second class of commutation-tickets are good for use on all lines, and as often in a day as required. These tickets are good for three to twelve months, and the price is so low that if the ticket is used three times a day the fare for each trip is less than 1 cent. In addition to this, combination-tickets are issued good for one line and part of another line; the tickets for school children cost only ·95 of a cent per trip.

The trolley-cars seat twenty to twenty-eight persons, and four passengers are allowed on the front and five on the back platform. As soon as every place is taken, however, the conductor lowers a sign of "Besetzt," or "occupied," and no one is allowed to come aboard until room is provided by someone leaving the car. This rule is very strictly enforced, and if the police detect a conductor carrying one more than his quota the conductor is fined 3 marks (72 cents), to be deducted from his wages and paid over to the police board. If the controller detects a surplus of passengers, the conductor is fined the same amount, and the money goes to a charity fund divided once a year among needy employés of the company.

SIMPLE TRICKS WITH COINS.

By Ellis Stanyon.

The Balanced Coins.

NO particular dexterity is necessary to perform the trick I am about to describe, although considerable care must be exercised for its successful execution. In effect it is as follows:—The performer having obtained the loan of three pennies (the trick loses half its effect if other than borrowed coins be used, and even then unless care be taken to satisfy the audience that no change is made) places them in a row, lengthways, on the palm of the left hand, inviting inspection of the coins as they lie. He then, with the thumb and third finger of the right hand, grips the edge of the outermost coins, raising all three into a perpendicular position, one on top of the other.

Having seen the trick performed, many will doubtless try their hands at it forthwith, and much amusement will be caused by their repeated failures. It is quite impossible to obtain the balance without a knowledge of the secret. While writing I call to mind various evening parties where I must have been the means of the sweeper reaping a rich harvest on the following morning.

Well, here is "How it's Done." The trick is performed with the actual borrowed coins, but its success depends upon the introduction of a little accessory which must never meet the eyes of the audience. This is a little strip of thin wood ¼in. wide, and in length about $\frac{1}{16}$in. longer than the combined diameter of the three coins. At the commencement this strip of wood is held concealed in the left hand, being gripped between the base of the thumb and the first joint of the middle finger. The three coins are laid carefully along this strip of wood, in which position they may be viewed by the curious with little chance of the secret being discovered. Now, by gripping the edges of the outermost coins together with the ends of the piece of wood, no difficulty will be found in securing the effect described above.

In conclusion, the coins are again laid carefully in the left hand, then tossed, with apparent carelessness, into the right hand, and forthwith handed to the owner for identification. The stick was, of course, "palmed" in the left hand, as already described, in the act of tossing the coins into the right hand.

Florin v. Penny.

Under this heading I shall give a series of sleights simple of execution, forming a most brilliant piece of sleight of hand. Two particular movements are necessary to bring about the desired results, and these I will first explain.

The Finger Palm. — This consists of secretly holding a coin between the first and second joints of the two middle fingers. The feat must be done with equal facility with either hand. With the coin in this position, the fingers being slightly bent, the palm may be shown without hesitation, which at once gives the impression that the hand is perfectly empty. N.B.—To show the hand with the fingers a trifle bent is much more natural than to stick it out stiff like a board.

The Thumb Palm.—This consists of secretly holding a coin between the first and second joints of the thumb. N.B.—A very little practice will make any person tolerably proficient in either of these sleights, which will be found of general utility in connection with coin tricks. It will also be seen that by a very simple movement, difficult to explain on paper, the coin may be readily transferred from the "thumb" to the "finger" palm.

I shall now pass on to the main part of the trick under consideration.

1. Having palmed a penny in the right hand ("thumb palm"), the performer obtains the loan of a florin, which he takes between the fingers and thumb (horizontally) of the left hand (held palm upwards). While showing the florin in this position, he secretly transfers the penny (in the right hand) from the "thumb" to the "finger" palm. He next announces that by merely stroking the florin a wonderful change will take place, and, suiting the action to the word, he passes the fingers of the right hand over the face of the coin. The thumb of the right hand is very naturally brought under the florin, which at the third or fourth repetition of the movement is palmed after the manner described, the penny being left in its place.

2. The change is made once again, but this time the penny in the left hand, instead of being "thumb" palmed, is allowed to fall to the position of "finger palm" *in the left hand;* this, obviously, for purposes of mis-direction. The palms of both hands should now be shown after the manner explained.

3. The change is made a third time. This time the florin is first openly transferred to the right hand. The left then makes the change, the florin being allowed to fall to the position of "finger palm" *in the right hand.* The palms of both hands should once more be shown to be empty.

4. The penny still held between the fingers and thumb of the right hand is now thrown, visibly, several times into the left hand; at the third or fourth time it is "thumb" palmed, the florin being thrown in its stead. The left hand is, of course, closed immediately the coin reaches it. Now while pulling back the sleeve a little, apparently to show there is no deception in that direction, the penny is quietly dropped into the breast pocket of the coat, and upon the left hand being opened the penny will seem to have changed to the florin.

The above series of sleights have been beautifully arranged under cover of natural movements, each one in order being of a more convincing nature than that immediately preceding it; the last forms a veritable *grand finale*, as the closest investigation of the hands and sleeves fails to disclose the whereabouts of the "trickery" coin.

Electrical Coin Transportation.—This is another excellent trick of the non-apparatus order. In effect it is as follows:—A number of borrowed coins are dropped audibly into a tumbler on the table; the tumbler is then covered with a borrowed handkerchief, and placed on one side of the room. A second tumbler, filled in like manner, is next placed on the opposite side of the room. These arrangements completed, the coins are commanded to leave the tumbler in which they were placed, and to appear in the empty one. The command is instantly obeyed, the handkerchiefs are removed, and the transpositions seem to have actually taken place.

The secret lies in the use of a third tumbler placed in readiness on the *servante* (a little shelf at the rear of the table), immediately behind the one on the table. Having obtained the loan of, say, six pennies, the performer holds them between the tips of the fingers and thumb of the left hand; he then appears to take them in the right hand, but really lets them fall into the palm of the left, which is forthwith lowered behind the rear edge of the table. (This pass, which is known as the "tourniquet," is of frequent use in sleight of hand. The noise of the coins as they fall into the left hand is quite natural under the circumstances.)

Still seeming to hold the coins in the right hand, the performer makes a motion as if placing them in the tumbler on the table, at the same moment he drops them into the tumbler on the *servante*. This movement constitutes a perfect illusion. Immediately after the coins strike the hidden tumbler the performer picks up the one from the table, grasping it for obvious reasons near the bottom, and covers it with the handkerchief. When covering the second tumbler, the performer, under cover of the handkerchief, adroitly changes it for the one on the *servante*, which, it will be remembered, contains the coins.—*Hobbies.*

FACING TOOL.

THE following description of a facing-tool was contributed to the *American Machinist*, by Mr. J. H. Gill, instructor in Machine and Tool Construction, University of Minnesota, Minneapolis:—I inclose a sketch of a tool that, for the work for which it was made, is about the simplest that I ever saw. It was used in our machine shop to face the flange of a 16in. cylinder which had been

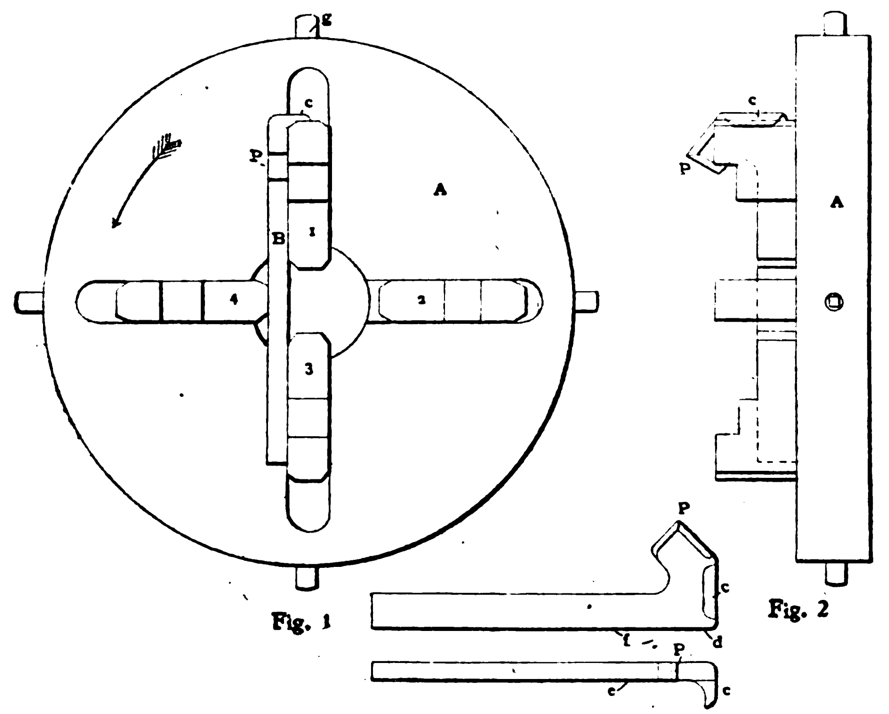

Fig. 1 Fig. 2 Fig. 3

bored with a boring-bar in the usual way. The cylinder only required to be faced on one end. The tool is shown as forged in Fig. 3. The steel (⅝in. by 1¼in. in this case) is bent back on itself, so as to throw the point P back of the heel *d*. The height of P should be a little more than that of the chuck jaw, as seen in Fig. 2. The toe *c* is drawn out and bent over as shown, so as to bear on the end of the chuck jaw. Figs. 1 and 2. The bottom *f* and the side *e*, Fig. 3, should be straight, and also square with each other.

To use the tool, remove the boring-bar and screw the four-jaw independent chuck on the spindle. Place the tool B against the face of the chuck, and also against the jaws 1 and 3, and clamp with jaw 4, Fig. 1. Do not clamp so tightly that the tool cannot slide. Begin at the inside of the flange and feed out by using the chuck-wrench on screw *g* every time it comes round. A star feed could be easily applied, if enough work was to be done to warrant it. Of course, the toe *c* could be on the other end of the tool, and then feed from the outside towards the centre, if desired.

If the tool seats well on the face of the chuck, and bears well on the side of the chuck-jaw, it will be found a very efficient tool, which requires the least fuss to use of anything I have seen for occasional jobs.

PULVERISED FUEL AND SMOKE PREVENTION.

THE attention which is now being directed towards the prevention of smoke in connection with the generation of power by the combustion of coal has awakened renewed interest in the possibilities of pulverised fuel. An exhaustive review of the past and present practice in this branch of engineering appears in a series of articles in the *Schweizerische Bauzeitung*, and in view of the schemes which have recently been discussed, this review is of present value.

Pulverised fuel has been the subject of experiment since 1831, when Henschel, at Cassel, charged air with coal-dust and used it for firing brick-kilns, and for welding and other smithy operations. Nearly 30 years later Pütsch attempted to use coal-dust firing for glass furnaces in England, and in the '70's Crampton made a number of applications of the principle to metallurgical operations.

In America the experiments of McAuley about 1881, and Hathaway in 1886, are well known, and at the present time the experiences of Wegener and others in Germany and elsewhere are attracting considerable attention.

Three fundamental principles are laid down for the successful use of pulverised coal as fuel. (1) The combustion-chamber must be maintained at a high temperature; (2) the powdered fuel must be delivered into the midst of the entering air current, and the intimate admixture of air and fuel delivered into the combustion-chamber in an uninterrupted stream; (3) the particles of coal must be maintained suspended in the air until they are fully consumed.

This last condition is very important, since if the particles fall out of the air current to the bottom of the combustion-chamber, mere coking will take place instead of a complete combustion.

A distinction must be made between powdered fuel and the ordinary coal-dust which is found at every mine. The coal for use in air-blast firing without grates must be finely ground in a mill, so that it will pass a sieve of 900 meshes per square centimètre (0·155sq. in.) and must be entirely free from any larger particles.

The first of the above conditions requires especial consideration in connection with internally-fired boilers, since the proximity of boiler-surface to the burning dust will chill the furnace to an extent sufficient to make the combustion imperfect. In order to avoid this it is necessary to line the furnace with firebrick, which by attaining a high temperature prevents the chilling of the flame, and acts to equalise the temperature. There is no loss of heat by using such a lining, as the firebrick occupies only an intermediate position, and the heat is ultimately transferred to the boiler surface.

The second condition, that of mixing the fuel with air, and feeding the mixture into the combustion space, is the one which must be fulfilled by the construction of the apparatus, and the ingenuity of designers is mainly exerted in this direction.

The third condition is mainly dependent upon the fineness of pulverisation, and it is the cost of grinding the coal to the necessary degree of fineness which usually limits the commercial application of any process.

The Wegener furnace, about which much has been said of late, is an attempt to apply pulverised coal methods similar to those which have been used successfully with low-grade hydrocarbons, and with petroleum refuse, in Russia. In this apparatus the finely-powdered coal is distributed into the incoming air by a revolving sieve, and the mixture is then driven into the combustion-chamber by a steam jet. A firebrick lining permits the high temperature to be maintained, and as this soon becomes white-hot, any slight inequality in the rate of firing does not permit a sudden chilling. The ash which exists in the coal is mostly fused to a liquid slag, which runs out at a tap-hole below, and it is found that there is no greater accumulation of dust in the boiler-flues than occurs with ordinary firing.

A number of tests, conducted with especial regard to smoke-prevention, have been made in Germany, and the details of these do not show any extraordinary evaporative performance, from 8lb. to 9lb. of water per lb. of coal being the average result. The absence of smoke was practically attained in all cases, however, whenever proper precautions were taken to provide sufficient fireclay surface in the combustion-chamber to prevent chilling of the flame. This has been found difficult of accomplishment in the case of water-tube boilers, unless an entirely separate combustion-furnace is constructed, since the presence of the tubes containing water checks the combustion to an extent sufficient to cause smoke to be produced.

The use of pulverised fuel can hardly be recommended on the score of economy, as the evaporation is little if any higher than that obtained by ordinary firing, while at the same time the cost of grinding the coal must be included. When, however, it is imperative that no smoke be produced, it appears that this is one of the various methods by which that desirable result may be attained.—*Engineering Magazine.*

THE MOON AND THE WEATHER.*

A BELIEF that the moon has a potent influence on weather changes is well-nigh universal. The moon's appearance goes through such marked changes each month that it would be very natural to attribute weather changes to these. In this way undoubtedly such sayings as these have arisen:—"The weather won't change till the moon changes," "If the moon lies so that water cannot run out we shall have a drouth," "A wet moon is one upon which a huntsman can hang his horn," &c. Diligent inquiry at one time as to the popular belief regarding this question brought out the view, more persistent than any other, that more rain will occur at the new than at the full moon. Singularly enough, in Connecticut, on Long Island Sound, there does seem to be such a law; but it does not hold in the interior of the country, and a test on the Pacific coast showed, if anything, exactly the opposite. At London, where observations have been made more than a century, a careful computation for the whole period has shown no effect.

If we reflect that the moon is dead and does not have any air, even upon it, that it always shows the same face to the earth, that its changes are simply due to changes in its position as respects the earth and sun, and that its varying appearances are all borrowed, we see how absurd the notion is that the moon does influence our weather. There is, however, another argument that appears quite valid at first sight. If the moon can raise a tide of 60ft. in the ocean, why may it not raise a tremendous tide in the extremely tenuous air, 800 times lighter than water, or a tide of about 48,000ft., and, if so, it seems easy to see that such a commotion would affect our weather enormously. The tide of 60ft. (the highest in the world) is experienced only in the Bay of Fundy and is due to the configuration of the Atlantic coast. In the open Pacific the tide is only a little over one foot. Most careful observations of a lunar atmospheric tide have been made at St. Helena in mid-ocean and have shown a tide a little more than ·001in. Since ordinary weather changes affect the pressure a thousand times as much, we see how extremely insignificant the moon's total effect must be.

There is a common saying, "The full moon has power to drive away clouds," and some computations seem to bear out this idea. If anyone will look to the east as the rising full moon shines through the clouds, he will often see the clouds disappear. There is a natural explanation for this, however, and in no wise dependent upon the moon. A long series of observations have shown a diurnal range in cloudiness with a minimum point or time of least clouds from 6 to 9 p.m.; hence we see that, as the full moon rises and advances in the sky during this period, there will often appear a diminution of clouds. Lord Rosse turned his big reflecting telescope (so big that a tall man walking erect in it could carry a spread umbrella) towards the moon, and found that, if anything, the earth received just a little chilling from the full moon. More recently the bolometer, an instrument which can measure less than one-millionth of a degree of temperature change, has shown that the earth receives a tiny bit of heat from the full moon. The evidence is cumulative and overwhelming that no weather changes can be ascribed to the moon.

Notwithstanding all these facts, repeated attempts have been made to find a supposed effect from the moon on our temperatures. The reasoning is as follows:—If we take the mean temperature for a few days at the time of new and full moon, we would obtain double the effect by subtracting one from the other. The latest effort of this kind has just come to hand, and was made with observations in London and at Blue Hill, Mass. The most remarkable result was that while the full moon seemed to have power to cool the air in London, it had just the reverse effect in this country. In one lunation in this country the full moon was 29° hotter than the new, and in eight lunations, for 88 per cent. of the time, the full moon was markedly warmer than the new. How is it possible to reconcile these extraordinary results with what has been said above? It should be noted that it is absolutely impossible for the moon in one part of its apparent diurnal revolution about the earth to cool the air, and in another part to heat it.

In studying a mass of statistics to obtain a suspected connection between dissimilar phenomena, it is very essential that three principles, at least, be distinctly borne in mind. (1) There should be data enough. "One swallow does not make a summer." (2) It should be possible to show by à priori reasoning how the relationship may exist. By the statistics the ancients were perfectly justified in their teaching that the earth was stationary

* By Prof. H. A. HAZEN, in *Popular Science*, N.Y.

and the whole universe revolved about it. Millions upon millions of such coincidences could not establish the true law. (3) The data must be homogeneous—that is, all sources of modification or variation must first be eliminated before study upon a suspected law or relationship can be begun. Statistics show that more adults die in winter than in summer, and we might conclude, contrary to almost universal testimony, that cold air is inimical to the best health. We find, however, that deaths in winter are due to exposure and not to the cold in itself.

To elucidate these points, let us take the temperature at Boston for 18 lunations, from January, 1898, to June, 1899, and arrange them as was done at Blue Hill—that is, the day of new or full moon shall be the middle of seven days, the mean temperature of which is taken for that lunation; then, subtracting the mean temperature at full moon from that at new, we shall have the figures following. In these a plus sign shows the new moon hotter than the full, and a minus sign the reverse:—

Lunation ..	1	2	3	4	5	6	7	8	9
Difference..	+3	+4	−8	+4	+8	+7	−1	−4	−4
Lunation ..	10	11	12	13	14	15	16	17	18
Difference..	−10	+2	−6	−6	−19	−1	+1	+1	+5

These figures show nine lunations in which new moon was the warmer, and exactly the same number when it was cooler than full. This was to be expected if the moon had no influence on temperature. If, on the other hand, we pick out the eight lunations—namely, from 7 to 14 (the ones used at Blue Hill)—we find that 88 per cent. show the new moon cooler than full. Finally, the greatest difference (−19°) at Boston (−29° at Blue Hill) occurred in February, 1899, and at just the time one of the severest cold waves ever experienced was felt in the eastern United States, and this remarkable cold at the time of new moon was due entirely to this cold wave, and in no manner whatsoever to to the moon. Thousands of statistics of this kind have proved beyond doubt that the moon has no appreciable effect upon terrestrial temperatures.

Just what influence the moon may have upon the electric condition of the atmosphere may be considered in doubt. It is a common belief, on Long Island Sound, that no thunderstorm can come up while the tide ebbs; also there seems good evidence to show that there are more thunderstorms during new than full moon. We may be absolutely certain that the moon has no appreciable effect on any commonly recognised meteorologic element.

DODGES IN ARITHMETIC.

By William Schooling.

THERE are many dodges by means of which calculation may be greatly simplified; some of these have been mentioned in our correspondence columns, and some more may now be given, accompanied by brief explanations.

Some of these dodges only consists in recognising what actually takes place, when the calculation is performed in the ordinary way, and in doing precisely the same thing rapidly instead of slowly. An instance of this may be found in the rule for multiplying two numbers by 11, which, briefly stated, is, "Between the figures write their sum." Thus 52 × 11 = 572; the sum of 5 and 2 is 7, and this number written between the 5 and the 2 gives the answer. If the sum of the two numbers exceeds 9, the unit figure of the sum must be written in the tens place and 1 added to the hundreds: thus, 58 × 11 = 638.

To multiply a number containing any number of figures by 11 it is only necessary to put down the right-hand figure, and then add each figure in turn to the figure immediately on the left of it, being careful to carry over when the addition of any two figures exceeds 9, thus 4,572 × 11 = 50,292; this result is obtained from right to left by first writing down the 2; after which 2 + 7 = 9; then 7 + 5 = 12, put 2 in the hundreds place and carry 1; then 1 + 5 + 4 = 10, put 0 in the thousands place and carry 1; then, finally, 1 + 4 = 5: this is obviously what is done if the sum is done by ordinary multiplication. Thus:—

```
  4572
    11
 -----
  4572
 4572
 -----
 50292
```

When a number has to be multiplied by some multiple of 11 it is very simple to split the multiplier into factors one of which is 11, and having first multiplied by the other factor, then multiply the result by 11 in the way just described: Thus 50,292 × 66 = (50,292 × 6) × 11 = 301,752 × 11 = 3,319,272.

Instantaneous Multiplication.

Another very convenient method of abbreviating work may be employed for multiplying together numbers of two figures each when the tens are the same and the units added together make 10. The rule is to multiply the units together, to obtain the units and tens of the answer, then add 1 to one of the tens, multiply the result by the other ten, and put the product to the left of the first two figures of the answer—thus 72 × 78 = 5,616. This is obtained as follows:—

```
      8 × 2 =  16
(7 + 1) × 7 = 56
             ----
   Answer 5616
```

There is, of course, no need to put down any figures for working out such a result as this, which is obviously the same thing as is done in ordinary multiplication, in which the process is—

```
 8 × 2   =                16
70 × 2 }
70 × 8 } = 70 × 80 =    5600
70 × 70}                ----
                 Answer 5616
```

A somewhat similar method may be employed for multiplying any two numbers that both end in 5. The rule here is to multiply the tens together, add to the result half the sum of the tens, and write 25 to the right of the result—thus, 65 × 45 = 2,925, obtained as follows:—

```
(6 + 4) ÷ 2 + (6 × 4) = 5 + 24 = 29
                          Add    25
                                ----
                       Answer  2925
```

This is only a shorter way of doing what is done by ordinary multiplication, in which the process is—

```
 5 × 5             =    25
60 × 5 } = 50 × 10 =   500
40 × 5 }
60 × 40            =  2400
                      ----
               Answer 2925
```

If the tens added together make an odd number, half the number next smaller than their sum must be odded to the product of the tens, and 75 instead of 25 be written to the right of it. Thus 85 × 35 = 2,975, obtained thus—

```
5 + (8 × 3) = 29
     Add      75
             ----
     Answer 2975
```

A Useful Dodge.

Another dodge of far-reaching utility is the application of the formula $(a + b) \times (a + c) = a(a + b + c) + bc$; thus suppose we want to multiply 402 × 408, we split the figures up so that 400 = a, 2 = b, 8 = c; then we have 400 (400 + 2 + 8) + (2 × 8) = (400 × 410) + (2 × 8) = 164,016.

Such an example as this can easily be worked mentally, and a very little practice enables the rule to be applied very extensively; it will be seen that it is only necessary to choose as the common base, here called "a," some convenient number by which it is easy to multiply, and then to add to one number the difference between the other number and the base; multiply this result by the base, and add the product of the differences between the numbers and the base. Take as another example, 106 × 108 = 11,448; here the base is 100, and we add to the number 106, the difference between the other number and the base; this gives 114, which, multiplied by the base, is 11,400; the product of the differences between the numbers and the base is 8 × 6 = 48, which, added to the previous result, gives 11,448.

The Master and the Schoolboy.

It is equally easy to multiply together two numbers which are less than a common base: the formula is $(a - b) \times (a - c) = a(a - b - c) + bc$. Take, for example, 197 × 192; we split the figures up so that 200 = a, 3 = b, 8 = c; then we have 200 (200 − 3 − 8) + (3 × 8) = (200 × 189) + 24 = 37,824. It will be seen that the rule here is to take the differences between the numbers and the base, subtract their sum from the base, multiply the result by the base, and add the product of the differences between the numbers and the base. An amusing instance of the application of this rule occurred to the writer when he was a little boy at school. Having become familiar with all kinds of dodges in arithmetic he possibly irritated the master by showing off; whereupon the master, thinking to floor him entirely, ordered him to square seven billions minus one. The boy chuckled, for nothing could well be simpler; on the face of it 6,999,999,999,999 × 6,999,999,999,999 looked formidable, but seven billion times seven billions minus seven billion times two with one added at the end was perfectly easy, and almost by the time the words were out of the master's mouth the answer was written down—

48,999,999,999,986,000,000,000,001.

Sad to relate, the answer was not taken seriously. The master considered that the figures were written down at random, and the boy got a licking.

Lightning Calculators.

If anyone wishes to pose as a lightning calculator it is perfectly easy, by attention to a few rules of this kind, to earn a considerable reputation. It should, however, be added that smartness of this kind of thing comes from mere knack and practice, and involves no mathematical ability.

As a final rule we may take the multiplication of two numbers, of which one is above and the other below some convenient base. Here the formula is—

$$(a + b)(a - c) = a(a + b - c) - bc;$$

thus—

$$106 \times 97 = 100(106 - 3) - (6 \times 3) = 10{,}300 - 18 = 10{,}282.$$

Where the two numbers have the same difference from the base, the process is even simpler, since the result is the square of the bas minus the square of the difference, thus—

$$63 \times 57 = 60(63 - 3) - (3 \times 3) = 60^2 - 3^2 = 3{,}591.$$

There are, of course, innumerable other dodges by which calculations may be made very easily and quickly, and anyone who cares to devote a little time to such matters soon finds himself able to see on the spur of the moment some convenient dodge for getting the result of almost any sum that is put before him. The essential thing in rapid calculation is to get out of one's head all notion of rules; and, although rules have been spoken of in this article, it is in no way suggested that the examples here given should be treated as rules of at all the same kind as most of us were plagued with at school. By adherence to rules arithmetic becomes a nuisance, and is a means of hindering calculation rather than helping it.—*Pall Mall Gazette.*

USEFUL AND SCIENTIFIC NOTES.

A useful catalogue of tools and appliances for mechanics, especially for amateurs, has been issued by Messrs. R. Melhuish, Sons, and Co., of Fetter-lane, E.C. It contains illustrations of all sorts of tools, and is more than a mere price list, as it gives directions in many cases as to the best method of using the tools. It is just what many amateurs in the country districts require. There must be very few useful tools which are not illustrated in this catalogue.

The Phenomenon of Pain.—The New York correspondent of the *Lancet* writes: — "Dr. Macdonald, of the United States Bureau of Education, has published the results of experiments in measuring pain by means of a peculiar instrument invented by him, and called a 'temple algometer.' He finds that the sensibility to pain decreases as age increases; the left temple is more sensitive than the right, and in that respect accords with former experiments that the left hand is more sensitive to pain than the right hand. There is reported an increase of obtuseness to pain from ages 10 to 11 years, then a decrease from 11 to 12 years, then an increase from 12 to 13 years; from 13 to 17 years, while the right temple increases in obtuseness to pain, the left temple increases in acuteness. Again, girls in private schools, who are usually of wealthy parents, are much more sensitive to pain than girls in public schools, so that the hardihood which the great majority must experience seems advantageous. University women are more sensitive than washer-women, but no less so than business women."

Platinum Toning.—Under the heading of "Printing Processes," Prof. Valenta contributes a paper to the *Archiv für Wissenschaftliche Photographie*, and in it refers to his experiments with various amines in the preparation of toning baths. Very favourable results were obtained with M-phenyl-endiamine, the formula for which is—

$$C_6H_4 <^{NH_2\ (1)}_{NH_2\ (3)}$$

It is obtained by reduction from m-dinitro-benzole with tin and hydrochloric acid. Although this substance decomposes solutions of gold chloride very quickly, which renders it useless for gold toning, it acts very slowly upon the salts of platinum. A very suitable platinum bath for toning matt papers may be prepared with it, and Brandt and Wilde's Anchor matt celloidin paper has given excellent results. Prof. Valenta recommends the following formula:—Water, 100 parts; potassium chloro-platinite solution (1 : 100), 10 parts; M-phenyl-endiamine solution (1 : 100), 10 parts. The prints should be vigorous, and washed slightly before immersion in the bath. Fix with 10 per cent. hypo. solution, and wash in running water. The tone is an intense black with pure white. If blue-black tones are wanted, the prints, after the first washing, should be slightly toned with a borax bath (water, 100c.c.; borax, 10 grammes; fused acetate of soda, 10 grammes; chloride of gold solution, 40c.c.) They should then be well washed, and toned with the platinum bath. The whites will suffer if the prints are insufficiently washed between the two toning baths.

SCIENTIFIC NEWS.

THE comet (*e*, 1899) announced to have been discovered by M. Giacobini, of Nice, is calculated by Herr J. Möller, of Kiel, to have passed perihelion on Aug. 27, and as it is receding its brightness is little more than half what it was at time of discovery. Its position on Oct. 19, Berlin M.T., was R.A. 16h. 57m. 8s., N. Dec. 0° 46·4'.

The Vienna Academy of Sciences has despatched a strong expedition to India to make observations of the Leonids during Nov. 14-15. The director is Herr Weiss of the Vienna Observatory.

The Lincolnshire County Committee have given their consent to the erection of an observatory in the keep of the old castle at Lincoln. A set of very valuable astronomical instruments has been offered by the executors of the late Canon Cross, of Appleby. The committee promoting the scheme propose to raise the funds for the erection and maintenance of the building by public subscription, and to ask the Lincolnshire County Committee to receive the whole of the property, including the instruments, in trust for the county.

We have occasionally in this country some extraordinary rainstorms; but unless there are some typographical errors in the following note, Boston, Mass., is beaten in record rainfalls only by the stations in India. It is asserted that on Sept. 20 last, the city of Boston, Mass., U.S.A., was visited by a remarkable rainstorm. There are three rain-gauges in the city, separated from two to four miles. They registered respectively 5·21in., 5·40in., and 5·85in., with the following extremes: 5in. in 7h., 4in. in 5h., 3in. in 3h., 2in. in 1h. 40m., and 1in. in 30m. There is probably some error in the reading of the gauges, for an inch of rain means 100 tons per acre.

A meeting was held in Newcastle-on-Tyne last week in support of the scheme for completing the building of the Durham University College of Science, Newcastle, which, it is estimated, will cost £50,000. Earl Grey presided, and said that the Newcastle College of Science stood next to Owens College, Manchester, in point of number of students. The comparison of the cost of work showed that Newcastle averaged £28 per student, as against an average of £51 per student at other colleges in Britain. It was no longer possible to provide accommodation in the existing buildings of the college for the increasing number of students. He appealed to firms on the Tyne, Wear, and Tees to follow the example of Birmingham in contributing from their profits, and hoped that before the year was out £100,000 would be raised. On the motion of Mr. J. W. Spencer, seconded by Alderman W. H. Stephenson, and supported by Sir I. Lowthian Bell, a motion was passed approving the movement to complete the buildings.

The total amount received towards the establishment of the University of Birmingham is £315,400, and at the meeting held recently at Mason University College it was announced that a letter had been received from Mr. Charles Holcroft, of Kingswinford, offering to give £20,000 to the scheme.

At a meeting of the Governors of the University College, Liverpool, it was announced that Mrs. George Holt and her daughter, Miss Emma Holt, had each sent a cheque for £5,000 to be devoted to the purposes of the physical laboratory. These ladies had already subscribed £2,000 to the medical school and £3,000 to the anatomical school.

Lord Farrer, who died last week at the age of eighty, was one of the most distinguished students of economic science the world has known. For many years he was permanent under-secretary to the Board of Trade, which office he resigned in 1866. Three years previous he received a baronetcy, and he was made a peer in 1893. In the early years of the London County Council, Lord Farrer was one of the most prominent and useful members of that body, acting for some years as vice-chairman. Trained as a barrister, he was very precise and clear in his arguments, a trait which was perhaps accentuated by his liking for economic topics. Like Sir Robert Giffen, he took a sanguine view of the future of Free Trade, and was always ready to do battle with anyone who challenged the doctrines of Cobden or the gold standard. His published works include "Free Trade v. Fair Trade," and "Gold Credit v. Prices." He was also the author of a pamphlet on "What is a Bounty," issued quite recently by Messrs. Cassell and Co. His remains were cremated at Woking on Saturday, and the ashes were deposited in the family vault at Brookwood Cemetery.

The death is announced of Dr. Alexander Wallace, of Colchester, in his seventieth year. He was born in Guilford-street, Russell-square, and practised in Colchester as a consulting physician. He was well known as an accomplished botanist and entomologist, and for his work in connection with the silkworm culture (sériciculture). The firm of Wallace and Co. introduced many novelties in lilies, &c., from Japan, Colorado, California, &c., and he was an authority in the horticultural world on the plants which he made his hobby. He wrote several works on his favourite subjects, and probably no one knew more about the plants of Japan than he did.

Dr. Oscar Baumann, who for a number of years held the position of Austro-Hungarian Consul at Zanzibar, and had acquired reputation as an African explorer, is dead in his thirty-fifth year. In 1885 Dr. Baumann, who was a native of Vienna, joined the Austrian Congo expedition, subsequently visiting the island of Fernando Po, the Cameroons, and parts of East Africa. Other expeditions followed, in one of which he fell into the hands of hostile Arabs, and was only released on the payment of a ransom. He was intrusted with the command of an expedition fitted out in 1889 by a German anti-slavery association. In the following year he explored the Usambara, and made preliminary observations for the purpose of tracing a projected railway in that region. In addition to a map of the Congo and numerous contributions to the reports of the Geographical Society of Vienna, Dr. Baumann published three books dealing with his travels and observations in Fernando Po and Usambara, and with the rising in German East Africa. He is credited with the discovery of the real source of the Nile—that is, the Kagera Nile—which, flowing from the Mountains of the Moon, is the largest feeder of the Lake Victoria Nyanza. He discovered the sources of that river in August, 1891.

Chief Justice C. P. Daly, who took much interest in geography and botany, is reported dead at the age of eighty-four. He was president of the American Geographical Society for thirty-six years.

The death is reported of Mr. Hamilton Y. Castner, from the Adirondacks, New York State. Mr. Castner, who was an American citizen, came over to this country about twelve years ago to work his patented process of producing sodium, which enabled aluminium to be produced at a comparatively low price. Perhaps the more important work accomplished by Mr. Castner was the establishment on a manufacturing scale of a process for the electrolytic production of alkali and bleaching-powder from common salt. This discovery of a practical and economic method of applying electricity to the decomposition of common salt is of the highest commercial importance, and Castner's process bids fair to eclipse altogether the purely chemical reactions by which hitherto these two products, so essential to the well-being of modern society, have been obtained. Mr. Castner was also the inventor of a cheap process of making cyanide, which is largely used for the extraction of gold in S. Africa. He was about forty-three years of age.

Vice-Admiral Philip Howard Colomb died on Friday, in his 68th year. He was not only an able commander of a fleet, but did perhaps more than anyone to introduce scientific principles into the work of the navy. He invented the system of "flashing" signals which is now used in all the navies of the world, and was the most distinguished naval critic (from the scientific side) that the century has produced.

Mr. William Ellis Metford, who died on Saturday, was the son of a Somersetshire doctor, began his career as a civil engineer, and was for many years on the staff associated with the late Mr. I. K. Brunel. In 1856 he went out to India to take up an appointment on the East Indian Railway; but his hobby was rifle-shooting, and when he returned to this country he devoted himself to the improvement of the rifle. Experimenting with the old match-rifle and smaller-bored weapons, he brought our military weapon almost up to its present pitch of perfection. Enfield has put on the finishing touch, but Mr. Metford was the discoverer of the essential principle—that of shallow grooves. "It is one of the first essentials in a rifle," writes Major the Hon. T. E. Fremantle, "that the bullet should fill the bore entirely as it passes up it, so that there may be no leakage whatever of the powder gases past it. It was Mr. Metford who discovered that this result could be obtained with much more ease and certainty by using a bullet of hardened lead and keeping the grooves quite shallow; and his method, which had other advantages. . . brought about a revolution in the practice of rifle-makers." Bullets, indeed, were a favourite study of his, and he was the true inventor of the Pritchett bullet. He was an advocate also of the increasing spiral, which, says Major Fremantle, is the only really scientific system, although the practical results following from it are not sufficient to make up for sundry little inconveniences to which it leads. Mr. Metford, like Sir H. Halford, was a highly-skilled mechanic.

The Council of the Institution of Mechanical Engineers will hold monthly general meetings during the session in the Institution House, Storey's Gate, St. James's Park, commencing with the ordinary general meeting on Friday evening, Oct. 27, when the chair will be taken at eight o'clock by the President, Sir William H. White, and the following papers will be read:—"The Incrustation of Pipes at Torquay Waterworks," by Mr. William Ingham, member; and, if time allows, a contribution by Prof. William Ripper, on "A Continuous Mean-Pressure Indicator for Steam-Engines." The dates of the other meetings are Nov. 24, Dec. 8, Jan. 26, annual general meeting Feb. 22, March 22, April 26. The annual dinner will be held on April 25. The graduates' opening meeting will be held on Oct. 30, and continued on the second Monday in each month.

An electrical omnibus with some novel features has recently been put on the streets of Berlin. It carries twenty-one persons, and weighs, with batteries and passengers, 6½ tons, of which the accumulators only weigh 1½ ton. Two motors are used on each axle, making four in all. These are so arranged that the wheels are driven independently. The motors drive by means of single-reduction gearing, with a ratio of 1 to 7·5 on the front wheels, and 1 to 8 on the back. The regulation is effected by means of series-parallel controllers in the usual way. The most important feature of the omnibus, perhaps, is its provision with a collecting bow so that a charge of electricity can be taken from the overhead wires of the tramway company.

According to a news par from America, Signor Marconi's work in connection with the yacht race has had an interesting development. It is stated that he has discovered that wireless telegraphy is facilitated by fog.

With reference to the establishment of sanatoria for the treatment of pulmonary diseases, the council of the National Association for the Prevention of Consumption has passed the following resolution:—"Having understood that apprehension is entertained as to the spread of consumption from sanatoria established for the treatment of this disease, the council desire to express their opinion that there is no danger of communication from any well-conducted hospital for consumption, or from any sanatorium where the open-air treatment for this disease is properly carried out; and, further, that the inhabitants of houses in the immediate neighbourhood of such institutions are perfectly safe from local propagation from this source."

It is stated that the Indian Government has under its consideration a somewhat comprehensive scheme for the establishment of research laboratories in various parts of India, and the appointment of health officers to the charge of them. The present laboratory at Muktesar will, it is understood, be further developed and the staff increased, the establishment becoming the central research laboratory for India, and health officers will be appointed to the charge of laboratories at Calcutta, Madras, Bombay, Agra, and Lahore, the new department of bacteriology manned by officers of the Indian Medical Service.

It is reported that numerous earthquakes have occurred recently in the vicinity of Lake Taupo, North New Zealand—almost daily.

Prof. Riccò has contributed a summary of the seismological report of the commission appointed

by the Italian Government to inquire into earthquakes to the *Rendiconti* of the Accademia dei Lincei. Prof. Riccò states that the earthquake of 1894 may be regarded as an after-shock of the great earthquake of 1783.

According to the American papers, Capt. Watkins has given an explanation of how the *Paris* got on the rocks off the Cornish coast in May last. It appears that one officer entered in the book that Cape La Hogue had been passed at 6.38 p.m., and another officer had recorded the passing of the Casquet Light at 7.35 p.m. The second officer wrote a much bolder hand than the first, and when Capt. Watkins entered the chart room to make his calculations for the run to the Lizard the dim light caused him to misread the 7.35 as the time of passing La Hogue. That mistake put him 18 miles out in his reckoning and sent the ship ashore.

At St. Helen's a glass manufactory has been started in which the old system of blowing is replaced by an automatic arrangement of moulds and blowpipes worked by compressed air. It is said to be capable of turning out 5,000 tumblers a day, lamp chimneys at the rate of 3,000 and 4,000 per day, and larger articles in proportion. Under the old conditions a gang would turn out only about 400 tumblers a day, against 5,000 by the machine process.

Seeing by Wire.—Out of Poland comes the realisation of that dream of inventors, a device for seeing at a distance, for transmitting vision over wires. Jan Szczepanik (pronounced Shtépanik) finds himself to-day, after starving and struggling through many vicissitudes, lifted from the obscurity of a Galician schoolhouse to a fine eminence, with scientists envying him, news-gatherers pursuing him, and capitalists tendering him millions—all at the age of twenty-seven. Almost as far back as he can remember Szczepanik had it in mind to invent a machine for seeing at a distance. Thus, on leaving the school at Crackow, where his aunt had placed him, he told a certain dark-eyed sweetheart, in all seriousness, that it was his intention to invent a machine which would allow him to behold her fair face however distant she might be. The "distance-seer" or "electroscope" is beautifully simple in its underlying principle. It depends on this familiar fact: that any vision or image produced on the retina of the eye is only the blending together of an infinite number of points projected separately from the object, seen by separate rays of light. For instance, when we see a man or a house we really receive in the eye perhaps a million, perhaps ten million, distinct pictures of distinct points on the surface of that man or house. Szczepanik has found a way of separating any image that may be formed, by an ordinary photographic lens, into its component luminous points, of transmitting these points separately, but with enormous rapidity, over wires, and of letting the eye reconstitute them at the other end into the original picture.—*Pearson's.*

Crustaceans for Curative Purposes.—The Rev. Thos. R. R. Stebbing, F.R.S., contributes to the October number of *Knowledge* another of his sparkling articles on the "World of Crustacea." Referring to the Pill-Millipeds, he says:—"In the latter genus the animal faces danger by rolling itself up into a ball. Here, then, was a little shining pill, evidently moulded by Nature for curative purposes. Modern human prejudice rejects the useless remedy with disgust, whereas the better-informed barndoor fowl eats this small game with avidity, not as a medicine, but as a substitute for the unattainable lobster. The Amphipoda have won rather more appreciation as food for man. Thus Risso, in 1826, describing the curious *Phrosina semilunata*, remarks of it that the flesh is tender and well-tasted, and that it might well supply a dish to those who dwell on the shores of the Mediterranean, where it occurs in abundance. Risso does not say that either he himself or anyone else ever had such a dish; but, for all that, an English author subsequently cites him as affirming that 'these crustacea are eaten as a luxury, and, moreover, serve as an article of food to the inhabitants on the shores of the Mediterranean.' It would be a tempting improvement to declare that those inhabitants never eat anything else. It is more to the purpose to repeat the Prince of Monaco's recommendation to the shipwrecked not to neglect the species of Hyperia, which may be obtained from jelly-fishes in the open sea. That the great amphipods, which abound in Arctic waters, would pleasantly satisfy man's appetite on an emergency can scarcely be doubted. The indiscriminating seal swallows them whole, as we know by specimens recovered in good condition from the seal's stomach. The amphipods, in revenge, if they meet with a dead seal, make short work of its carcase—a devouring crowd compelled by the nature of their jaws to savour and enjoy every morsel of the much-divided feast."

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the Editor *of the* English Mechanic, 332, *Strand, W.C.*

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no moe than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

DR. LEWIS SWIFT—STELLAR PARALLAX—ABSOLUTE ZERO OF TEMPERATURE — VISIBILITY OF DISTANT OBJECTS AND THE VAGARIES OF REFRACTION—AN IMPOSSIBLE DIAL —LIGHT IN AN OBSERVATORY— EQUATORIAL ADJUSTMENT— HERTZIAN WAVES — WIRES FOR FINDER — A "GHOSTLY" PHOTOGRAPH — THE GREAT GLOBE AT SWANAGE: THANKS — PAPERS IN THE "PROCEEDINGS" OF THE ROYAL ASTRONOMICAL SOCIETY— BICYCLES AND PERAMBULATORS— LIGHTING THE WIRES OF A TRANSIT INSTRUMENT—THE COMES TO ALDEBARAN — CRATERLETS NEAR TIMOCHARIS.

[42928.]—Astronomers will, I feel convinced, learn with real regret that that veteran observer Dr. Lewis Swift has been compelled practically to relinquish his so-long-continued and valuable work in the discovery of nebulæ and comets, owing to failing eyesight. It is only the other day that I was commenting, half-jocularly, on the number of medals which had been won by the indefatigable head of the Lowe Observatory (letter 42776, p. 88), and now comes the melancholy news that the original discoverer of so many of those celestial objects, to which his observations and attention have been chiefly devoted, will have to bring his protracted researches to a practical end. The proprietor of the Echo Mountain Observatory will be fortunate indeed if he succeeds in finding a worthy successor to the man who has so enriched our knowledge of the more mysterious constituents of the bodies studding the celestial vault.

In an attempt to make a fresh determination of the parallax of 61 Cygni, Dr. Schur, of Göttingen (*Astronomische Nachrichten* No. 3590), during the years 1897, 1898, and 1899 selected four comparison stars, which for our present purpose may be called *a*, *b*, *c*, and *d*, and, on reducing his results, discovered that while *c* and *d* remained sensibly at the same distance from each other, an annual parallactic displacement was visible between *a* and *b*, whence he deduced the parallax of *a* as being = 0·6″, the probable parallax of 61 Cygni itself being, it will be remembered, only some 0·40″ to 0·45″. Prof. Schur intends to reinvestigate the parallax of this star *a*. It will be situated approximately on January 1900 00 in R.A. 20h. 55m. 14s. and in 38° 9′ 28″ North Declination.

The question put by "F. J. G." in letter 42903 (p. 185) is not a very easy one to answer. Everyone must feel, with your correspondent, the difficulty of conceiving what I perhaps may call an abstract zero of temperature; just as it seems impossible to imagine that space can be otherwise than infinite. But, as far as we know, the physical constitution of liquids and gases would be so wholly changed at the temperature of − 461° Fahrenheit, that no comparison could be instituted between the existing condition of things and that which would then obtain; so that anything like a conception of *differential* temperature then would seem impossible. I am no merely blind follower of all Lord Kelvin's hypotheses; but I think that in this particular case his reasoning is sound. Of course, though, we do not know what might happen when we began to approach his theoretical zero.

I should like to say, in connection with reply 96601 on p. 187, that Mr. Garbett considerably underestimates the height of Beachy Head, which is, in reality, 575ft., while the distance from there to Boulogne in a straight line differs but little from 59 miles. Taking the average amount of refraction, then, from Beachy Head to the visible horizon would be 32·83 miles, and from that point to Boulogne 16·77 miles, in all 49·6 miles—a considerable departure from the theoretical distance. But every observer must be familiar with the pranks played by abnormal refraction. Most people must remember Dr. Vince's account of his observation on August 6, 1806, when, at 7 o'clock in the evening, he saw Dover Castle apparently brought over on to the Ramsgate side of the Deal promontory, and, as he adds, the image was so strong that the hill could not be seen through it! So again, more recently (i.e., on May 10, 1868), the dome of the Cathedral at Boulogne and Napoleon's Pillar could be discerned from the Crescent Walk at Dover with the naked eye, while, with an ordinary telescope, the entrance to the port, the lighthouse, the shipping, the surrounding houses, the valley on the hillside of Capecure, and the little fishing village of Portel were all distinctly visible; while, on the eastern side, all the landscape, the lighthouse on Cape Grisnez, and the adjacent windmill, &c., stood out with extraordinary clearness. Meanwhile a locomotive was seen to leave Boulogne and travel towards Calais, the puffs of steam enabling its course to be followed. In connection with refraction, by the bye, the *Comptes Rendus* for July 31 contains an account of a series of investigations and experiments on the displacement of the horizon by refraction, made by M. Forel at the surface of Lake Léman (the Lake of Geneva). The position of the horizon was determined by observations directly and by reflection, and M. Forel found that the angular distance between the true and apparent horizon varied from + 501″ to − 272″, or a total variation of 12′ 53″, a very notable quantity indeed in calculating the Dip, or the like.

Seeing that all that a dial can indicate is the angular distance of the sun (or moon) east or west of the Meridian, "Achernar" (query 96789, p. 192) is making a senseless request even as far as sunrise and sunset are concerned, and *a fortiori*, one impossible to answer in connection with a body whose R.A. and Declination change so rapidly as do those of the moon.

"Oculus" (query 96802, p. 192) should only use one thickness of red silk over the bull's-eye of his lantern. This is what I do when observing delicate objects, and I never have the slightest difficulty in reading books or tables with it.

I am afraid that the next query (96803) put by the same correspondent is unanswerable without a personal inspection of his instrument. There must be an extraordinary and inexplicable amount of unequal wear of the ends of the declination axis to produce an error of 3′ or 4′.

I would recommend to "H. B." (query 96804, p. 192) the same book I advised "Curious" to obtain (in letter 42838) on p. 134—viz., "Light, Visible and Invisible," by Silvanus Thompson, published by Macmillans. It contains an excellent rudimentary account of Hertz's experiments, and will serve as an introduction to the work recommended on p. 213 by Mr. Bottone.

Mr. MacLachlan (query 96810, p. 193) will find fine wire the best material to employ for the cross-wires of his finder. Spider-lines, hairs, &c., are much too fine, and are wholly invisible save on a very bright moonlight night. A tiny drop of solder will fix them to the brass ring.

The Editor of the English Mechanic has very kindly forwarded to me four curious photographs taken by a gentleman named Panton at Levant. They appear at first sight to be ill-defined pictures of the seated statue of a female; but I am informed that they were taken from an image thrown on a blind by the sun's rays passing through a distorting pane of glass, such distortion being caused by a curved line in it of the kind often seen in the old-fashioned blown window-glass. Mr. Panton is under the impression that this may throw some light upon, or possibly help to explain, the very astonishing photograph of the "ghost" of a deceased peer which was so fully discussed in your LXVIIIth volume; but, while thanking him for the suggestion, it seems to me that the totally different circumstances under which the two apparitions became visible form a very serious barrier to the institution of any comparison between them. All the same, the illusion in the case of your correspondent's photographs is a very remarkable one.

Let me thank Mr. Carr-Greg (letter 42921, p. 210) for the information he kindly gives with reference to the Great Globe at Swanage. Since I asked for details concerning it, an old friend and ex-President of the Leeds Astronomical Society has furnished me with particulars concerning this curious and valuable monument. It is just one of those things that appeal to the unlettered man in a vivid fashion, and tend to establish the truth of Horace's dictum that: "Segnius irritant animos demissa per aurem, quam quæ sunt oculis subjecta fidelibus."

If Mr. Wood (letter 42924, p. 211) takes any interest in the papers, contributed to the Royal Astronomical Society, but imagines that they are subjected to no criticism, he is curiously mistaken, and I strongly advise him forthwith to subscribe to the *Observatory*, which gives a monthly detailed report of the society's meetings, and of the discussions which ensue there on the papers read before them. To suppose that the *printed* dicta are "never challenged by the members" is an entire mistake; but, of course, none of the oral criticisms and comments ever appear in the *Monthly Notices*, so that unless any

Fellow sets himself to combat views advanced in one paper by a formal reply in another, the outside public knows, and can know, nothing of what the opinion of either a majority or minority of the Fellows really is on the original thesis.

"Rota" (reply 96759, p. 212) may read with advantage 5 and 6 William IV. c. 50 sec. 72, the Local Government Act, 1888, sec. 85; the Towns Police Clauses Act, and the by-laws framed by the county council of the locality in which he is resident. A perambulator is a wheeled carriage, just as much or as little as a Bath-chair or a bicycle, and if the police proved before me that a perambulator obstructed the pavement in the very smallest degree, I should convict without any hesitation whatever. In strict law the road is the place for perambulators, and not the pavement at all. I must repeat that the police wink at the presence of perambulators on the footpath, but that does not make the practice any more *legal*.

I suspect that the lantern employed by "R. A." (query 96834, p. 214) gives but a very feeble light, because a proper one should afford ample illumination through a hole ⅜in. in diameter in the transit axis. Is there a lens (as there should be) covering the aperture in the pivot? If other means fail, a little disc of bright tin about the size of a threepenny-piece might be soldered on to a wire and placed at an angle of 45° in front of the object-glass. This might be lighted from the side, so that the light would be transmitted by the objective simultaneously with that from the star. By the bye, I suppose that the diagonal reflector in the middle of the telescope tube is all right, and that its reflecting surface is intact?

In reply to query 96860 (p. 215), I can find no measurement or estimation of the magnitude of the *comes* to Aldebaran later than that given in the last edition (1894) of Webb's "Celestial Objects," where it is described as being of the 11·2 mag. This *ought* to be glimpsed without difficulty with 3in., or even 2¾in. of aperture, on a moonless night—if Aldebaran itself were hidden. The distance of the twin star in 1877·9 was, according to Burnham, 113·9″. As α Tauri itself has considerable proper motion, this distance is increasing. I have not myself measured this star for x years, and it is for obvious reasons not very favourably placed at this time of year.

In redemption of the promise I made to "R. P." (in letter 42896, p. 184), I examined the lunar formation Timocharis on the night of the 13th inst. The sun was rather more than sufficiently high upon it; but I saw, of course, without the slightest difficulty, the small crater to the N.W. which both Elger and Neison describe and figure, and a corresponding one at nearly double the distance to the S.E. of it. Nothing whatever, though, was discernible in the shape of a craterlet either due W. or S.W. of Timocharis. Is "R. P.'s" lantern-slide properly orientated?

A Fellow of the Royal Astronomical Society.

ON THE OBSERVATION OF THE INTERIOR PLANETS, WHEN NEAR SUPERIOR CONJUNCTION, WITH COMMON TELESCOPES.

[42929.]—It is usual for telescopic observers to regard the period of superior conjunction as a sort of close time for Mercury and Venus. At, or near, this time it is taken for granted that even equatorially-mounted instruments cannot be used to any good purpose, and that instruments not so mounted cannot be used at all.

Now I think that this diversion of telescopic endeavour from the study of these planets during this period is too absolute, and that perhaps more might be attempted with advantage. And, first, as to the possible value of observations made about the time of superior conjunction.

Apart from the consideration, which, perhaps, may be more curious than practical, that these planets when seen (as with good instruments they may be) within a degree or two of the sun's limb, are shining through the corona, and may possibly have something to teach us about it, there is an important practical fact. Schiaparelli has obtained his best views of Mercury when that planet has been near to superior conjunction. "The defect in diameter," he remarks, "is compensated by the possibility of seeing nearly all the disc, which, under these circumstances, is more strongly illuminated."

Moreover, the observation of the interior planets at the time of superior conjunction need not be left entirely to the users of equatorials. The recent occurrence of a superior conjunction may even be regarded as a blessing in disguise for the telescopist who wishes to pick up Mercury or Venus in the daytime with an altazimuth-mounted instrument. The method by which this end may be sometimes accomplished shortly after superior conjunction might be called "the method of the trap," since it simply consists in setting an optical pitfall in the path of a planet. It requires no apparatus but a clock or watch. It is suitable to any kind of telescope, and requires neither circles nor a meridian landmark. In my own case the instrument used is an achromatic of 2$\frac{1}{10}$in. aperture on the ordinary tripod table stand, and it is used from the window-ledge of a top window in a town house overlooking neighbouring chimneys. The only requisites for success are (1) a telescope which will remain pointed where it is placed without the tube dropping down, as it generally does in cheap telescopes; (2) a clear sky—the deep blue line between solid-looking cumulus cloud is good; (3) a declination in the case of the planet not very widely differing from that of the sun. Nothing more is needed but to be handy in managing the telescope, to have care and patience, and a little good luck. *Experto crede.*

On September 28 a study of the *Companion to the Observatory* and of a celestial globe showed that Venus was 13 days past superior conjunction, that she was within about 4° of the sun, and that her diameter was almost at its minimum figure, being only 9·8″. Her declination, however, was nearly the same as that of the sun, and she followed him with a difference in R.A. of nearly 15 minutes. A view was obtained of her as follows.

At about 2 p.m. the telescope, armed with a power of about 20, having a field of 1½°, was directed at the sun, and, a dark glass being held before the eye, was carefully focussed on a group of small spots. The sun having been placed in the centre of the field, the telescope was left for nearly a quarter of an hour. The field was then examined; but, as was expected, was too bright. Re-examined with a light screen-glass, it showed nothing. A power of 40, having a field of about 45′, was now substituted, and the group of spots again used to secure an accurate focus. The eyepiece was provided with a light green screen-glass, the sun brought to the centre, and the instrument again left for 15m.

This time, on returning to the telescope, the tiny pearl-white disc of Venus was immediately detected in the middle of the field. It was now found that the planet could be seen without difficulty when the screen-glass was removed, but the sky background was unpleasantly bright.

In the use of this method it is very important to have the telescope accurately focussed beforehand, so that the object of search may stand out sharply and catch the eye. A blurred or diffused image is easily passed over in a bright field. Also, although a large field has an obvious advantage in grasp of space, its advantages are much diminished by the small image which it gives, which, when faint and seen on a bright background, is easily overlooked. With Venus as she is at present, a power of 40 with a field of 45′ seems to answer better with 2$\frac{1}{10}$in. object-glass than a power of 20 with a field twice as big.

Even when the declination of the planet differs from that of the sun more than it did on Sept. 28, the same method of search may be successfully employed. Note carefully the direction taken by the sun in passing across the field of the finder (do not forget to hold a dark glass before the eye), focus carefully, put the sun in the centre of the field of the finder, then move the telescope in the direction required along a line at right angles to that taken by the sun. The extent of the movement is estimated by the known diameter of the sun's disc, and by that of the field of view of the finder.

For example, on October 8 the declination of Venus was 1° 16′ more S. than that of the sun, and the difference in R.A. was about 23m. The sun was allowed to traverse the field of the finder to give the direction of a declination parallel. It was then placed on the centre of the cross-wires, and the telescope moved at right angles to that direction till the sun's limb was at the margin of the field. The semidiameter of the field of the telescope being 90′, this was equivalent to a shift of 1° 16′ (very nearly). On looking into the telescope after the proper lapse of time, the planet was found to be in the field. On October 9 Venus was again found by the same method. When examined with powers of 65 and 80, "the uninteresting little disc," as the writer of your excellent "Astronomical Notes for October" severely calls it, appeared to be not quite circular, but, of course, showed no other detail, though definition on October 8 was very sharp.

I have not hitherto succeeded in picking up Mercury in the same way, although I have tried several times. With a diameter of disc only about half that of Venus at present, and with an albedo which is only about one-fourth that of Venus, he is probably beyond my small optical equipment. I hope that others may be encouraged to give a trial to this method, which, I think, deserves to be better known among amateur telescopists than it is at present. **R. J. Ryle, M.D.**

15, German-place, Brighton.

LUNAR RAINBOW.

[42930.]—About 9h. 5m. this evening, as I was beginning observations of variable stars, I was rather suddenly surprised by some raindrops pattering on the telescope. On going out to close the roof of my little observatory, I at once saw a very pretty lunar rainbow in the N.E. quarter of the sky. It was sharp and well defined, but colourless, or nearly so. It was projected on a nearly clear sky, in which the stars were shining. Altitude about 1° or 2° less than that of Capella at the time, and the line joining the ends of the arc on the horizon must have subtended approximately a right angle—altogether a very pretty sight. It only lasted about two minutes.

At 9h. 25m. ± rain clouds came up, the moon was for a few moments hidden behind a passing small cloud, and as soon as she shone forth the bow again appeared; this time not complete. The end nearest the north was most perfect. It was projected on a dark background of cloud now, and looked quite brilliant for a few moments or so. It might have been some curved beam of electric light (if that were possible) or the curved tail of some great comet bending up from the horizon. The other end of the bow towards the east was not so distinct; this time I should say it lasted some five minutes.

I suppose the phenomenon has been seen and noted hundreds of times and by hundreds of observers, so, on principle, I record my sight of it; the more so, as it is the first time I have ever had the good fortune to witness the delicate beauty of the ghostly-looking bow so exquisitely symmetrical in shape, and as I saw it under such favourable circumstances, albeit I did get my overcoat a little damp over the observation.

The moon was just past her first quarter, and shining serenely in a clear part of the S.W. sky, somewhat low down.

E. E. Markwick, Colonel.

H.M. Gun Wharf, Devonport, Oct. 12, 1899.

[42931.]—It may be worth while to record that two lunar rainbows were observed here this evening between 6.30 and 7 o'clock. A stormy afternoon was followed by a clear evening, with brilliant moon shining over the sea. At 6.30 a few heavy rain clouds blew up from over the land, and the rainbow was projected right across these in a perfect arc, followed after a short interval by another, but less perfect, one as fresh clouds came up over the horizon. The wind was about N.W., rather fresh. No colour was observed but a perfectly distinct white arc. Directly overhead the stars were shining, but a shower fell shortly after. **Ch. Mallett.**

Lower Penn, Otterton, South Devon, Oct. 12.

ε LYRÆ.

[42932.]—Those of your readers who are interested in the group of ε Lyræ, will find a fine sketch of the same in the "E. M.," No. 603, p. 117, with a very interesting and exhaustive letter by Mr. Albert P. Holden. **C. M. Gaudibert.**

Vaison 1, Vaucluse, Oct. 14.

METEORS AND THUNDERSTORMS.

[42933.]—In my letter (49211) I made a slip as to the rate of approach of meteors. But let us make it 5,000,000 of miles per day, and the conclusion will be the same if these bodies are of the very small dimensions usually assigned to them. Moreover, a meteor may strike us on the return from perihelion as well as on its approach to it—in which case it has been exposed to more intense solar heat before the collision than we have. Why, then, should it be cold when it enters the atmosphere?

As regards thunderstorms, I think, when they pass overhead, they should take as long to recede as to approach; nor do I see the necessity for a change in the direction of the wind at the surface at the moment that the thunderstorm passes overhead. What occurred to me was that the thunderstorm might arise (at least, in part) from the electricity developed by the friction of two masses of air moving in opposite directions—the long roll of the thunder indicating the travelling of the electric disturbance along the region of friction. With regard to this roll of the thunder, I heard a perfect reproduction of it during the blasting operations for the extension of the Dingwall and Strome Ferry line some two or three years ago. At the first instant the sound of the explosion was not like that of thunder; but afterwards the resemblance was perfect. At Strome Ferry it was no doubt the reverberation of the explosion among the surrounding hills. Is there any similar reverberation in the case of ordinary thunder?

I have not a copy of Kaenitz's Meteorology at hand, but I think he saw reflected lightning in the sky at distances exceeding 200 miles. The conditions of this reflected (or heat, sometimes called sheet) lightning require further investigation.

Since writing the above I met with a copy of the *Glasgow Weekly Herald* of Oct. 7, which enabled me to trace part of the track of the thunderstorm which visited Dublin on Sept. 30 (in the afternoon). At Fraserburgh it commenced about four o'clock on the morning of the 29th, and was very violent from six o'clock to 9 o'clock, after which hour it died away. At Forfar the sky became overcast in the S.E. about two o'clock in the afternoon, and the storm reached its height about half-past four. At Kinross the period is given at 4 p.m. to 10 p.m. At Perth a church was struck apparently after dark, for the report speaks of the mischief having been

discovered in the morning. I should be glad of any further information on the subject. It is curious that the sky at Forfar should have become overcast in the S.E., as the storm was evidently coming from the N.E. W. H. S. Monck.

METEOR.

[42934.]—A very vivid meteor was seen in Lancaster on Friday, Oct. 13, at 5.17 a.m. G.M.T., by Mr. P. Mulligan, of Mill-street Dry Dock. By his account it lasted between two and three seconds, and passed across the sky with an illumination sufficient to throw deep shadows. The colour was of a vivid green, and it left a distinct trail in its course. The radiant point was a little south and preceding ψ^1 Orionis, and the vanishing point was 28° south-west of the astronomical South.

You may probably obtain notifications of this meteor from other sources, or they may be elicited by this letter. John Bone, F.R.A.S.

St. Thomas Vicarage, Lancaster.

[42935.]—The meteor mentioned in your last issue (42912-3) was seen here on Sunday week (the 8th inst.), rising almost from the horizon about half a point W. of S.W., passing overhead, and disappearing almost on the horizon about N.E.

Scayne Hill, Hayward's Heath. L. B. B.

ROTARY ENGINES.

[42936.]—The Toennes rotary engine, illustrated and described on p. 202, seems to differ little in principle from many that have gone before. The question is, Will it work economically? An economical steam rotary engine (not a turbine) is now wanted for motor cars. Is there any place where they can be seen and tested? B. L. Smith.

IMPROVEMENTS IN ROTARY ENGINES.

[42937.]—"W. D. G." (letter 42925) asks for some amplification of the few notes in my earlier letter. I give these with pleasure; but they are from memory only, for I have but little print relating to those early days. I well remember that Mr. Wimshurst used to go to Messrs. Silverlock and Co., printers, of Waterloo Bridge-road. Perhaps they may be able to help him; but the experiments began about 1840, and not the "fifties," as he supposes.

First, then, the Brynton engine was difficult to keep tight: the packings at the angles of the piston, and at the shaft, gave trouble; then the top packing, which rubs on the internal drum, becomes really a friction brake.

These same faults exist in the second rotary, which has the four pistons. Moreover, considerable friction occurs by reason of the pistons *sliding* through the internal drum.

The engine with six pistons had an improved shape to the piston-ends, and improved packing. Moreover, the pressure on the pistons was carried upon anti-friction rollers, and having so many pistons there was no packing fitted to rub on the internal drum. This engine, when completed by the Butterly Co., was first tested by a 10ft. diameter wheel keyed to the shaft, and a lever brake; this would not scotch it. Next it was placed over their coal-pit, 172 yards deep; an unbalanced rope and chain with load of coal was connected to the 10ft. wheel or drum. The load was 90cwt., and was lifted the 172 yards in 32 seconds.

Then it was put into the s.s. *Zingaree*, and gave equally good results. The run from Gravesend to Blackwall was quite unintended. The *Zingaree* was out to test some small matters, she dropped anchor a little above the Town Pier, and refreshments were being served in the cabin when I saw the p.s. *Meteor* leave the Terrace Pier. I went to the skylight, and asked should we run up after her; the reply was "Yes." I at once went to the engine-room, gave word to open up the fires, shut the doors, and then go ahead. Then I got the men to the patent capstan to lift the anchor. My fear was that it would come into contact with the screw, for the speed of the vessel caused it to show abaft the ship. The result was we reached Blackwall first.

Disputes upon mechanical matters then caused the rotary engine to be taken out of the ship, and a well-known firm fitted ordinary engines, when, with the same boiler and propeller, her speed was reduced to eight knots.

As to modern men repeating the work of others, we daily see this, sometimes with, and sometimes without, improvement. For instance, a fan or turbine engine is often spoken of, yet, speaking of fifty or fifty-five years back, I well remember seeing in a warehouse, at the upper end of the Surrey Canal Docks, the actual propeller of the *Archimedes*, placed in a large tank of water, and driven by a fan or turbine engine, the revolutions by the fan engine being ten revolutions more than the ordinary engines of the *Archimedes* had driven it when in its place in the ship.

The Editor recently stated that when space admitted, certain papers referring to the early introduction of the screw-propeller should be reprinted in these pages. When they appear, they probably will contain some dates which may be useful to you. J. W.

GILBERT'S NEW POWER MACHINE.

[42938.]—One would have thought that much less than 20 years would have sufficed to convince Mr. Gilbert that man is not capable of creating energy, which is the only possible solution of the perpetual-motion problem. His devices, which are merely variations on those of the Marquis of Worcester, Jackson, and a host of other early experimenters, quite fail to achieve the result he aims at. Surely a little consideration should show him that the circumferential weights are of no use as a source of motive power, the additional energy exerted by a weight further removed from the centre being only obtained at the expense of the energy necessary to move it into position, and his wheel, if once set in motion, would run much longer wanting all these devices, which only serve to introduce additional friction. I would sincerely urge Mr. Gilbert to abandon the futile pursuit of a "will-o'-the-wisp," and devote his talents and energies to attacking the many problems in practical mechanics which lie ready to his hand, the solution of which would redound to his credit and be of service to his fellow-men;—a consummation never to be achieved by vain endeavours to make something out of nothing. W. J. G. F.

[42939.]—As A. E. Gilbert invites ventilation through your columns as to the "long forsaken problems of perpetual motion," I venture to ask, Has the problem been long forsaken? I think not, because the subject crops up very frequently. The pity is that it has not been forsaken for ever. This perpetual-motion system has been attempted for years past, long before the present generation, and always with one end—viz., non-success, and it always will be, from the very nature of it. If A. E. Gilbert would but just calmly think for a moment and ask himself the question, Can I obtain power from nothing? which is the absolute fact necessary to be done, I am inclined to think he would see the absolutely impossible feat and forsake the business altogether. The drawing he gives, Fig. 1, appears to me to be incomplete, as he does not show how or to what the levers for lifting the weights are hinged. If they are hinged to the spokes they would travel with the wheel and be inert; and why does A. E. G. lighten the weight (by which the machine is apparently supposed to operate) by making holes through a portion of the weight? From the drawing there are five weights doing useful work, which are supposed to be lifting eight similar weights on the opposite side of the circumference, and raising vertically two others outside the circumference at an increased rate of motion, which effort alone would probably absorb all the power exerted by three of the useful five weights, leaving two weights only to elevate the eight inert ones. Now with regard to Fig. 2, it appears that A. E. G. has two 2ft. diam. solid weights to lift perpendicularly. The friction of and power required for lifting these against gravity must be enormous, and, moreover, the first and last weights which we will suppose have been lifted have very little effective use; the three nearest the horizontal line would, of course, be doing the most work, and although the idea may be ingenious, yet A. E. G. may rest assured that the machine will not only never even start by itself, much less develop any useful power. I shall be anxiously looking out for Nos. 3 and 4 drawings; but unless A. E. G. can devise some totally different method to that shown in No. 1 and 2 the efforts put forth and energy absorbed by A. E. G. will, I fear, have been totally wasted, and I cannot help saying that, in my opinion, it is a pity A. E. G. does not exert his undoubted abilities to a more profitable object.

The problem to be solved is (as doubtless A. E. G. may know) to make a machine or some part of it commence to shift its normal position from a state of absolute rest without any exertion from an outside source being applied to it. If A. E. G. or any other body can do this—well! next the Millennium.

Dudley. Webster Michelson.

MOTOR CYCLES.

[42940.]—The writer of the interesting and instructive series of articles on the above subject says, in issue of July 21, p. 497, discussing the subject of ignition and dealing with the coil:—"The platinum contacts on the vibrating armature must be especially heavy, to withstand prolonged use with as little burning as possible."

Is not a vibrating armature in this case entirely unnecessary?—as it appears to me the make-and-break of the primary circuit by the ignition-cam does all that is necessary.

I had just decided on the making, during the winter, of a motor cycle, when the footnote to the final article in Oct. 6 issue made me pause and wonder which I should prefer—that, or a motor car. I should like to suggest that the first article should include a general drawing of the finished car; a statement as to whether the engine already described will be the one used, or, if not, if parts can be obtained from the same firm or—? My reasons for suggesting this are that if we wait to the end of articles running through several months to see the finished result, most, if not all, of the available winter evenings will be gone, whereas otherwise progress can be made week by week if the latter is decided on.

Plymouth. E. H. Micklewood.

AERIAL NAVIGATION—PILCHER'S FATAL ACCIDENT.

[42941.]—As the dead cannot defend themselves, and as Mr. Thos. G. Challis has sent you a letter appearing in your issue of the 13th inst., calling in question the skill of a practical engineer and devoted student of aëronautics, will you grant me a small space to defend him, and to point out that Mr. Challis is not qualified to pass judgment upon him, either on the grounds of theory or practice? As a fellow-engineer, but as a personal stranger to Mr. Pilcher until he left Glasgow for London, my defence is solely based upon the merits of his public work, his enunciations, and upon the personal explanations to me of his views, and his showing to me both his designs and models. I might add, also, his specially designed dynamometer for gauging the thrust of the propeller, which was quite a departure from the form used by Mr. Maxim. This latter disclosure was made to me quite recently, therefore I feel that science has lost a devoted worker in many branches.

Now, first, Mr. Challis must accept my assurance of wishing to give him credit for sincerity, and although the vague references he has made in other scientific journals as to his own plans indicate that he himself is a long way off grasping this important solution of aërial locomotion, yet I wish him success in his efforts.

Then, secondly, in respect to Mr. Pilcher's work, his principles and methods for the demonstration of aërial support (viz., "soaring," which was all he intended to demonstrate) were perfectly true in all respects; but for some reason, whether oversight or other cause, the mechanical construction and carrying out of those principles were faulty. Scientifically, he was no more to blame than the driver of an engine on land or water would be if some part of the engine broke and caused destruction to the train or ship. The true causes of the fatal result were two:—First, the neglect of providing sufficient strength in the tail-piece and connection to the wing-body. Second, the excess of wing area in proportion to the load-weight, and the placing of part of that load-weight so near to the plane of support. It was this question of "wing-area" and position of load-weight which was the chief factor in causing the death of De Groof, at Chelsea, many years before Maxim did any public demonstration.

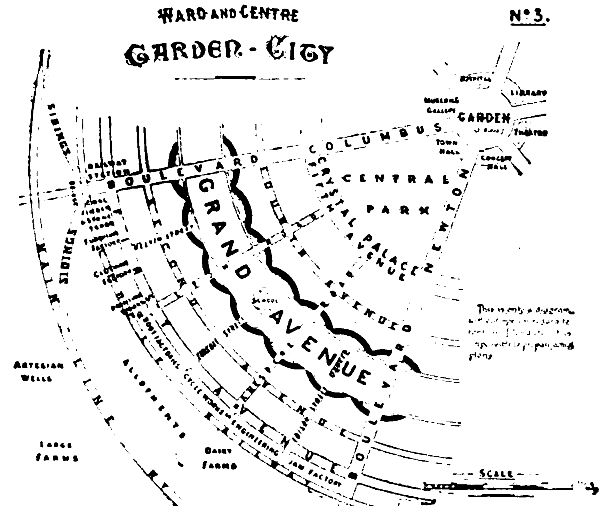
Mr. Challis makes two other mistakes. First, to sneer at the use of gas-support for aërial navigation, by saying no "gas-bags" will be required for it. Secondly, by asserting that the perfect flying-machine can be produced by himself only, and by ignoring the sudden and overpowering disturbances of air and the atmospheric elements of rain, snow, and lightning. It is self-evident to every competent mechanic or man of science that unless a flying-machine (a purely mechanically-supported and propelled machine) is capable of supporting and balancing itself safely without motive power, it is unfit for safe use, because otherwise any accident or stoppage of the motor—even momentarily—would destroy the equilibrium beyond recovery. Hence true mechanics and competent men—like Langley, Maxim, Lilienthal, and Pilcher—direct their first efforts, not to fly, but to prove "plane" support by various devices. Aviator.

MAGNETO IGNITION.

[42942.]—In reply to "Monty." Whether with or without coil, the larger the armature, the lower the speed required to produce a given result: the power exerted remaining practically the same. Our firm is perfecting a new form, which shall be shortly illustrated in this periodical. Till then I must crave your indulgent patience. S. Bottone.

GARDEN CITY.

[42943.]—Mr Garrett, in your issue of Oct. criticises the diagram of Garden City as shown in "To-Morrow," and gives one which he, as its author, naturally prefers. I do not propose to follow his criticisms upon my plan, for really I regard that plan, and still more the names given to the roads and avenues, as very far from being essential features of the project, merely using the diagrams in my book and in my lectures as showing what may, if contours admit of it, be done in the way of affording suitable and conveniently-placed sites for parks, schools, factories, workshops, stores, &c.



But perhaps your readers may like to make a comparison, and to help them in this I send you one of my diagrams.

But there is one really fatal criticism, if Mr. Garbett could substantiate it—namely, that I have made no provision for growth of population beyond the limited one of 30,000. Now, this is precisely what I have been very particular to do; but to do in such a way as to prevent altogether the evils which now ever attend the growth of our cities, and to secure for all time the combined advantages of town and country life. Perhaps the city of Adelaide affords the best illustration of the principles I advocate. South Adelaide is inclosed by a wide belt of green called "Park Lands," and the further growth of the town takes place by leaping over these park lands, and by building beyond them—hence North Adelaide. In a sense, therefore, it might be said of Adelaide, as Mr. Garbett says of Garden City, that its growth is checked by the Park Lands; but in truth it is not: its growth is simply made healthy, natural, and beautiful. I have carried out, but to a somewhat greater extent, the same principle. Garden City is surrounded by, say, 5,000 acres of agricultural land, and when it has filled up the 1,000 acres assigned to it, it will grow by leaping over the 5,000 acres which surround it, and by building a new city which will in fact, though not in name, be a part of the same community—a process which may continue till there is a whole group of cities, forming, in fact, one; for every resident of each will, owing to a system of rapid communication, be, in truth, a resident of one large city, and yet have ever the beauty of the country within most easy access.

There is another most essential feature of the project, compared with which the question whether a road shall be called "First Late Cheap" or "Boulevard Columbus" is as the dust of the balance. When starting to build on a new area as I advocate, it is most essential that provision be made that the whole of the added value given to that area by the presence and the energy and the industry of the inhabitants shall be, not the property of a few favoured individuals, but the property of the whole community. On these principles I show how a rent (less than under ordinary conditions would be paid for the ground on which the factories, shops, and houses, would stand) would, if paid to the community, meet not only the interest on the purchase money, and provide a sinking fund, but would suffice to carry on all the public services of the town; so that all its residents would be for ever free of rates. In my book I show how these results can be secured, while giving to the inhabitant the largest measure of freedom; the area of choice, so far from being curtailed, being, in fact, vastly extended.

These advantages (and many others which I must not occupy your valuable space by dealing with) are so real, and appeal so strongly to the common-sense of the people, that they will hasten to avail themselves of them; and thus, by a healthy and natural process of evolution, will two urgent problems which now confront our statesmen be completely solved—the housing problem, and another closely connected with it—how (in the words of Sir John Gorst) "to back the tide and stop the migration of the people into the towns, and get the people back to the land."

The first annual meeting of Garden City Association will be held at Memorial Hall, Farringdon-street, on Thursday, Oct. 26, at 7 p.m., Mr. I. H. W. Idris, J.P., L.C.C., chairman of the council, in the chair, and in view of the importance of the subject, I hope all who read this will make a point of being present. E. Howard.

11, New-court, Carey-street, W.C.

GARDEN CITY.

[42944.]—As honorary secretary of Garden City Association formed to consider the project of Mr. Ebenezer Howard, allow me to say a few words on Mr. Garbett's proposed improvement, leaving professional experts to deal more fully with it on some subsequent occasion, either in your columns or elsewhere. To those who are acquainted with the scheme, it may be sufficient to say that it is one for a concerted migration on a large scale to some agricultural land, purchased in the open market, laid out under the best professional advice according to a careful plan, and made subject to conditions securing the increased value of the land to the settlers themselves. Now assuming that I rightly understand Mr. Garbett's plan, the following objections to it suggest themselves to me. (1) The future extension of the city beyond a population of, say, 32,000 is eminently undesirable. (2) The splendid parks provided by the Howard plan are not visible anywhere. (3) Nearness to work, to the parks, to the public buildings, to the allotment gardens, in fact to every part of the estate, is not attained. (4) Railways through the town would be an annoyance, not a convenience. Water-ways and tramways are suggested by Mr. Howard in his book "To-Morrow."

If those who think with Mr. Garbett will join the Association, and help us to discuss this and other matters, we may hope to discover what plan is really the best. May I add that our first annual meeting will be held at Memorial Hall, Farringdon-street, Thursday, October 26, 7 p.m.?

Francis W. Steere, Hon. Sec. G. C. A.

4, Stone Buildings, Lincoln's Inn, London.

CHARLES BABBAGE.

[42945.]—I WAS much interested in your article last week on Babbage and his wonderful machine, and imagine many other readers were also. Some of them may perhaps like to read one or two anecdotes about Babbage, which I lately came across in a volume entitled "Recollections of an Octogenarian," published anonymously, and apparently for private circulation only, and printed at the Chiswick Press. I picked the volume up at a second-hand bookstall, and if I am inadvertently infringing any copyright, I tender my excuses to the unknown author, if he has not by this time joined the majority.

"Charles Babbage was an honourable, just, truth-loving, kind-hearted man. He had his failings (so have you and I). Jealousy was not one of them. A Swede came over with a calculating machine which he had contrived. Babbage did not act on the old adage 'two of a trade,' &c. He made much of the Swede, and everywhere praised the ingenuity of the contrivance. Poor Babbage doubtless had his life embittered by his inability to persuade Spring Rice, Chancellor of the Exchequer, to advance some thousand pounds for the completion of his calculating engine. Spring Rice took advice from the Astronomer Royal. He told him, 'The calculations we have to go through are very laborious; but you can get a charity boy to do them.' 'But he may be wrong.' 'Get two charity boys.' And so economy got the better, and our country lost the opportunity of abridging human labour in about the same proportion that Napier did by his glorious invention of logarithmic tables. Few have any conception of the amount of labour in physical problems. Hutton wanted to ascertain the specific gravity of the earth. He suspended a pendulum near the mountain Schehallion in Perthshire, and observed how much the pendulum was drawn from the perpendicular. The mountain was not a very regular figure, and it was composed of five or six irregular masses of different rock, each with its own specific gravity. The computations covered hundreds of quires of paper; and the result, 'Specific gravity of the earth, 5½,' came out at the end of *twenty-two months*. A noble ironclad, the *Captain*, was being built. When near completion some alteration was ordered which would alter her stability, or, as Scott Russell used to call it, her stand-up-at-iveness. She was hurried to sea to join the Channel Squadron before the computations of her stability under the altered build were completed, and in the first heavy gale she capsized. Two months after she was lost the computations were finished, which showed she could not bear to be heeled more than so many degrees—I forget what—without being upset. Her fate was that of Madame Blaise—

> 'The doctors found, when she was dead,
> Her last disorder mortal.'

Babbage's engine would have made the computations in a couple of hours. And so a splendid ship, a noble captain, a fine crew, and £400,000 or £500,000 of money went to the bottom of the Bay of Biscay, because the Astronomer Royal thought a charity boy cheaper than a calculating engine.

"Babbage carried his analytical mind into every-day life; into his charities. He told me when he was accosted in the streets by a person with a long story, and 'Oh, sir, if you would come home to our poor house and see my wife and seven children,' he used to take the man at his word and go home with him, and invariably found there was imposture. He determined never to give to street beggars. But by so doing he might be neglecting a deserving object, and he had to guard against encouraging in himself a habit of niggardliness. Accordingly, whenever he was so accosted he refused, but when he went home he threw a shilling into a drawer. Whenever this fund had accumulated to twenty, he put a sovereign into the box of St. George's Hospital, and began again.

"Babbage loved fun, and was ready in answering. One day Sidney Smith called upon him. 'Babbage, I have discovered that there is an eleventh commandment wanting.' 'What is it?' 'Thou shalt not be found out.' 'Then what on earth is the use of the other ten?'

"I happened to call on him just as the news came of Sir Charles Napier's rapid victories and his annexation of Scinde. Many thought the latter to be a mistake, that our empire was already wide enough. Of that mind was Babbage. I said, 'Napier's despatch might be very brief—Veni, vidi, vici.' 'Oh, it might be shorter,' said Babbage; 'he should have written simply, Peccavi—I have Scinde.'

"I was talking to him one day of the schism in the Church in consequence of many divines, with Maurice at their head, revolting at the idea of eternal condemnation. Babbage asked, 'Who is there on the other side?' 'Why,' said I, 'there is the Archbishop of Canterbury.' 'Oh,' said he, 'is the archbishop in favour of eternal damnation! Then let him be damned eternally.'

"He took me one day into his workshop. He pulled down a parcel of toothed wheels. 'There are,' said he, '40,000 of these wheels, and (pulling down another parcel of smaller wheels) there are 40,000 of these; and if *any one* of the first be fitted to *any one* of the second, I will engage they shall do their duty.' They were finished to the thousandth of an inch. And when Babbage began the construction of his engine, there were no mechanists in the country who could grind brass to the required accuracy; he had to create engineers before he could begin on his engine. Mr. Forster told me Babbage went all round his works at Stourbridge. His head engineer told him afterwards, 'Wonderful man that be, Sir; knows more of machinery than me: odd name, like cabbage.' . . . .

"Herschel and Babbage, like many great mathematicians, used to amuse themselves with deciphering and inventing ciphers. Herschel invented one which he thought would baffle the most acute. He wrote a letter to Babbage in this cipher, which ended with, 'If you can make out this, you are the devil himself.' Babbage, in a forenoon, deciphered it, and answered Herschel in his own cipher, signing himself 'Diabolus ipse.' Such are the pleasantries of profound mathematicians. But the palm for deciphering must be awarded to Wheatstone. Among the papers of the luckless Charles I., which fell into the hands of the Parliament, many were in cipher, and have long been read. But there was one in the British Museum which had baffled all. Sir Henry Ellis, the Keeper of the MSS., applied to Babbage, who advised him to put it in Wheatstone's hands. I happened to call upon him (Wheatstone) the day on which, having completed the solution, he was writing it out for the press. The ink was wet when he put the last sheet in my hands. And now that I know the key, the more marvellous does the achievement appear. In the first place, in what language is it? After much labour, Wheatstone found it was in French, and to make matters worse, very bad French, for Charles wrote 'as tur' for 'à cette heure.' The symbols were all numerals.

The first line runs, 42 . 56 . 90 . 93 . 83 . 99 . 20 . 95 . 43 . 60, and so on for seven folio pages. The numerals are about three hundred. Some represent alphabetic letters, many representing the same letter; thus there are nine ways of representing *e*. Then some numerals represent the more common words, as 'les,' 'que,' 'pour,' 'comment,' &c. And again some numerals represent a name, as 'Prince of Orange,' 'King of France'; no division between words or sentences. The document itself is of the highest interest historically. It is a despatch from Charles to his minister at the Hague, in which he instructs him to persuade the Prince of Orange to enter into a league with him and France. France was to send over 2,000 cavalry and 4,000 infantry in transports, protected by fifteen or twenty men-of-war, to bring his subjects to reason. The Parliamentary debates of the time show that this was suspected; but Charles declared on the word of a prince that there was no truth in them. For the deciphered despatch, see 'Memoirs of Wheatstone,' published by the daughters."

Kappa.

MOSQUITOES AND MALARIA.

[42946.]—This subject is now engaging attention. There can be no question or doubt that flies of various kinds carry the germs of disease—as with the blowfly that has left putrefying offal to settle on a sore in a living being. While in Egypt in the year 1856, on several occasions on awakening in the morning I found myself nearly blind with purulent ophthalmia. This was caused by flies coming from the eyes of natives suffering from a similar complaint. Frequent applications of zinc lotion and the use of gauze goggles soon cured the evil. When we got into localities where flies were scarce, we were not afflicted with ophthalmia, although mosquitoes might be abundant. These horrible pests do not necessarily live by sucking human blood; the majority of them never have a chance of obtaining this food. I have seen them settle on the flesh and drink the blood of a recently slaughtered animal, and, in fact, a piece of raw meat placed near a sleeper serves as a protection, and attracts them in preference to attacking the sleeping man. I have also seen them congregated on putrid carrion, from which they might bring to us the germs of dangerous fevers and malaria. Their indiscriminate mode of feeding leads to the idea that they might be effectively poisoned in the same way as our common house-flies by means of a suitable kind of bait. Of course, the experiments could not be tried here, but must be carried on in countries where mosquitoes abound. For alleviating the irritation of a bite, I used immediately to touch the spot with a dot of moistened cyanide of potassium, which counteracted their poison.

F. H. Wenham.

STEREOSCOPIC VISION—THE BALANCE.

[42947.]—There is one curious circumstance in connection with the above which appears to me to be entitled to a note in passing. It has come under my observation as a result of the extensive employment of photography in modern illustrated journalism. Given a subject well adapted for stereoscopic effect, a pillared portico, a lavender field, or something of that sort, with the lines running well into the foreground, I should like to ask any of your readers who can trust the evidence of his own senses, whether the stereoscopic effect is not much improved and increased by the use of one eye in preference to two. For my own part I think that binocular vision produces a distinctly flattening effect in such a case.

I have often looked for some description of the balance in your columns; the conditions which determine the perfection of its working both in the simpler and more complicated forms, &c.

Carlos.

The first electric locomotives exported from the United States were recently shipped from the Baldwin Works to Japan. The machines weigh nearly five tons each in working order.

Messrs. Webster Michelson and Co., of the Eve Hill Works, Dudley, send an illustrated catalogue and price list of their electrical appliances, notably dynamos and motors, which contains a great deal of information that will be useful to those who desire to set up electrical plant, either for lighting or for motive-power purposes.

Cornell University is the only college in the United States which has a forestry department. A year ago it secured 30,000 acres of woodland in the Adirondack Mountains for the exclusive use of the University's forestry department. The land has been divided into a number of sections, and several seed-beds have been laid out, in which there has been planted over a million small trees of different varieties. The students of forestry will study the theory of the subject from October to April, and from then until commencement they will study the practical side of forestry.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[96555.] — **Equation.** — Surely Mr. Burgess knows the difference between an exact and an inexact number. The expression $\frac{2}{3}\sqrt{7}$, for instance, is a surd which can only be represented by an interminable row of decimal figures—and then it won't be exact. Now, if in the original given equations we put x = the above expression, it might pass in the first equation, as only the square of x appears, which is an exact number; but in the second and third, on substituting the above inexact expression for x, impossible equations are the result, as you cannot have an equation between several numbers one of which is a surd. Again, looking at the first of the given equations, the smaller the second term is the greater will be the first, and if the second were nothing at all, x would work out to a little over 3; it can never be greater than this, whatever y and z may be. (Note that x, y, z are either all positive or all negative.) Consequently the long row of possible candidates for the value of x as given by Mr. Burgess dwindles down from 20 to 2; the two being $\frac{1}{2}$ and $\frac{2}{3}$ as given by me. This method will be more easily understood if we take one of Mr. Burgess's own derived equations (see p. 187)—$n = \frac{q\,a - b\,p\,m^2}{p\,c - b\,m\,q}$. Instead of finding n in terms of m, let us find m in terms of n. Then, restoring the numerical values of the letters and working out the quadratic equation, we get—

$$m = \frac{5}{9}n \pm \sqrt{\frac{25}{81}n^2 - \frac{25}{21}n + \frac{100}{81}}$$

Or—

$$m = \frac{9}{5}n \pm \frac{5n}{9}\sqrt{1 - \frac{27}{7n} + \frac{4}{n^2}}.$$

Now, as in the other case, the terms under the radical sign must be a square number, putting $n = \frac{p}{q}$, where p and q are whole numbers, these terms will be $1 - \frac{27q}{7p} + \frac{4q^2}{p^2}$. Now, in order that these three terms may be added and subtracted, as indicated by the signs, the denominators must be equal, and therefore—

$$p^2 = 7p, \text{ or } p = 7.$$

The expression therefore becomes—

$$\frac{49 - 27q + 4q^2}{49}$$

Now, to make the numerator also a square number we can put it in the form—

$$(7 - 2q)^2 + q, \text{ or } (7 - 2q)^2\left[1 + \frac{q}{(7 - 2q)^2}\right]$$

The terms in brackets represent a square whole number; therefore the denominator must = 1, or $q = 3$, and the whole expression reduces to 4, which is a square number. Thus $n = \frac{p}{q} = \frac{7}{3}$, the radical term becomes $\sqrt{\frac{4}{49}}$ or $\frac{2}{7}$. Hence m will be found $= \frac{5}{3}$. As $m = \frac{y}{x}$, and $n = \frac{z}{x}$, and $z^2 = \frac{p}{a + b\,m\,n}$ (using Mr. B.'s symbols), where $p = \frac{27}{4}$, $a = \frac{2}{3}$, $b = \frac{3}{5}$, the values of x, y, and z are easily found. From the above it will be seen that the third given equation is not required at all. It is a mere sequence of the other two.

Bath. M.I.C.E.

[96599.]—**Cutting by Circular Saws.**—Saws should cut "down" on the work, as a rule, because if they cut upwards there is always a risk of slewing the work; but if that is clamped firmly there is no choice in the matter. As a rule, girders, rails, &c., are cut with the saw running against the bed, and so having something solid to work on.

T. M. L.

[96633.]—**Green Water.**—I cannot tell the querist (p. 211) where to send the water for analysis; but I presume there is a county analyst. It is possible that a little alum in powder would cure the greenness, or some permanganate of potash. The question is certainly peculiar, as it is quite unusual for water to turn green, especially when derived from a chalk well, meaning a well in the chalk (about the purest source we have), and I should like to know something more about this matter, as it is rather curious. I do not know what analyst's fees are, but it would be interesting to learn why the water turns green.

M. T.

[96633.]—**Green Water.**—This greenness is undoubtedly due to swarms of the little flagellated chlorophyll-containing infusorian *Euglena viridis*, which often occurs in such myriads as to give large volumes of water a brilliant green appearance. The analyst will not help "Quex," but any friend with a microscope can do so. If "Quex" will place some of the green water in a clear glass bottle, then cover all of it but a strip, he will find that the little organisms will crowd densely into the illuminated portion. If he will place a bottle containing them where light will impinge upon it through a prism, he will find that they will come to the blue and violet rays, forsaking the others. See any book on elementary biology.

J. Sinel.

[96637.]—**Catarrh.**—I suffered while in Egypt from this complaint, and at the suggestion of a German doctor cured the complaint with cold-water compresses on the stomach at night. I found the treatment safe and speedy and trust "Sufferer" may do the same.

Cairo.

[96728.] — **Gold.** — There is neither an atomic nor molecular difference between Australian and Californian gold, regardless of what Mr. Howse says. Australian gold contains: Gold, 99 per cent.; silver, 1 per cent. Californian contains: Gold, 90 per cent.; silver, 10 per cent.

W. Ewart Gibson.

[96750.]—**Spring Tides.**—The relative heights of spring and neap tides are about as 7 to 4. The interval between corresponding tides of successive days is less than the average, being only about 24h. 38m., and then the tides are said to be "prime." At neap tides the interval is 25h. 6m., which is greater than the mean, and the tides "lag." When the moon is in perigee tides are nearly 20 per cent. higher than those occurring when she is in apogee. The highest occur when a new or full moon occurs, at a time when moon is in perigee, especially if this occurs about Jan. 1, when earth is nearest to the sun. The "tide-raising" force varies inversely as the cube of the distance: slight variations in the distance of the moon and sun from the earth make much greater variations in the height of the tide—greater nearly in the ratio of 3 to 1. Beardmore's Tables also have much on the subject. Your lat. and long. indicate Isle of Anglesea, and with tidal ranges of 16, 17, 18, upwards, 19ft. curves, showing tidal range equivalent to 30ft. spring range from Liverpool. He gives Spring Tides Tables for river Mersey, 1844; also neap tides for twenty-four hours; also tides of Irish Sea; also a table for computing time of high water for twenty-four places, of which I take Holyhead as central for your locality.

Moon's transit.	Holyhead.
0h. 0m.	1d. 10h. 47m.
1 0	1 10 30
2 0	1 10 18
3 0	1 10 10
4 0	1 10 07
5 0	1 10 16
6 0	1 10 46
7 0	1 11 16
8 0	1 11 31
9 0	1 11 31
10 0	1 11 20
11 0	1 11 06

Shows the semi-menstrual inequality + a constant, representing interval between the moon's transit, two days preceding a London tide, and the time of high water, the moon's parallax being 57′, her declination 15°, the sun's parallax 8·8″ and declination 15°. Following is table of correction for the moon's declination and parallax. For moon's declination no correction from 14° to 16°; ditto parallax for 57.

Name of Port.	Moon's declination.					
	0° to 6+	9° + and 21° −	12° + and 18° −	24° −	27° −	30° −
Holyhead	·32	·29	·13	·49	·69	·90
	Moon's parallax.					
	54′	55′ − and 57′ +	56′ − and 58′ +	60′ +	61′ +	—
Holyhead	·70	·49	·24	·79	1 07	—

Constants to be added to or deducted from times and heights of high water, e.g.—

Ports.	M.S. Gauge.	Time.	Height.

Regent's Park.

[96724.]—**Oil-Engine Castings.**—First plane up the facings on the bedplate, &c., to the proper sizes; fit keeps and brasses to main bearings. Bore out the brasses $\frac{1}{32}$ smaller than crank-shaft. Turn crankshaft and bed in to brasses with red-lead and oil. Fit brasses into each end of connecting-rod, and bore them out to take crank-pin and gudgeon-pin respectively. Finish cylinder and piston, and put them in place, with connecting-rod attached to crank-pin. Now mark off holes on to

bedplate; tap them and fit studs. I don't know of what make your castings are; but if vaporiser and combustion chamber are a separate casting, fit on next, keeping the valves fair for the valve-rods. Grind in valves with fine sand and water, afterwards with chalk and oil. You can then fit flywheel and pulley, valve-springs, ignition-tube, and chimney lubricators, two to one gear, and the various cocks and connections. W. Ewart Gibson.

[96759.]—**Bikes and Prams.**—It has been decided in a court of law that bicycles are carriages within the meaning of the Act—consequently it is illegal to wheel a cycle on a footpath. Perambulators not being carriages, are controlled by local regulations. In return for this contribution, will "Rota" please oblige by ceasing to use the word "bike"? R. R.

[96778.]—**Barometer.**—So many accidents may happen to a barometer sent on a sea voyage without screwing up the cistern, that it is highly probable the instrument in question can only be repaired by the maker. If there is no fracture in the tube, it is possible that a particle of dirt or a bubble of air may have found its way into the tube, and in this case the instrument should be taken down and put aside in an inverted position for several hours, and on replacing it, it is possible that the obstruction will have disappeared. By inclining the barometer with the cistern uppermost and slightly tapping the tube, any air will also in this way be removed.

Nerps.

[96794.]—**Bluing.**—The steel-blue colour you mention can be given to iron articles as follows:—Clean and emery the articles to be blued carefully, taking care not to mark them with the fingers after emerying them; also be careful to keep them free from grease of any kind. Then place them in a sand-bath (preferably silver sand) and heat them carefully until they turn the desired blue, then dip them in linseed-oil and dry them out in a little hard-wood sawdust to which a small quantity of pencil blacklead has been added. The sand-bath I use is a simple affair. I knocked up a small iron box about 10in. by 5in., put four legs on same to keep it up off the bench, and placed an atmospheric gas-burner under it; a bar burner with holes along it is best, and gives an even heat with less trouble. T. W. L.

[96795.]—**Varnish and Stain.**—Pulverise and dissolve three parts of light-coloured shellac, two of sandarac, two of white resin, and half of camphor in 24 of alcohol of 80 per cent. Put first the shellac, sandarac, and camphor in the alcohol; tie up the vessel with a piece of wet bladder, and shake it for half an hour; then add resin, and let the mixture boil up several times in a suitable vessel. Filter the ready varnish while yet warm through cotton or felt, and to clarify it let it stand in a well-closed bottle for 12 hours. No more varnish than is to be used in two or three days should be prepared at one time, since age impairs its beauty and hardness. ("Standage on Varnishes.") One for wood naturally coloured or stained. Amber Varnish: Clear pale amber 6lb., fuse it, add of hot clarified linseed-oil two gallons, boil until it strings well; then let it cool a little, and add of oil of turpentine 4gal. or q.s. Nearly as pale as copal varnish, it soon becomes very hard, and is the most durable of the oil varnishes; but it requires some time before it is fit for polishing, unless the articles are stoved. When required to dry and harden quicker, drying-oil may be substituted for the linseed-oil, or driers may be added during the boiling. (J. Cameron, "Oils and Varnishes.") The following is said to defy action of boiling water:—Boil in untinned copper boiler 750 parts of linseed-oil. Suspend in this, in bag not touching bottom, 150 parts of litharge and 90 parts of minium. Let oil boil until it becomes dark brown, remove bag, replace by one containing 7 or 8 bulbs of garlic. Melt 500 parts of pulverised amber in 60 parts of linseed-oil over a strong fire; add it, while boiling, to the prepared linseed-oil, and let it boil two or three minutes longer, stirring vigorously. Take it from fire, allow to settle, pour off clear liquor, and when cold put into bottles and hermetically close them. To use varnish: Polish wood first, and give desired colour. When stain is dry, apply four coats of varnish with fine sponge (or perhaps soft brush may do), allowing each coat to dry. Nut-brown colour may be got by laying on thin coat of mixture of lampblack and oil of turpentine. Regent's Park.

[96808.]—**Dynamo Switchboard.**—I am sorry Mr. Bottone cannot give you the desired answer; but it may assist the querist to know a very clear engraving and full description appears in Mr. Allsop's article on "Electric Lighting" in his excellent book of that title, or Vols. LI. and LV. English Mechanic, pp. 280 and 493 respectively.

Twenty Years' Subscriber.

[96819.]—**Electric Bell.**—Yes, the over-driven staple would be the cause of your cells becoming crystallised; but in fitting bells, telephones, &c., the safest way is to staple the wires separately.

S. Elliman.

[96820.]—**Sand-Blast.**—I have a small sand-blast machine, and should be pleased to show it to your correspondent, if he can call.

C. Mitchell.

23, Blenheim-street, King's-road, Chelsea, S.W.

[96825.]—**Meteorites.**—Having had an occasion to-day for consulting the Reports of the British Association, I took the opportunity of more particularly examining the catalogues (by Mr. R. P. Greg) referred to in my former reply to this query (p. 214). I find they contain many more instances of British-fallen meteorites than does any other authority with which I am acquainted. Perhaps,

Date.	Place of Fall.	Remarks.
1360. —	Yorkshire	Stone-fall.
1628. April 9	Hatford, Berkshire	Weight 24lb. +; 5 p.m.; stone-fall accompanied by detonations.
1642. Aug. 4	Near Woodbridge, Suffolk	Weight 4lb.; 4.30 p.m.; stone-fall.
1676. —	Orkneys	Stone-fall; fell into a boat.
1680. May 18	Near Gresham College	2½in. diam.; stone-fall; several fell.
1695. —	Ireland	"A shower of unknown matter."
1723. Jan. 10	Tregony, Cornwall	Stone-fall.
1725. July 3	Mixbury, Oxfordshire	Weight 20lb.; stone-fall.
1731. Mar. 12	Halstead, Essex	Stone-fall (?) and fireball.
1779. —	Lettiswood, Westmeath	Weight 5oz.; stone-fall; 1771 (?).
1780. April 1	Beeston, Nottinghamshire	9 p.m.; stone-fall; April 11 (?); iron-fall (?).
1795. Dec. 13	Wold Cottage, Thwing, Yorkshire	Weight 56lb.; 3 p.m.; stone-fall; sp.gr. 3·70.
1802. Sept. 15	Loch Tay	Stone-fall; doubtful.
1803. July 4	East Norton, Leicester	Stone-fall (?); meteor and detonation (?); struck a building; electrical.
1804. April 5	Possil, near Glasgow	S.E. to N.W.; a.m.; stone-fall; day-time; sp.gr. 3·53.
1806. May 17	Basingstoke	Weight 2½lb.; stone-fall, after a detonating meteor.
1810. Aug. —	Moores-Fort, Tipperary	Weight 7¾lb.; 11 30 a.m.; stone-fall; sp.gr. 3·67.
(early part of) 1813. Aug. or Sept.	Malpas, Cheshire	1 p.m.; stones fell.
1813. Sept. 10	Adare, &c., Limerick	Weight 17 + 65 + 24lb.; E. to W.; 9 a.m.; stone-fall; sp.gr. 3 64; 6 a.m. (?).
1816. Aug. or July	Glastonbury	Stone-fall.
1819. —	Pulrose, Isle of Man	Stone-fall; light and scoriaceous; fell 1813-1819.
1821. June 21	Mayo, Ireland	Hailstones fell with a metallic interior.
1825. May 12	Bayden, Wiltshire	Iron-fall (?)
1827. —	Newstead, Roxburghshire	Weight 18lb.; found in this year; iron-fall.
1830. May 17	Perth	Stone-fall (?)
1830. —	Launton, Oxfordshire	Weight 2½lb.; N.E. to S.W.; 7.30 p.m.; stone-fall with noise and light; sp.gr. 3·625.
1842. Aug. 5	Harrogate	5 p.m.; stone-fall; very doubtful.
1844. April 29	Killeter, Tyrone	3.30 p.m.; stone-fall; no meteor; many small ones; musical sounds in the air; sp.gr. 3·76.
1846. Aug. 10	County Down	Iron-mass and meteor (?)
1860. June 9	Raphoe, Donegal	2 p.m.; stone-fall; size of duck's egg; June 8 (?)
1876. April 20	Rowton, near Wellington, Shropshire	Weight nearly 8lb.; two detonations; iron-fall.
1881. Mar. 14	Middlesbrough	Stone-fall.

therefore, it will be of assistance to the querist and of interest to some other readers if I supplement my last week's answer by abstracting the entries in question from these very extensive catalogues. Some further examples are added in order to bring the list more nearly up-to-date.

Clapham Common. Walter E. Besley.

[96829.]—**Women as Inventors.**—The idea that women lack the faculty of invention is a ridiculous one, and has been frequently refuted. Woman probably is a better inventor than man, but, from apparent causes, her capacity has lain dormant. As good a defence of women as inventors as I remember was contributed by Miss Gage to the *North American Review* in 1883. It was, I think, in the April or May number of that year, and can doubtless be seen at the British Museum library. Miss Gage claimed that bread-making was invented by Isis, who taught it to the Egyptians. The hunter's net, the warrior's axe, the art of making pottery, the method of manufacturing silk were all discovered by women. Lace-making is another pre-eminently womanly invention, and it is worth notice that the well-known "Venetian Point" lace originally invented in the thirteenth century, but afterwards lost, was reinvented by Signora Bessani, an Italian workwoman, who reaped, I believe, substantial sums from her patent. Pillow-lace making was invented by Barbara Uttmann; Cashmere shawl-making by the celebrated beauty, Nourmahal; and Japanese relief decoration by Kamejo. The important industry of straw bonnet-making in America is due to the genius of Betsy Metcalf, who made the first straw bonnet in 1798. The cotton-gin was the invention of Catharine Littlefield Greene, whose attention, as a planter's wife, was called to the matter by the frequent prophecies of the fortune that awaited any-one who could devise a mechanical plan for separating the seeds from the cotton. The cotton-gin gave an immense impetus to the cotton-production of the Southern States. One well-known American mower and reaper is the invention of Mrs. A. H. Manning, and her husband, who patented it, always acknowledged his wife's claim. A little girl invented the "gimlet-pointed" screw, which has probably made more money for its makers than any other modern patent. Hundreds of other instances might, I believe, be given. Kappa.

[96829.]—**Women as Inventors.**—All nonsense. Women are, in my opinion, superior to men as inventors. A woman of this town has just invented a very clever machine for shearing by means of electricity. A thin blade is made white hot, and cuts through the fleece like magic, without perceptibly burning the wool or the animal.

Bradford. T. C.

[96829.]—**Women as Inventors.**—Many of the greatest men are entirely devoid of inventive genius, so that invention cannot be taken as a criterion of superiority. However, as it happens, there are inventions patented almost every week the year round by women, as a man with any small knowledge of invention would know, for the names appear in the *Journal of Patents* every week.

A. R. F.

[96829.]—**Women as Inventors.**—Women contributed 683 applications for patents during last year, being more than 2·4 per cent. of the total number; about 150 relate to articles of dress, and 80 to cycling.

161, Albion-road, N. A. Clarke.

[96830.]—**To Practical Electricians.**—You will require about 50H.P. for driving five hundred 16c.p. lamps, and the dynamo will need to run at full speed, whether you have one lamp only or 500 in circuit. The amount of current sent through the accumulators, and consequently the energy stored, will depend entirely upon the size of the accumulators. The output of accumulators is not reckoned in volts, but in "ampère-hours"—i.e., if 10 ampères are passed through an accumulator for 1 hour = 10 ampère-hours, the accumulator will be capable of supplying a circuit with approximately this amount of current for the same period, or with 20 ampères for half an hour—the exact amount depending upon the efficiency of the accumulator. For 110-volt circuit you will require 60 cells. As there are a number of different types on the market, it is impossible to specify any particular make unless the nature of the factory and the work the battery will be required to perform is known. If the cells are properly insulated, the leakage is so small that it need not be taken into account; the cost will entirely depend upon the size of the battery. If the same is required to supply, say, 50 lamps for 3½ hours, or the equivalent, e.g., 25 lamps for 7 hours, or 100 lamps for 1¾ hour, the cost would be £114. Owing to the heavy cost of accumulators, the size is usually cut down to the lowest permissible limit. If you charge the accumulator direct from the dynamo you will require a voltage of from 130 to 150 volts; this would not, of course, be suitable for lighting the lamps at the same time unless the voltage were reduced by means of back E.M.F. cells or some

other method. Although it is difficult to say, without a knowledge of the size and plan of the factory, I should advise you to adopt either 100 volts, if the area of lighting is of limited extent, and, perhaps 200 volts if the lighting is extended. The dynamo would probably be best compound-wound if used chiefly for lighting the lamps direct, and the storage battery could be charged by means of a "booster," inserted in the charging circuit to raise the voltage to the requisite degree. I shall be glad to supply any further information.

G. W. LUMMIS-PATERSON.
Heaton, Newcastle-on-Tyne.

[96830.]—**To Practical Electricians.**—(1) Yes, it is quite feasible to charge and light simultaneously. (2) 100 volts. (3) 50 cells, size and type would depend upon the work they were required to do. If to run 250 lamps for three or four hours, each cell would require to contain about 38 plates, each having an area of about 2sq.ft. (4) "Electric Light," by J. W. Urquhart, C.E., Crosby Lockwood and Son; or "Electric Light Installations," by Sir D. Salomons, Whittaker and Co., might be of service. (5) The accumulator will return about 90 per cent. of the energy put into it, and cost, roughly, about £350. (6) To get 110 volts you would require 55 cells, and the dynamo would require to have a voltage of at least 120 volts. If querist cares to write to me, I will be glad to give him what further help I can, should he require it.

Moffat. W. J. G. FORMAN, C.E.

[96830.]—**To Practical Electricians.**—What you propose in your query can be done without difficulty; but five hundred 16c.p. lamps will require at least 50 B.H.P. If you use 110-volt lamps you will require 58 to 60 cells, and the probable cost can only be stated when we know the number of lamp-hours or ampère-hours' capacity you require. In case you have 60 cells, your dynamo must be for a voltage of 150.

WEBSTER MICHELSON AND CO.
Eve Hill Works, Dudley.

[96830.] — **To Practical Electricians.** — A dynamo to light 500 lamps of 16c.p. 110v. will absorb between 18 and 20 H.P. to drive it nicely. If your dynamo is properly wound, you may drive it at full speed, whether you have only 1 lamp or all 500 on, and you may have accumulators in parallel across the mains without affecting general results, provided of course you have one of our automatic cut-ins and cut-outs, to prevent back discharge in case engine turn slow, &c. If you charge accumulators at 110v., you can only charge 44 in series at a time, since each cell takes 2·5 volts to charge it, and since you can only get 2 volts per cell out, they would return you only 88v. You cannot better the E. P. S. type. See Allsop's "Electric Light Fitting." If by leakage you mean difference between energy expended and that recovered, it amounts to about 25 per cent. The cost will vary according to capacity of accumulators from £1 3s. per cell, up to £6 or more. To charge a set of 55 accumulators to give 110 volts, the dynamo must be capable of giving 137·5 volts, at least.

S. BOTTONE.

[96831.—**Cotton-Covered Wire for Coil.**—To MR. BOTTONE.—No use at all for sparking coils, and not much good for "shocking" ones.

S. BOTTONE.

[96838.]—**Chords of a Circle.**—If C be any chord of arc A or angle ϕ, d being the diameter, then—

$$C = \sin.\frac{\phi}{2} \times d.$$

For by Euclid, Prop. 47, Book I., C is the hypothenuse of the right-angled triangle whose base is the versed sine, and perpendicular the sine of ϕ, both $\times$ radius or $\frac{d}{2}$.

$$\therefore\ C = \sqrt{\left\{\frac{d^2}{4}(\sin.^2\phi + \text{vers.}^2\phi)\right\}}$$

But vers. $\phi = 1 - \cos.\phi$, and by two well-known formulæ we have—

$$\text{(i.)}\quad \sin.^2\phi + \cos.^2\phi = 1$$

$$\text{(ii.)}\quad \sin.\frac{\phi}{2} = \sqrt{\left(\frac{1-\cos.\phi}{2}\right)}$$

And $\sqrt{(\sin.^2\phi + \text{vers.}^2\phi)}$

$$= \sqrt{(\sin.^2\phi + 1 - 2\cos.\phi + \cos.^2\phi)}$$

$$= \sqrt{(2 - 2\cos.\phi)} = 4\sin.\frac{\phi}{2}.$$

$$\therefore\ C = d \times \sin.\frac{\phi}{2}.$$

If $A = \frac{1}{16}$, $\phi = 360^\circ \div 16 = 22\frac{1}{2}^\circ$, and—

$$\sin.\frac{\phi}{2} = \sin.\,11\tfrac{1}{4}^\circ = \cdot 19509.$$

$$\therefore\ C = \cdot 19509 \times d.$$

There are so many able works on trigonometry that it is really difficult to make any selection; but if "F. G. M." fancies an up-to-date book, wherein lines are described as "point-transferences" and angles as "revolutions" running into thousands of "degrees," he cannot do better than secure one of the very excellent treatises by the Rev. J. B. Lock, M.A. (Macmillan, 2s. 6d. and 4s. 6d.)

West Norwood. HENRY T. BURGESS.

[96833.] — **Wimshurst.** — To MR. BOTTONE.— (1) base 65in. long, 34in. wide, the case itself being 60in. long, 28in. by 66in. high; (2) sectors 4⅝in. long, ⅝in. wide at top, ¼in. at bottom, 36 on each plate; (3) 3½in. diameter, 3in. wide; (4) spindle diameter, 1in.; (5) large balls on dumb-bell conductors 2¼in. diameter, small sparkers 1in. diameter; (6) 18⅜in. long, 2in. in diameter; (7) 180 revs. per minute would be the hghest permissible speed with glass plates. The length of spark depends somewhat on the capacity of jars used. You would probably get from 12in. to 15in. sparks. We get 9in. to 10in. easily out of our 6-plate 12in. machines.

S. BOTTONE.

[96839.]—**Spark Coil.**—To MR. BOTTONE.—The thickness of the tinfoil would produce no appreciable effect on the result; but if you interpose thick glass, or even thick paper, between the tinfoil of the condenser, you injuriously affect the condensation, as the capacity of the condenser decreases. But you can hardly say what is amiss until you have put in a contact-breaker in parallel with the condenser.

S. BOTTONE.

[96840.] — **Microscope.** — Impossible to say, unless "Micro. Amateur" will describe his lenses in full—i.e., say whether they are convex or concave, &c. If he will do this, I will endeavour to help him. OPTICIAN.

[96841.] — **Decomposition of Mercury.** — Mercury is an element, and therefore cannot be decomposed by any known means. If mercury is confined, and a sufficiently powerful current of electricity is sent through it to volatilise it suddenly, this sudden expansion will cause an explosion, if the containing vessel is not strong enough to resist the increase in pressure.

S. BOTTONE.

[96841.]—**Decomposition of Mercury.**—Mercury is an element. How, then, can it be decomposed? It is a good conductor of electricity, being a metal, and would therefore simply allow the current to pass through it. OPTICIAN.

[96841.]—**Decomposition of Mercury.**—Mercury being an element, it is a physical impossibility to decompose it. W. J. G. F.

[96846.] — **Voltaic Cell.** — Any manual of electricity will give all the information needed; but as to the actual ingredients of the cell, particulars as to what it is wanted to do should be stated. A Leclanché would do best for bell-ringing, a Daniell for steady and continuous work, a Bunsen for special "energetic" work. In the Leclanché the carbon is usually placed in the porous cell, but it is not necessary; the positions of the zinc and carbon can be reversed; all which has been explained many times. VIDEO.

[96846.] —**Voltaic Cell.**—There is no "best." It depends entirely on what you want the cell for. A good all-round cell is made as follows:—Zinc in outside cell; carbon in porous pot. Chromic acid 3 parts, oil of vitriol 3 parts, and water 20 parts, in along with carbon; oil of vitriol 1 part, water 12 parts in the zinc compartment. Always remove zinc when not using the cell. S. BOTTONE.

[96848.]—**Failure of Dynamo.**—Your query is not very clear. We should imagine you have got your lamps in series instead of in parallel, or that your dynamo series winding is opposed to the shunt-winding. This is the most probable reason of the failure.

Dudley. WEBSTER MICHELSON AND CO.

[96848.]—**Failure of Dynamo.**—You do not say if, when the dynamo is running without any lamps in circuit or with one only, the full voltage is generated. If this is the case, the fault may be due to the belt slipping, or to the armature shaft seizing, or to the series coils being connected incorrectly in regard to the shunt coils. If the latter, the ends of the coils will need to be changed over at the terminals. If the full voltage is not obtained when first started, the speed may be insufficient, or the shunt coils may be short-circuited.

G. W. LUMMIS-PATERSON.
Heaton, Newcastle-on-Tyne.

[96849.]—**Board of Trade Exam.**—The querist says he has "served five years in the drawing office," and yet has to ask about becoming a certificated marine engineer. He must go to sea in the engine-room for at least a year before he can "sit" for the exam. He can obtain full particulars by referring to the indices of back volumes or from the Board of Trade (Marine branch) itself. Some sea service (in the engine-room) is a necessary qualification before sitting for the examination. No difficulty about it, provided the candidate has the requisite qualifications; but there must be some service at sea in the engine-room. M. T.

[96849.]—**Board of Trade Exam.**—Make application to the Chief Examiner of Engineers, Mr. J. A. Rowe, 79, Mark-lane, E.C.

REGENT'S PARK.

[96851.] — **Colouring Photographs.** — To "CURIOUS."—The prints you name are not coloured by hand. If you require paints to obtain a similar result, and will forward 2s. to J. Hunt, 454, Chester-road, Manchester, he will forward you seven liquid colours he has made for his private use, which are easily applied without any previous preparation to photographs, and they can be used on any photo paper. NO NAME.

[96852.]—**Bicycle Rims.**—What "Benvenuto" requires is the "Roman" rim. This would, I think, exactly suit him. R. R.

[96857.]—**Test for Diamond.**—Distinguishing characteristics of pure diamond:—Name and colour—white, pink, yellow, red, blue, green, black, orange, brown, opalescent. Lustre—adamantine, reflects prismatic colours. Specific gravity—3·4 to 3·6. Hardness—scratches all other precious stones. Composition—pure carbon. System of crystallisation—monometric or cubicle. Form of crystal—cube, octahedron, rhombic dodecahedron, tetrahedron, hexa-octahedron. Refractive index—white 2·455, brown 2·487. Dispersive power—0·38. Electric properties—acquires positive electricity by friction, non-conductor of electricity. Fusibility—infusible, volatilised by long-continued heat. Diaphaneity—transparent and translucent. Carbonate opaque. These may partly help, but possibly following may be handier, although unsafe. Put the stone into a leaden cup with some powdered fluorspar and a little oil of vitriol; warm vessel over fire where a copious draught to carry off noxious vapours evolved. When vapours have ceased, stir the mixture with a glass rod to fish out the diamond. A genuine stone will remain intact, but a fictitious one will be corroded by the hydrofluoric acid generated around it. Perform only in the open air—dangerous. REGENT'S PARK.

[96858.]—**Doublets.**—The power of scratching glass as a diamond will. Pieces of crystal with colour between them, also piece of paste or glass covered by veneer of real stone. The real diamond has iridescence when catching light at a certain angle, the pale sapphire rendered colourless by exposure to regulated heat for some hours does not, although passed off at times. When set doublets are difficult to detect. When under part is of glass, application of a file to under as well as upper surface shows the imposition;—frequently sold by Cingalese to Europeans. Sometimes blue glass cut into facets are sent from Birmingham and Paris to be palmed off. REGENT'S PARK.

[96859.]—**Precious Stones.**—All bosh!

OPTICIAN.

[96861.]—**Shortness of Breath.**—Dr. Ruddock, speaking in his "Vade Mecum," gives thus:—Dyspnœa or difficult breathing may result from wasting disease in lung substance. Adventitious deposits in these organs; false membrane in air-passages, as in diphtheria and in asthma; a spasm of the muscular coat of air-passages or tubes causing dyspnœa. Asthma: After giving symptoms, physical signs, diagnosis, causes, he gives epitome of treament for attack. 1. Acon., ipec., cup., lob., ac. hydrocy., nitrate of amyle (by inhalation). 2. Asthma of children: Samb., ipec., gels. 3. From suppressed eruptions: Graph., sulph. zinc. 4. Chronic asthma: Ars., nux v., sulph., arg. nit., cocc., plumb., K. hydrid. Accessory means:—During fit, striking relief may be often obtained by putting feet and hands into hot water; smoking stramonium at the commencement of fit removes it like a charm in some. Inhalation of aconite vapour more certain and efficacious; also of sulphur, turpentine, or common salt, either inhaled from hot water or by spray-producer. Coffee as strong as possible, and as hot as it can be taken, without milk or sugar, is sometimes palliative. Holding breath as long as possible helps to relax spasm. Relief often obtained by fumes of burning nitre on a plate, done by placing pieces of blotting-paper, about size of hand (you can buy at many chemists this kind of paper or skin), previously saturated in a solution of the nitrate of potash; one of these dried pieces ignited and diffuses vapour in chamber; influence soon felt. After fumigation open room window wide to obtain fresh current of air. Dietary:—He gives some pages. Condensed: Avoid pastry, highly-seasoned dishes, too great a variety or too great a quantity at one meal, coffee and heating beverages. Much may be done on the side of the stomach. Sometimes diet should be weighed, hours of meal fixed and adhered to. Important point to take last solid meal at such hour as to allow time for its complete digestion before retiring. Suppers generally injurious; but a cup of bread-and-milk or a small sandwich is desired at times and may be taken. Shower-bath valuable. Exercise in the open-air not within one or two hours after meals, &c. REGENT'S PARK.

[96863.] — **Sticking Solution.** — Many things sold by stationers, such as seccotin, stickphast paste, Huggins' paste. Magnesite, sold by oilmen and colourmen, is a good sticker, and dries slowly. If you prefer making something yourself, try this: Strong glue, 50; dissolve with a little turpentine in

q.s. of water over gentle fire. Add thin paste of 100 parts of starch; applied cold, and dries rapidly.
REGENT'S PARK.

[96865.]—**Laminated Drum Armature.**—To MR. BOTTONE.—It would be practically impossible to get a working current of 20 amps. at 50 volts pressure out of an armature 4in. long by 3in. dia., because the wire you would need use to get the voltage would be too fine to carry the current without excessive heating. (2) The quantity of wire to be used for armature should be 100yd. (say 4lb.) No. 16 d.c.c.; and the F.M.'s would require about 12lb. No. 22 d.c.c. As you see, you would not get this amount of No. 16 on the A.; and if you used a similar wire, the armature would soon burn up its insulation. S. BOTTONE.

[96867.]—**Silencer for Oil-Engine.**—There is a patented silencer for gas-engines, and presumably it will do for oil-engines. It consists simply of a box containing stones, and has been described many times in these columns. Perhaps the patent has run out (I do not know the date), but I do know that the method has been frequently described. Hence I can advise the querist to look through the indices. There is no difficulty in taking the exhaust in such a way that it does not "annoy the neighbours." One way is to increase the size of the pipe (suddenly, as it were); but taking the exhaust through a box containing stones is a perfect cure.
L. M.

[96867.]—**Silencer for Oil-Engine.**—Turn your exhaust into a tub buried in the earth, attaching a small pipe to the inside of it for ventilating purposes. This would deaden any noise.
Dudley. WEBSTER MICHELSON AND CO.

[96868.]—**Oil Engine, Dynamos, and Cable.**—To MR BOTTONE.—(1) Depends on whether the insurance company would allow you to do it. If not insured, there is practically no objection, if the insulation of cable is good, say, at least, 350 megohms. (2) Yes, a trifle; a hundred revs. per minute more would suffice. (3) If the dynamo be a good one, 2,000 revs. would push up the output to about 58 volts; the ampèrage would, of course, be $\frac{50}{x}$, in which x stands for the total resistance.
S. BOTTONE.

[96870.]—**Perambulators.**—A good distance between the oil-holes in centre of large wheels is 21in. L. W.

[96871.]—**Image in Mirror.**—There is no image actually formed behind the mirror. The image seen is a virtual one, and has no actual existence. The chief difference between a real and a virtual image is that a real image is formed by rays of light converging to a point called the focus, and a virtual image is seen when diverging rays entering the eye appear to diverge from a certain point. This imaginary point is where the image is said to be formed. In the case of a plane mirror rays of light diverging from a point five yards away falling upon it are reflected. After reflection the rays have the same amount of divergence as before, and consequently will appear to diverge from a point the same distance behind the mirror as the object is in front, which in this case is five yards. You can find illustrations showing the course of the rays in almost any book treating on light. C. A. NAYLOR.

[96872.]—**Telephone Wire.**—(1) Yes. (2) No. (3) Because it is stronger for a lesser weight, and a better conductor. S. BOTTONE.

[96872.]—**Telephone Wire.**—Yes, it will do; but I should advise you bronze. The reason bronze wire is used so extensively is that it offers very little resistance and lasts much longer. S. ELLIMAN.

[96873.]—**Whole-Meal Bread.**—A MR. W. T. Hibbard, of Gloucester, some years ago read a paper on flour blended to give an ideal loaf, sweet and nutty flavour, of good size and appearance, of fine bloom, to keep nice and moist for days.

	Per cent.
For sponge :—	
High-grade spring American patent....	20
" " from white Dantsic .	10
For dough :—	
High-grade Cones flour	25
Talavera straight grade	25
Fine winter American, or Polish patent	10
Fine Hungarian	10
	100

Hard spring Americans include Manitobian, North Minnesota, South Minnesota, winter Americans, soft wheat, and hard Kansas. In whole-meal breads, hydrochloric acid and sodium carbonate in the exact proportions in which they neutralise each other. They then not only evolve carbon dioxide gas, but also yield sodium chloride or common salt. Thus:—

$$NaHCO_3 + HCl = NaCl + H_2O + CO_2$$

Sodium bi-carbonate. Hydrochloric acid. Sodium chloride. Water. Carbon dioxide.

Salt formed lessens quantity which would have to be added to the bread. Great care requisite in proper mixing of acid and carbonate; with meal right proportions to be taken. A rough measurement of strength of acid may be made by taking weighed quantity, say, 1oz. of the bicarbonate of soda, dissolving it in a beaker of boiling water, and then adding a few drops of litmus solution. Hydrochloric acid should be measured, or else a quantity placed in a beaker and weighed in it; then add acid little by little until one drop changes colour of bicarbonate of soda from blue to red. Then weigh acid-containing beaker; the loss in weight gives quantity of hydrochloric acid, equivalent to 1oz. of bicarbonate of soda. Commercial acid usually sold with guaranteed density of 1·5, or about 30 per cent. of anhydrous acid. As 84 parts of sodium bicarbonate are exactly neutralised by 36 5 of anhydrous hydrochloric acid, and as this amount is contained in 122 parts of the commercial acid, the bicarbonate of soda and hydrochloric acid of this density should be in the proportion of 2 to 3 by weight. It has been recommended that 3lb. each of acid and bicarbonate be used to the sack of flour; these proportions leave, however, a considerable excess of carbonate in bread. The great objection to acid method is that commercial acid almost invariably contains traces of arsenic. (Jago on Bread.) Not so long ago there was a formula for Hovis whole-meal bread. REGENT'S PARK.

USEFUL AND SCIENTIFIC NOTES.

AN electric tramway is now in operation between Cannes and Mentone. The tramway owes its origin to English enterprise.

THE State authorities of Pennsylvania, U.S.A., the centre of the oil, coal, iron, and steel products of the Atlantic Coast, are urging upon Congress the necessity for deepening the river Delaware. It appears that the Delaware River has only a 24ft. channel, while Baltimore has a 30ft. channel, Norfolk a 29ft. channel, New York a 30ft. channel, and Boston a 27ft. channel. It is estimated that the cost of excavating a channel 30ft. deep and 600ft. wide from Philadelphia to the sea would be £1,187,000.

The Largest Railway Station.—Describing the new Waverley Station at Edinburgh, *Engineering* gives a table which compares it with those of the Great Eastern Railway Station at Liverpool-street, London, and the London and North-Western Railway Station at New-street, Birmingham. These three stations are assumed to be the largest in the kingdom. The Waverley Station at Edinburgh is the largest. It covers 23 acres of ground, one-half of which is under roof. Liverpool-street Station covers 22½ acres, or half an acre less than the Waverley. It has 6½ acres under roof, or 5½ acres less than the Waverley. New-street, Birmingham, covers 10¾ acres, or 12¼ acres less than Edinburgh. It has 8¾ acres under roof, or 2¾ acres less than the Waverley. So far as platform accommodation goes the Waverley Station also heads the list. Alongside its platforms 130 carriages could stand, while at Liverpool-street Station 103 could be provided for, and at New-street Station, Birmingham, 69. In Edinburgh Station the lines are worked from 565 signal and point levers. One of the four signal cabins is believed to be the largest yet constructed, containing as it does 260 levers. Liverpool-street Station has three signal cabins, containing in all 424 signal and point levers. New-street, Birmingham, has six signal cabins, containing in all 584 signals and point levers.

The Great Earth-Mill.—Writing under the title "Secrets of the Earth's Crust," Prof. Cole, in the October issue of *Knowledge*, says:—"The central axes of our mountains . . . where denudation has had full play, show us the crushed and crumpled rocks brought up by folding from below. In certain regions, again, such as Scandinavia and north-west Scotland, mountain ranges have been worn down to the roots, have been laid bare in horizontal section, and here we come into touch with some of the more intimate secrets of the crust. . . . Rocks composed of more perishable or softer materials naturally suffer in still greater degree from the earth-mill. Gabbros go to pieces, the augites becoming dragged out as bands of brown-grey powder, and the basic felspars forming a compact and almost porcellaneous ground. In a great complex series of rocks, subjected throughout to pressure-metamorphism, it may often become impossible to recognise the character and relations of the original constituent masses. . . . It is odd to look from our microscopic section to the map of Europe, and to trace in both the action of the great earth-mill. The waves of contorted rock, pent up against some pre-existing crystalline core, and broken against it in all the complexity of overfolds and regional faults—what are these but the features that mark a gigantic foliation in the crust? The massive breccias that occur along the thrust-planes appear as films of flowing mylonite. At one point, an 'eye' provides attractions for the Alpine climber; at another, the yielding ground-mass has been seized on by the peasant for his fields."

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered, are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[96876.]—**Model Yacht.**—I am thinking of making a model yacht as much as possible on the lines of the *Shamrock*, and I should be much obliged if some correspondent could give me the principal measurements. I propose to make the hull about 2ft. long.—HAROLD.

[96877.]—**Electric Light.**—I am thinking of putting the electric light into a shop. Can any reader give the consumption in units per hour of 16c.p. incandescent, the large incandescent, and 500c.p. and 1,000c.p. arc lights?—A. COLTMAN.

[96878.]—**Trigonometrical.**—A B C is an equilateral triangle, and P is any point in its plane. Having given that the lengths of P A, P B, P C are a, b, c respectively, find the length of the side of the triangle, both when P is within and without it.—RADIAN.

[96879.]—**Rainbow.**—To "F.R.A.S."—Will you be kind enough to explain the cause of three very remarkable rainbows which myself and others saw in Tunbridge Wells on the 11th inst., time just before and after four o'clock? The tops of two bows pointed towards the sun, a part of one appeared perpendicular in the usual natural position. The two were high in the zenith. I hope they were observed by yourself.—H. HARMAN.

[96880.]—**Refraction.**—To "F.R.A.S."—Will you kindly explain how to correct the mean refraction for barometrical pressure when observing on a plateau about 5,600ft. above sea level. Most tables only provide for cases in which the barometer stands at 28in. and over. I wish, very precisely, to correct for refraction on observation under the following circumstances—viz., app. alt. 14° 40′ 0″, external thermometer 35° Fahr., bar. 24·3in., attached thermometer 35° Fahr. Thanking you in anticipation—MINER.

[96881.]—**Malting Wheat.**—Would any reader tell me how wheat or wheaten bran is malted? I know how barley is malted, but I am informed that wheat is treated differently.—MERCHANT.

[96882.]—**Vinegar Plant.**—Will someone describe a vinegar plant and how to keep it?—F. A. M.

[96883.]—**Diamond.**—Will an ordinary diamond be damaged if subjected to fire? If so, what heat would destroy it?—CHUCK.

[96884.]—**Zincos.**—Can any of "ours" kindly inform me how to make printers' zincos., or name a good book on the subject?—J. L.

[96885.]—**Egg-Shaped Mallet-Heads.**—I wish to know the way to bore egg-shaped mallet-heads? And can they be bored with lathe?—H. F. Y.

[96886.]—**French Verbs.**—Recently looking over an old French grammar (1814) I noticed that regular verbs of the first conjugation—(in *er*)—take *ois* in the imp. indicative, also in the conditional. This struck me as being so remarkable that I am induced to ask my fellow readers for information on the subject. I presume the pronunciation has changed with the spelling?—W. B.

[96887.]—**Clocks.**—Will any reader kindly inform me where I shall find particulars of the old clock in the "Rotunda" at Woolwich Arsenal?—H. D. H.

[96888.]—**Mountains Quaking Without an Earthquake.**—In Exodus xix. 27 we read, "The whole mountain (Sinai) quaked greatly." But "F.R.A.S." assures us, any earthquakes at that time (p. 184) have their existence in the imagination of your correspondent only, for assuredly the Bible says not one syllable about them. But how does the mountain quake without the earth? Shortly afterwards, the earth swallowed up Korah and his company (Numb. xvi. 33). I know of no story of earthquakes more plain in any history.—E. L. G.

[96889.]—**Objectives.**—Will "F.R.A.S." kindly say what is the value of an object-glass formed by two lenses of same kind of glass, with the transparent liquid element between—e.g., double convex lens, then water or HCl glycerine, then double concave or convexo-concave, or plano-concave lens? Any information will much oblige.—CURIOUS.

[96890.]—**Lahmeyer Dynamo.**—To MR. AVERY.—I have made a dynamo according to instructions given by you in the ENGLISH MECHANIC of May 7, 1897, with a four-pole armature. When driven at 3,000 revolutions it just gives current enough to deflect a galvanometer needle when put in circuit. I have tested the F.M. and A. insulations, and find them all right. The F.M.'s were magnetised by two bichromate cells. Is that enough, or should more cells be used? Is the quantity of wire right: 4oz. No. 20 on A., and 5oz. No. 20 on each pole-piece? I shall feel obliged if you will let me know the probable cause of its failure.—J. F. SEERVAI.

[96891.]—**Sun Views by Projection.**—Proctor, in his "Half-hours," recommends the use of a circular piece of glass ruled in quotations of $^1{}_{200}$in. apart, to form a network of lines across the image of the sun. What should be the cost of this (approximately)? Is there any other contrivance which would do as well, or better? Proctor says that a Huyghenian eyepiece should be used. Another book I have says that the Ramsden is employed. Are both forms suitable, or is there a mistake somewhere? If I use an ordinary diagonal to throw the image of the sun on a screen, in what way will the image be inverted? By using a diagonal I shall be able to screen myself from the sun, which otherwise is extremely difficult in this country.—E. G. R., Masulipatam.

[96892.]—**Harrison - Cox - Walker Telephone Instrument.**—Would anyone kindly give a diagram showing the internal and external connections of these instruments?—W. H.

[96893.]—**Gains and Losses.**—A limited company shows an annual profit of £1,520. Its (erroneous) trial monthly balance-sheets show that it has made £3,630. These trial monthly balance-sheets, although wrong as to actual amounts, are correct as to ratio, and show a *loss* as follows:—January, £670; February, £10; March, £750; April, £810 = £2,250. And they show a *gain* amounting to:—May, £1,310; June, £1,650; July, £900; August, £160; September, £610; October, £390; November, £90; and December, £770—in all, £5,880. How can you determine the actual gains and losses of each month, taking the ratio of the erroneous monthly balance-sheets as a basis to work upon?—E. P. P.

[96894.]—**Crickets.**—Having recently moved into a new house, we find it is infested with crickets. Could any of your correspondents give us a remedy to get rid of them? We have tried several powders, but they have not answered.—Cricket.

[96895.]—**To "Monty."**—Thanks for reply. What pressure per square inch is best in firing tube lamp? Will it work well if tank is below lamp, if the pressure is sufficient? Would a porcelain, platinum, or nickel tube be best? Do you consider that, taking into account the weight, complication, and cost of electrical ignition, it is to be preferred to the firing-tube and lamp? I have drawings of Pennington motor of about four years ago, to which you referred, and find that the petrol is fed into the air-pipe by a needle-valve, as you said. I should not think that this would be quite satisfactory, but should like to hear your opinion as to whether a vaporiser which thoroughly mixed the air with the vapour, and being heated, say, by the waste heat of the lamp, would not be quite as efficient and more simple than the carburettor described by "The Writer of the Articles."—Investigator.

[96896.]—**Drawing an Eccentric Ellipse.**—I wish to draw an ellipse as exactly as possible, having a major axis of about 20in., and a minor axis of about 3½in. This is a rather extreme eccentricity, and makes it a matter of some difficulty to draw this ellipse exactly. The foci are so very near the vertices that the most exact measurement I could make of it would perhaps give a serious error in finding points of the curve. The common method of finding the curve by means of a taut thread and two pins does not give trustworthy results, owing to the stretching of the thread at some parts, and fine wire is little better. Perhaps some of your readers may be able to advise me as to the best method of drawing an eccentric ellipse exactly, or what precautions should be taken in either of the two methods I have mentioned to secure accuracy? I use, of course, logarithmic paper.—B. B. M.

[96897.]—**Slade Micrometer.**—Can any reader suggest a handy way of illuminating a Slade micrometer, fitted on an ordinary 4in. equatorial refractor, German pattern, equatorial head, as usually made?—Fleur-de-Lys.

[96898.]—**Nickel-Plating.**—What is the best way of reducing the solution when it has become very acid, owing to the anodes failing to replace the equivalent of the deposited nickel? After neutralising with ammonia there is a precipitate, ammonium sulphate presumably. Will the addition of nickel sulphate—the single salt—set it right by combining with the matter in suspension, and forming the double sulphate? Any practical information will oblige.—E. A. W., Rhyl.

[96899.]—**Tides.** — Will some nautical reader, or perhaps "F.R.A.S.," kindly explain the following point to me? In the Admiralty tide-tables a list of ports in all parts of the world is given, with their respective times of "high water, full and change of the moon," from which the establishments of the ports are deduced. The expression "Time of high water, full and change of the moon" leads one to suppose that, at any given place, high water occurs at the same time both at full moon and new moon, and also that at each full moon and each new moon high water still occurs at a fixed time; but the moon does not become full or new at the same hour each lunation, nor does full moon occur at the same hour as new moon in a particular lunation. How, then, can high water occur at a fixed hour?—Fleur-de-Lys.

[96900.] — **Grammaphone.** — Will Mr. Bennett kindly inform me where to look for the fault in my grammaphone? It screeches every now and then, and the sound is not perfect. Is the diaphragm to be as thin as you can get it? Could any reader tell me how to drive my grammaphone with a weight running down a distance of 3ft.? I find that it requires to go round about 200 times to run a record down.—A. Walford.

[96901.]—**Wimshurst.**—To Mr. Bottone.—To make 18in. by $^1/_{16}$in. ebonite discs more rigid, and to dispense with washers between the two plates (which are now ⅜in. apart), I propose to fasten on outside of discs, with tire cement, two well-varnished wood discs, say, ⅛in. thick (or other material you may suggest). Will you please advise as to the wisdom of the idea, and also the largest diam. allowed without in the least reducing the efficiency of the machine?—Wm. Milnes.

[96902.]—**Gas Explosions.**—If you try to light the jet of a hydrogen bottle before all the air is expelled, an explosion occurs. If you light an ordinary gas-jet into which air has leaked, you get a blue flame, but there is no explosion in the pipe leading to the burner. Why is there this difference?—L. L. L.

[96903.] - **Double Contact Relay.**—Will someone please tell me how to manage this? I want to close two distinct electric bell circuits with one relay. In theory it appears simple; not so in practice, because if the two connections are made to back of relay, and the other connections to contact-pillar, if both batteries are not exactly equal the storage has a tendency to short circuit itself through the other when contact is closed.—Parallel Arc.

[96904.]—**Ashes or Cinder Sifter.**—Can anyone tell me some simple plan of "riddling" these without being a nuisance to the neighbours, and smothering myself with dust? There is a galvanised-iron arrangement patented that answers well, but it is too expensive. I have an idea of a sack-bag to fit the riddle and another to cover it. Will someone please put this into a practical form? Any suggestion will oblige.—Hard Up.

[96905.] - **Negatives of Diagrams.**—Will someone give me hints upon taking photographic negatives of diagrams drawn in black upon white paper? I fail to get sufficient contrast between the lines and the ground of the negative, with the result that while the diagram prints out, some light gets through the body of the negative as well, and what should be the white ground of the print becomes discoloured. My method has been to fasten the diagram to the wall opposite to the window, so as to secure a good light, and then to photograph it.—A. P.

[96906.]—**Arc Lamp.**—Will some electrical reader kindly explain—1. Whether a hand-feeding arc lamp can be got to burn steadily without spluttering? 2. Why some carbons have a soft core in their centre? 3. What is the best diameter for + and − carbons for lantern use, having special regard to steadiness? I have recently been experimenting with a Ross-Hepworth arc lamp, with the intention of using it for illuminating cinematograph pictures, but have not been able, so far, to get it nearly steady enough for my purpose. I have been using it with 13 amps. 60 volts. I got a very good quality of light, the only objection being the spluttering. Is this the fault of my inexperience, or what?—Lanternist.

[96907.]—**Wireless Telegraphy.**—To Mr. Bottone.—1. I have made a coherer on Marconi's plan with filings in a glass-tube in circuit with a relay and a Leclanché cell. The relay has a soft-iron core, horseshoe shape, wound with 2oz. of No. 30 s.c. wire. The armature is soldered to a thin strip of brass cut from a cartridge-case, and adjusted with two brass screws, which make a connection with a similar cell, an electric bell, and the decoherer. At the transmitter end I have a ½in. coil, three brass balls arranged thus—o O o, connected with a vertical wire 8ft. high. With this I can ring the bell in any part of the house; but when rung the bell will not stop until disconnected from the cell, notwithstanding the vigorous working of the coherer, as the slight sparking of the relay and the bell appear to excite the coherer afresh. How can I prevent this? 2. The vertical wire of the coherer is only 24in. high, as I wish the bell to be portable. Would a strip of metal arranged horizontally like wings be more effective? And would the addition of another ball, thus—o O O o, increase the power and range of the electric vibrations? The length of the vertical wire at the transmitter end is limited to the height of the room, and the effect of the discharge is not always sufficient to ring the bell on first pressing the push. Is this due to want of sensitiveness in the coherer and relay, or to the shortness of the vertical wires?—G. M. S.

[96908.]—**To Mr. J. Dormer.**—Will you be kind enough to answer the following questions? (1) Whether I can take antiquarian photo. prints by electric light in an ordinary flat printing frame? If so, how many are lamps shall I require, and what candle power? (2) Recipe for ferro-prussiate printing paper. (3) Whether I can put sensitised solutions on parchment without it crinkling up. The reason I ask No. 1 is because I have a flat frame and want to save buying a special cylinder, if I can do without.—W. J. A.

[96909.]—**Gilding.**—Will any of "ours" tell me how to gild the edges of a few books? I want to do them myself if possible.—Gilder.

[96910.]—**Belt Lacing.**—Will some reader tell me how the leather is prepared that is used for belt lacing? If it is not a trade secret a full description will oblige.—Oudeni.

[96911.]—**Accumulators.**—Will any of our readers please say in what respects (apart altogether from the expense of forming) the "pasted" plates are better or worse than the Planté method.—L. W.

[96912.]—**Pasting Accumulator Plates.**—Will some electrician kindly tell me if there is any chemical that may be mixed with the red-lead paste so as to make it harder or less liable to fall off when in use? Also, how may spongy lead be made satisfactorily, as I have tried making it from lead acetate, precipitating it with zinc, but it crumbled and became hard when pressed into the grid? It is also a rather expensive way when a lot of plates are to be pasted. And how can I make porous lead plates like those made by the Crompton-Howell Company, as their way of casting a large block and sawing it into plates is impossible for an amateur?—P. A. S.

[96913.]—**Workshop Lamps.** — All things considered, what is the best lamp for a workshop where plenty of artificial light is required, by burning paraffin-oil—duplex, round wick, or the patent lamp requiring no chimney and wound up with a key? What class of reflectors are the most suitable, giving back the greatest amount of reflected light? Can I increase the reflection by a block-tin reflector round top of chimney, or shall I require a white enamel one? In fact, I want all the light possible to be obtained from such lamps, and as they are so varied and numerous on the market, it is hard to choose.—Jasmine.

[96914.]—**Astronomical.**—Would any reader kindly show me how to find (in mean solar time) how long a star which rises exactly in the east remains above the horizon?—Novice.

[96915.]—**Comets.**—What is the origin of this statement? Astronomers say that in the solar system there are at least 17,000,000 comets of all sizes. Why "at least," and who are the astronomers?—D. B.

[96916.]—**Isle of Man Steamers.**—Thanks for "Red Admiral's" reply to my query in last week's edition. There is one thing not mentioned, the speed of the two steamers *Mona's Queen* and *Peveril*. He gives the *Tynwald*. If unable to give it, perhaps he could give the *Duchess of Devonshire*, of Barrow. That boat left same time as *Mona's Queen*, and kept almost level with us, so if he could give some particulars of this boat will oblige. Or could he give the distance in miles from Peel to Belfast, Douglas to Fleetwood, and Douglas to Ardrossan? Time taken 4 hours, 3½ hours, and 7 hours respectively.—Alexander.

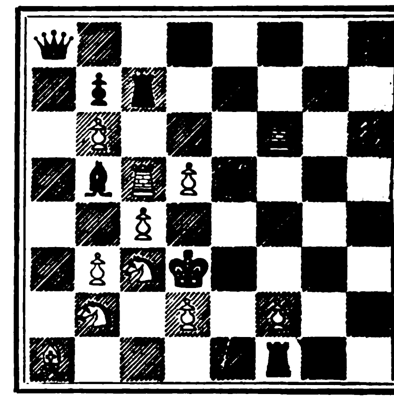
[96917.]—**Faint Stars.**—Among several correspondents to the "E.M." in 1876, re faint stars between ε 1 and ε 2 Lyræ, Mr. R. A. Proctor, in No. 597, p. 640, sends a chart of the stars observed by Mr. Bassnett in the "clear air of Western America," with a 6¼ refractor, by Fitz, of New York, of "singular excellence." The chart contains about 100 minute stars! Isn't there some mistake? If a correspondent of less weight than our revered "R. A. P." had spoken it, and apparently thought so much of the chart and of the observer's trustworthiness, I would not have mentioned it. Mr. Proctor, too, mentions somewhere of Vega's 36 companions (in his "Half-hours," I believe), observed at Harvard. Isn't there some mistake here, too?—A. Ashby, Croydon.

CHESS.

All communications for this column to be addressed to The Chess Editor, at the Office, 332, Strand.

PROBLEM No. 1697.—By A. F. Mackenzie.

Black. [7 pieces.



White. [13 pieces.

White to play and mate in two moves.

(*Solutions should reach us not later than Oct. 30.*)

Solution of Problem No. 1695.—By C. A. Gilberg.

Key-move, B-K sq.

NOTICES TO CORRESPONDENTS.

Problem No. 1695.—Correct solution has been received from Joseph Elster, F. B. L. (Devonport), Rev. Dr. Quilter, Richard Inwards, A. Tapman, J. E. Gore (we noticed the coincidence too late), G. W. U., F. B. (Oldham), T. Clark, Quizoo, T. Jones, W. Walton.

F. Chipperfield.—Only solution of No. 1694 as published last week.

Whin-Hurst.—May he win a V.C.!

The North Bessemer Tunnel on the Pittsburgh, Bessemer, and Lake Erie Railroad is nearly 1,000 yards long, of horseshoe section, 23½ft. high, and 26ft. wide. The excavation was carried on from the ends and two intermediate shafts, and consisted first in driving a top heading of from 19ft. to 21ft. bottom width, and 8ft. high at the centre. This heading was followed by two benches, the first or upper bench being loaded by means of chutes into side dump-cars. The lower bench was blasted loose, and loaded into grading-cars by steam shovels.

To Preserve Fish Glue for Process Work.—Herr Gaedicke recommends the following method in the *Photographisches Wochenblatt*. Clear the whites of some fresh hens' eggs and beat them to froth. Let them settle for twelve hours, and pour off the clear fluid. The following stock solution should then be made up:—Albumen 7c.c., fish glue 7c.c., distilled water 14c.c., carbolic acid (five per cent.) 1c.c. After well mixing, filter the solution thrice through cotton-wool. The solution will become perfectly clear if it is allowed to stand for some weeks; but this is unnecessary, as the particles which produce the cloudiness are so fine that they may be disregarded. A 10 per cent. solution of ammonium bichromate should also be prepared. Both solutions are stable. For use mix four parts of fish-glue solution with one or two parts of bichromate solution, and then add ammonia drop by drop until the fluid is of a greenish straw colour. The sensitised solution should be mixed fresh each day, and the unused portion thrown away. This method will be found conducive to regularity and certainty of results.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, OCTOBER 27, 1899.

INLAYING.—III.

APART from the commonly-known woods, such as pine and its varieties, as red, yellow, white, American, and that beautiful class known as Swiss—all of which, by the way, come very acceptable as grounds to work upon—we have the choice of the more expensive, such as mahogany, birch, oak, walnut, and Hungarian ash—woods that are light-brown tint is employed, coloured woods show up well, without any adjunct whatever. Oak is seldom used; mahogany is the general medium as much in years past as at the present day. Most of our work will be in mahogany, so need not comment further here.

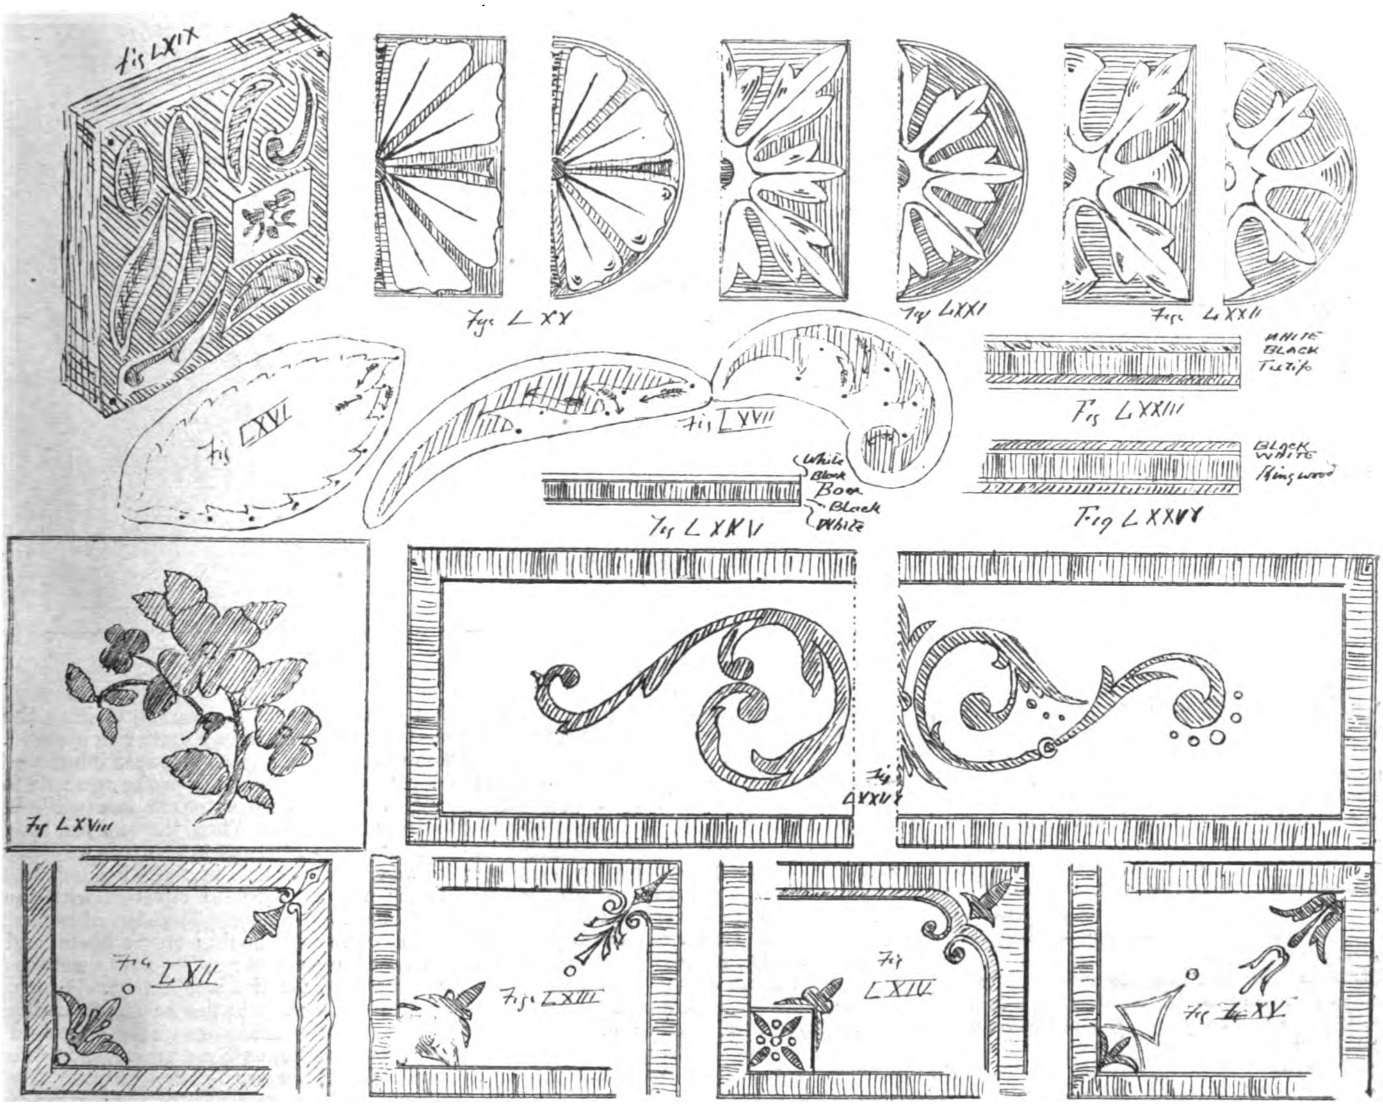
Kingwood, from its rich dark browns, reds, and yellows, is also an excellent banding, and when used in widths up to 3in. show up grandly. Coromandel forms an excellent medium for silver ornament, its dense brown red and straight figure lending well to ornamentation when in small panels or friezes.

Other woods again can only be employed in direct conjunction with those of greater or lesser contrast; as, for instance, Amboyna much sought after, and in general use for a better class of work. Though possessed of a certain amount of colour and figure, they are not so beautiful as the rarer kinds, known as rosewood (a misnomer), or, more properly speaking, polysandra, and tulip wood, which has another name, "Bois de Rose." The former is a fine medium for white ornament, and is also used for flowers, though we must candidly confess there are many pieces of cutting of this sort that should not have been recognised, some flowers almost merging into the ground. Good contrast can always be got with little trouble, if a panel is formed of another colour ground, and then superimposed, so to speak, on the greater, or rosewood, ground. Either of the above woods looks well as a banding, both wide and narrow, and give effect and relief that cannot well be described on paper. Walnut is largely used for both flower and ornament, and if the burr or Turkish walnut of a medium with neat flowers, will bear a satinwood or black banding, or both together if of narrow dimensions, or, if with boxwood ornament, cut in has a pleasing effect, and can either carry a border or not. Boxwood, by the way, is not used for panels and such portions, but is invariably used either as stringing or cut, as above stated.

A choice variety of rarer woods can be got with such as acacia, hawthorn, snakewood, partridge, pear, apple, and quince; for flowering ornament, green and violet ebony, and pomegranate in narrow bands look well with coloured ornament cut in. Amaranth, a rich purple which darkens when exposed to light, looks rich if cut as an ornament, and let into a satinwood or Hungarian ash ground. Coral and sandal look well as little ornaments superimposed on dark grounds. There are many more; but we think the above quite sufficient, for even the most fastidious cutter.

The principal wood used in dyeing is holly. From its whiteness and even texture it is largely in demand for white ornaments and coloured flowers. It is, in fact, the marquetry cutters' typical wood, not only for reasons above stated, but because it holds up well under the saw, whether cut across or with the grain, and takes the different dyes admirably. Plain grain sycamore and chestnut are both white or nearly so, but are not used to any extent, therefore call for little comment.

The different colours and tints in request are gained by steeping the veneers in a boiling solution for a given time, or pouring the hot liquid on the veneers, which lie in troughs or other receptacle, and letting them soak, sometimes for days together.



For small pieces of veneer, an ordinary frying-pan and an inner dish, well glazed (a pie-dish will do), and of such size as will leave a space all round ½in. less than the pan, will be about the size. The pan will require a thick layer, ½in. or so, of silver-sand, in which the dish with the required dye is laid. The pan with the sand will be required to shade our work when cut, so need not be cast aside. We use the sand wet to dye with, and dry when shading. The different tints or tones of colour are gained by a shorter or prolonged immersion. Hot liquids with the articles therein take less time, as a rule.

As blackwood plays an important part, and is largely used, the method of dyeing will be treated first. A two-solution dye is needed to gain the best results, although those who are able to purchase the French stain that is in the market will avoid much trouble. For those who cannot, the following

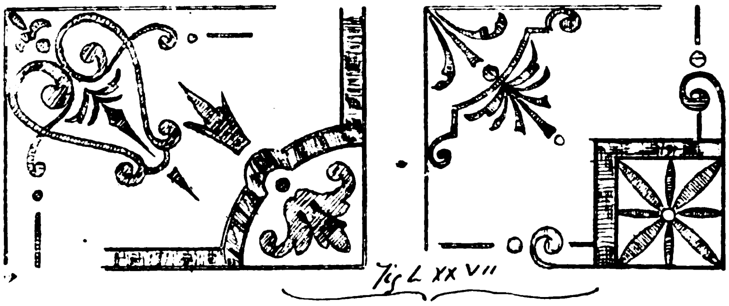


Fig LXXVII

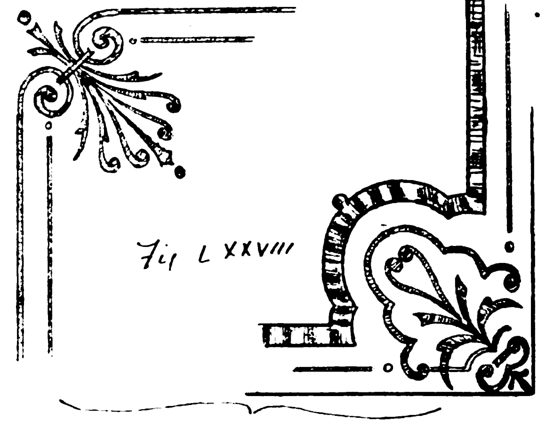

Fig LXXVIII

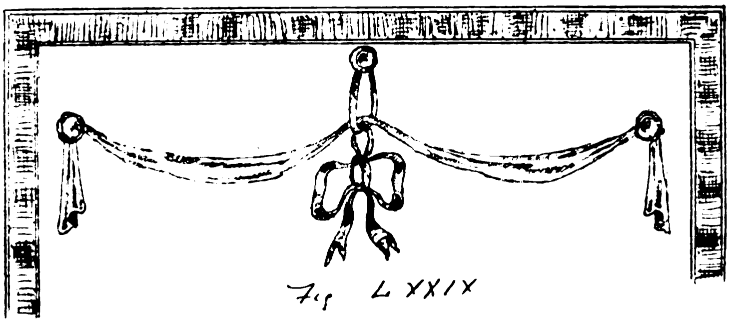

Fig LXXIX

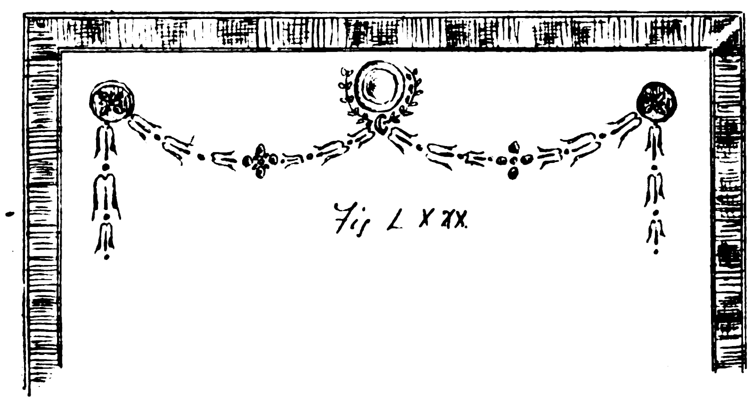

Fig LXXX

Fig LXXXI

is reliable:—To ¼lb. of logwood chips are added three pints of water, some walnut peelings, and half a pint of vinegar; the whole to be made quite hot in using. The second solution is simply ½oz. green copperas dissolved in a pint of water, also made hot. The process is to immerse in the first liquid or decoction until thoroughly permeated; when partially dry, the wood can then be immersed in the second until the desired depth of black is gained. Test it by cutting a piece off.

Let us here caution the manipulator to keep all veneers as flat as possible; that is easily done by pressure. When the veneers are half-dry, they should be retained under pressure until thoroughly dry. Changing the position by bringing the centre pieces to the top and bottom will improve matters. It is a difficult job to cut six or eight thicknesses of veneer if they are buckled or uneven, irrespective of breaking saws innumerable. A hot solution of nitrate of silver will blacken if the veneers are exposed to the light or sun's rays for a short time. The persulphate or acetate of iron can be used in lieu of the copperas solution.

Reds and scarlets are gained—the former with cochineal, the latter with scarlet lac dye, or some pieces of scarlet cloth boiled in with the veneers, adding a little chloride of sodium or common salt. Chloride of tin and Brazil-wood chips, or a strong solution of logwood ditto, will give good reds.

Sulphate of indigo is in general use for blues, and the addition of potash will give any tone from light to very deep. A saturated solution of verdigris, or the chloride of tin above mentioned in solution as the preliminary dyeing, after immersing the veneers in hot fustic liquor. With this recipe any tint can be gained at will.

A violet tone is got by using the tin mordant. Afterwards lay the veneers in a hot solution of logwood.

Yellows are got by means of turmeric and saffron, with a little picric acid. (The latter is poisonous.)

The above are the principal solutions in use; but much may be done by resorting to the natural coloured woods where applicable, although the process of dyeing is simplicity itself. It is far better to purchase the veneers ready for use if possible, and that applies to the narrow strips or stringing, as above mentioned. Yet we shall in future chapters explain the method of making-up bands, narrow borders, stringing, &c. Handle your veneers with wood forceps or tongs; if cuts or bruises are prevalent, the above solutions will not tend to mend matters.

For ivory work much of the above may be used; but let us here say, cut your articles, or, rather, ornaments first from the natural ivory and then dye them. Artificial ivory must be purchased already stained, as we know of no method of doing it (it being a patent). Soda tends to darken mahogany; potash also darkens—especially is that so with oak.

Preparing the Wood for Cutting.

If only one or two veneers are chosen, then a backing of some sort, preferably the waste pieces of pine used to make small boxes are excellent, and not costly. Some fine wire nails will be required, called "veneer pins." They can be purchased at any veneer merchant's. A given quantity of veneers are cut of an even size—say, for convenience sake, about 6in. square. When the veneers are pinned together at the four corners, the pounced design is glued on the uppermost veneer. Thin glue is best for this reason: in cutting we must keep the work as free from sticky matter as possible. Some cutters used greased paper interposed between the veneers. We prefer as a rule to apply a little beeswax to the saw while in the act of cutting. When the saw has been thrust to its limits from the cutter, we apply the wax, which is held in the left hand, and of such a size as not to interfere with the handling of the veneer. The saw, of course, cannot be turned, having only a lateral and downward movement; consequently we must turn the work for the saw to cut. A little practice will soon gain the knack of turning to a nicety, the guide answering a twofold purpose: it enables us to cut square, and takes the weight off the wrist of the cutter.

The first four examples that are given at Figs. 62, 63, 64, and 65 should be sufficient to enable the cutter to overcome some of the obstacles that may appear difficult in future designs. Assuming, then, the earlier and simple examples have been tried, upon reference to the rough sketch in perspective of our work, it will be seen to have a few round dots marked. That is a guide to a system that must be adhered to throughout the cutting examples, and is explained to suffice for all. All work must be started from as near the centre of its bulk as possible, and *worked outwards*. For that reason we bring into service the handy little tool the Archimedean drill, and drill a hole through the entire thickness and at the spots, as dotted. Were we to start cutting our ornament from the outer edges, it is just possible the veneer at that part cut would foul the jaws of the donkey, and break up. To avoid that, we ever endeavour to keep the outer portion intact.

Again, the more surface there is to be grasped in the jaws, the better the holding;

Fig LXXXII

Fig LXXXIII

Fig LXXXIV

Fig LXXXV

whereas, if we commenced at the edge, more than half our work would be cut away.

The other reasons will be self-evident as we proceed in our work. It must not be inferred that as we sketch our panel, corner, or whatever it may be, so it is cut. Not so. For economy's sake we subdivide it, and glue the leaf upon the green veneers, the bud upon the red, or whatever colour is needed—in short, our little blocks of 6in. square are mostly of the one colour, but can be of two or three shades. The same applies to the flower blocks. The design as cut in paper form must be as close to the dots (the pouncing) as the scissors will permit.

Fig. 57 indicates the travel of the saw as the arrows point. To cut a sharp angle as at A, it is necessary to draw the saw back gently. Cut a little space away as at B, which will enable one to make the back of the saw take the place of the teeth. In that way we shall be able to retain sharp and definite serrations at the bottom, as shown at Fig. 57. It then remains to cut outwards. By turning the saw completely round, a hole will be made sufficient to commence the second downward cut, and so on until the whole side has been cut. To return the saw to our starting-point—as, for instance, in a leaf—a little of the waste can be cut away to give freedom, finally meeting the two cuts at the base of the leaf. As dexterity in the use of the saw is gained, so can the operation be varied; but in no wise should a slender piece of work be cut on one side entirely. Endeavour to cut from both sides, leaving the greater bulk, which is the strongest, till last. One of the most difficult pieces of work we have to contend with is an ornament, flower, or leaf in *cross* grain. To get the point intact, the weakest support should be cut away first. It may happen that there is little perceivable difference; in that case it is advisable to cut on both sides a little at a time, and that very gently, until substance remains to stand the strain of the saw. Reference to Fig. 67 will assist us in our meaning. In work of more complicated a nature, a duplicate-formed design will be needed to assemble the cutting upon, for reasons previously stated. A duplicate design is got by taking a rubbing with heelball.

Having blocks ready with the designs glued on, and the holes drilled, the saw is released in the front clamp and guided through one of the drilled holes, with the design facing the cutter. Spring the frame together, and clamp the saw tight. The frame is best taken out of the sockets, and by turning the frame completely over, resting on our left side, it should not be a difficult matter to slip it through the hole and pinch up without breaking the saw.

Do not hack your work; endeavour to thrust the saw through its entire cutting length; but in turning, and on very delicate portions, due care must be exercised, otherwise broken work or broken saws will follow.

We must not overlook this fact: that we shall require as many pounced designs as we have different coloured woods. For instance, a given design, as at Fig. 68, contains two reds, two greens, one blue, and one white. If our blocks of veneers contain two or more shades of a given colour, then one paper-pouncing of each will suffice. The two flowers should be got from one block, the five leaves from one block, the two little centres of white from one block, and the bud, if not of the colour desired in the flower block, must be cut from a separate block of lighter tints. If a vase is required, one block only will be needed. The cutting of the design will require a slight modification where it is intended the saw cut or kerf should show a division, then the pouncing need not be cut up; but where the jointing is desired close, separation is necessary to enable one to cut half the dots (pounced) away, so that when brought together a close joint is attained.

Fig. 68 shows how a ground-work design is glued on to cut away so as to leave room for the different pieces that are cut separately. Fig. 69 gives the nailed-up block of veneers, and shows the manner of utilising our blocks to the best advantage. Figs. 70, 71, 72 are practical illustrations of adapting the square design to a circular, or *vice versâ*. Figs. 73, 74, 75 show how narrow banding is glued up for small quantities. The cutting-gauge has to take the place of the circular saw. The best method is to cut from cross-grained woods, of such selection as pleases the reader, and to unite them on a piece of paper by gluing the paper with thin glue, and working up the amount that may be required. Whether it is only two breadths or twenty, the process applies to all. A thin lath is nailed down on the paper as a guide, the paper being still tacky. The first line or string is put close up to the lath, the other lines and landings are worked up until the amount required is made up. Where the widths are supposed to separate, do not put any glue, but the other jointings may as well be glued. It remains, when dry, to separate each width with a thin knife. It may be found, in working up wider bands than a ½in., necessary to apply a few weights or heavy piece of flat wood, to keep them flat. The bandings can be let in before veneering. In that case, they are assembled in conjunction with the marquetry cutting, and held together here and there with a few veneer pins, allowing them to stand up when the work is complete. A piece of paper is glued and laid on bodily, forcing adhesion of the paper to the veneers with a stiff shoe-brush. If it is found necessary to apply weights or a piece of heavy wood, the veneer

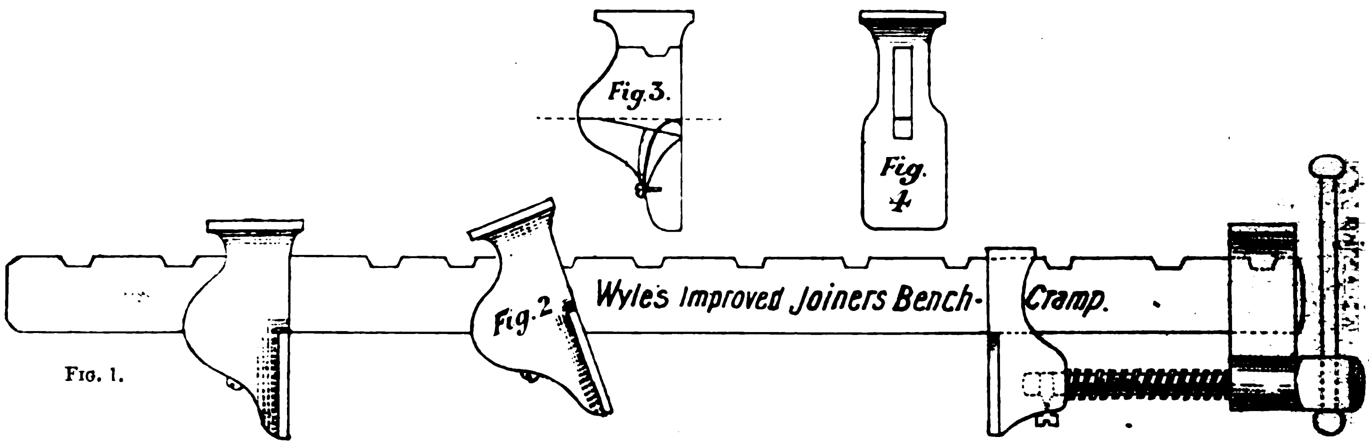

Fig. 1.

pins should be gently prised up; but in no case should they be bent over on a piece of delicate work. A heavy piece of wood, that is flat, should prove efficient without warming, but if the air is cold, and unavoidable delay has chilled the glue, then warming the wood first will be of service.

Fig. 76 shows the half-lengths of two simple little friezes, and can be cut with the banding, or simply a broad line; or the cutting can be simply in a ground only. It is suggested to cut them in box or holly, as an object-lesson, and as progress is gained, they can be altered to suit the taste at will, if cut as above in holly and let into a walnut ground have a graceful appearance. As a light little ornament on a bookcase frieze, or even on a door or drawer front, their uses are many, and they will well repay careful cutting.

Fig. 77 shows four corners, requiring just a trifle more care and patience than previous examples.

Fig. 78 shows some still more difficult, and can be utilised for doors, panels, or wide drawers' fronts, and, if cut in holly and let into a walnut ground, will give satisfaction. A better effect is gained by cutting the ornament in boxwood, let into a rosewood ground; but due care is necessary in cutting, as boxwood is more brittle than holly.

Figs. 79, 80, and 81 are panel tops. The latter is a very effective panel, and should be enlarged four to eight times, and may be in two colours only for the first trial, viz:—The flowers and buds in red, and the leaves and stem in greens, but is intended mainly as an example of judicious display and graceful development.

Fig. 82 is a more difficult lesson in twisted leaves, and may be cut in any waste, not being intended for use. Further designs will give the twist in conjunction with flowers, &c..

Fig. 83 is a bolder design. Figs. 84 and 85 show a coarse specimen of flower-cutting, and an example of buckled or bulged leaves.

IMPROVED JOINER'S BENCH OR SASH CRAMP.

THIS Cramp is a very useful one, and well worth the attention of builders' toolmakers. Fig. 1 shows the shoe in position, Fig. 2 shows the shoe at liberty to slide to any part of bar. Fig. 3 is half of shoe. The thick curved line indicates spring which holds shoe in position on bar. Fig. 4 is a front elevation of shoe. The advantages of this cramp are that the edge of the bar does not in any way damage the work. The shoe when in position (Fig. 1) is perfectly rigid and square to the work. There is no loose pin to fall out or wedge to slip. As will be seen by illustration, it will stand firm on its back on the bench. Fig. 4 is a front elevation of shoe. This invention is to be disposed of by the patentee, Mr. J. A. Wyles, 3, North Fields Cottages, Stamford, Lincolnshire.

THE deepest-running stream in the world is said to be the Niagara River, under the Suspension Bridge.

MILLWRIGHT'S WORK.—XIV.

TO set end brackets like those in Fig. 44, p. 52, a plumb-line is set in relation to others on the line of the shaft, by centres, and sighted along. This gives the horizontal position. For the vertical position a parallel strip is used from the faces of the brackets, or from the bottom seating of the bearings. When the vertical centre and the height are thus fixed, a templet (Fig. 83) is used to set out the bolt holes in the wall, and the work proceeds as in previous cases.

Parallel lines of shafting are laid out either by marking them with chalk lines on the ground, and plumbing by them, or by working from one shaft already fixed, using a gauge which measures the exact distance between the shafts; or if the shafts are parallel, but not in line, a cord may be extended from one already fixed, and measurement taken from the cord to the shaft adjacent.

Pulleys are set in line by means of a cord strained from the edges of the fellow. In case the pulleys should be badly hung, which, of course, should not be the case, the shaft may be turned a quarter round and tried again. There are two excellent tests of the mutual fitting of a shaft and its bearings. The first is the turning of the shaft by hand, when the good fitting or otherwise is indicated by the degree of freedom with which it can be revolved completely and in

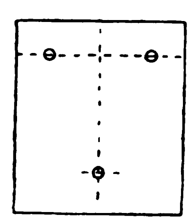

Fig. 83.

different positions of rotation. The other is seen in the results of lubrication. If a bearing is being cut away by its shaft, the waste lubricant is coloured and thickened more or less deeply by the abraded metal or alloy. If it is not, the lubricant remains clear for an indefinite time, so clear that it can be used repeatedly.

The erection of shafting has been much simplified and cheapened by the use of swivel bearings. When bearings can be adjusted in place, there is less necessity for the care in setting the pedestal bracket, hangers, &c., described in the last article. It is extremely difficult and tedious to fix up these to beams, walls, and pillars by the aid afforded by straining lines, straight-edges, levels, and strips. These are all open to errors, slight in themselves, and relatively to the nature of the aids and appliances used, but of considerable magnitude in relation to the linear truth of shafting. It must be clear to anyone that there is a vast difference between fixing a bearing true by its foot to a beam, wall, or pillar with bolts, and adjusting a swivelling bearing in its foot, or surrounding framing. Apart from the awkward character of the work in many locations, it is not possible to obtain so great exactitude in the first case as in the second. A number of little liabilities to error creep in, all more or less cumulative. Even the final tightening-up of bolts will draw the work out of truth to an extent greater than is really permissible in the correct alignment of shafts. So that men will not infrequently spend as much time in making minute adjustments, without anything to show for their work, as would suffice to erect and finish a line of adjustable bearings. And then there is the possibility that similar adjustments will have to be performed again within a year or two.

In erecting rigid bearings adjustments have to be made in vertical and horizontal directions, and

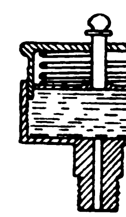

Fig. 84.

it is the combination of these which wastes so much trouble and time. When one is got right, the other is often found to be wrong, and the work has to be gone over again.

One method of erecting shafting takes advantage of the use of a water-trough, laid down in place of the levelled blocks alluded to in the last article. The Webster Manufacturing Co., of Chicago, have improved on this by the employment of a hydrostatic level. It consists of two tubes set vertically on feet, connected with a length of hose, and fitted with stopcocks. The tubes are divided into inches and parts of the inch, and will indicate to 3¼in. variation in height. Within that limit the level of the water in the tubes will give truly horizontal positions anywhere up to 25ft. apart.

In a bearing of great length, and well fitted, there is practically no wear, and a most minute expenditure of oil. With short and rigid bearings an enormous quantity of oil is wasted without much to show for it. It becomes literally squeezed out, leaving the metallic surfaces in contact and liable to abrasion.

There are two principal methods of lubrication adopted—the fluid and the solid. In the first, the oil is either poured or fed into the bearing, and allowed to run into waste cups or trays below, to be thrown away or filtered and used

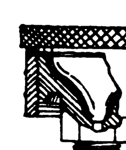

Fig. 85.

again; or it is used on the self-oiling principle, being carried over the bearing constantly with chains, as illustrated in a previous article. In the second method, solid lubricant is employed, being pressed down by a small piston or cap. Each method has its advocates; each has given excellent results.

The needle lubricators for oil have the disadvantage that they feed without intermission. They are, however, vastly more economical than the older crude methods of hand oiling. The

present tendency seems in favour of solid lubricants, used in Stauffer's and Reisert's and similar vessels, in which the supply is constant without waste. The cover is generally screwed down by hand at intervals of a few days, or it is loaded with a shot or with a spring.

Two or three types of lubricators for solid lubricant are shown in the figures. In one, Fig. 84, gentle pressure is exercised by a coiled spring over a piston, and the cap is screwed down as the lubricant diminishes in quantity. In Fig. 85, pressure is exercised only by the screw-down cap. In Fig. 86, the type by Trier Brothers, a tell-tale indicates the diminution of the lubricant. A cylinder standing over the screw-cap incloses a piston A, actuated by a weak spring. A rod B attached to the piston passes through the top, and shows

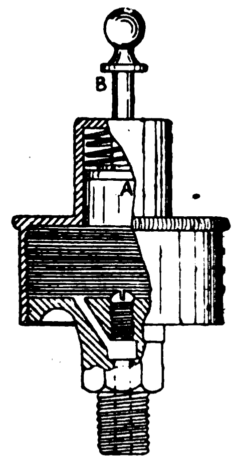

Fig. 86.

by its descent the working of the lubricator. By reason of the difference in the diameters of the piston and of the reservoir, the former descends more rapidly than the lubricant sinks. When it has reached the limit of its movement, the turning of the cap raises it anew to the top.

The Reisert lubricator, by the same firm, is a very good type. It consists of a glass reservoir, slightly conical in form, in which works a soft leather piston which is attached to a hollow stem. The piston is weighted with shot or washers. The conical form of the reservoir permits of equal pressure on the lubricant, whether the latter is full or only partly so.

There are many varieties in the Stauffer type of lubricator besides those shown. Conditions vary so much that one type would not cover all the cases that arise in practice. A great advantage of these is, that the flow being due to exercise of pressure, position is of no consequence. They can be stuck above or below bearings, or horizontally, or diagonally, and will be efficient in either case—saving much of the trouble which attends the fitting of oil lubricators in any but vertical positions. They save time spent in oiling, since a turn of the cap about once a week suffices in ordinary shafting. J. H.

The method of finding the Sidereal Time at Local Mean Noon at any other station is described on p. 454 of Vol. LXVIII.

As the period of Sunspot Minimum has now definitely arrived, the sun has lost all interest to the observer possessed of any ordinary telescope. The last minimum, it will be recollected, occurred in 1889·6, so that 10·1 years only have elapsed since; the period of 11·11 years of certain textbooks having thus broken down entirely.

Mercury

is an Evening Star, attaining his greatest elongation east of the sun (22° 18′) at 4 p.m. on the 16th. His very great and increasing south declination, though, will seriously interfere with his observation in these latitudes, and he will be wholly invisible to the naked eye. His angular equatorial diameter increases from 5·2″ on the 1st to 9·2″ by the last day of the month.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	15 38·0	21 32·1	0 55·6 p.m.
6	16 6·9	23 20·4	1 4·8 ,,
11	16 34·5	24 37·9	1 12·7 ,,
16	16 59·2	25 20·6	1 17·7 ,,
21	17 17·9	25 23·9	1 16·6 ,,
26	17 25·2	24 42·8	1 4·2 ,,

It will be seen from the above ephemeris that, starting from a point in Libra, Mercury will cross the northern spike of Scorpio, and be found in Ophiuchus during the remainder of the month. He will be pretty close to the 2·5 mag. star δ Scorpii on the 4th, and pass some 2° to the north of Antares on the 9th, but will approach no other conspicuous star. He will be in conjunction with Mars (1° 48′ south of that planet) at 7 a.m. on the 4th, with Uranus at midnight on the 8th (Mercury 2° 37′ south), with Venus at 11 a.m. on the 26th (0° 43′ south of her), and again with Mars at 9 p.m. on the 30th, Mercury being 0° 23′ N. of him.

Venus

is an Evening Star, too, and just as badly placed for the observer as Mercury, whose path in the sky she more or less follows. Her gibbous little disc subtends an angle of only 10″ at the beginning of November, increasing imperceptibly to 10·6″ by the end of it.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	15 14·0	17 46·4	0 31·7 p.m.
6	15 39·4	19 30·9	0 37·3 ,,
11	16 5·3	21 2·1	0 43·5 ,,
16	16 31·6	22 18·4	0 50·1 ,,
21	16 58·5	23 18·4	0 57·2 ,,
26	17 25·6	24 1·2	1 4·6 ,,

As in the case of Mercury, Venus thus starts in Libra, crosses the spike of Scorpio somewhat to the north of the path of the former planet, and is at the end of the month in the confines of Ophiuchus and Sagittarius. She passes some 2° N. of δ Scorpio on the 9th, but this is her nearest approach to any moderately bright star. She will be in conjunction with Uranus (0° 24′ south of him) at 5h. p.m. on the 14th; with Mars at noon on the the 16th (0° 11′ North of him); and with Saturn at 9h. p.m. on the 27th; but in neither case will the phenomenon be, in any legitimate

Shooting Stars

Of all the meteoric showers that occur during the year, there is no more important one than that of the Leonids which appears annually from about the 13th to the 16th of November. Many of our readers must be familiar with the account of the tremendous display of these bodies in the year 1833, as witnessed in Canada and the United States, when many of the labouring classes, and notably the negro slaves, believed that the last day had arrived; and more must remember the astonishing spectacle witnessed in 1866, when the sky seemed really to be snowing fire. We have spoken of the annual display of these meteors, which travel round the sun in an orbit identical with that of Tempel's little Comet I., 1866 (a fact first established by Schiaparelli); but it is necessary to add that, although practically filling this orbit, the aggregation of the component meteors is very far from being uniform throughout it. In fact, while sparsely scattered over a considerable part, they are thickly clustered in one portion of it, which has been called "the gem of the ring," and as the period of revolution of the entire stream is approximately 33 years, it is only after that interval that our earth plunges into the thick of the stream, and such astonishing displays occur. We had them in 1833 and in 1866, and quite obviously must expect one this year. We have spoken of them above as the Leonids, a name they derive from their apparent radiant point at the apex of a triangle whereof γ and ζ Leonis form the extremities of the base, and we would here reiterate our annual caution to the observer that it is useless to commence his watch very long before Leo rises, which is not much before midnight. The early morning of November 15 is that on which the grand display is to be anticipated this month. Space imposes a limit upon any more detailed account of this phenomenon here; but everyone interested in it should most certainly provide himself with Mr. Denning's excellent little pamphlet "The Great Meteor Shower of November," published by Taylor and Francis, for a small sum. This, however, is not the only apparition of shooting stars of importance to be looked for in November, as persistent watch may well be kept for a night or two before and up to the 27th of November for a display of the Andromedes, which appear to emanate from a point to the north-west of that beautiful star γ Andromedæ. That they are in some way connected with the lost and disintegrated comet of Biela appears extremely probable; in fact, some writers assert categorically that we are simply plunging into what remains of that body, whenever the Andromedes appear. Without expressing any opinion on this, we may yet urge the student to maintain a watch on the part of the sky we have indicated from the 23rd to the 27th inclusive. Minor displays from different radiants are predicted for the nights of 1st, 2nd, 7th, 10-12th, 16th to 28th, 20th, and 30th.

* Early morning of the 2nd.

The method of finding the Greenwich Mean Time of Southing of either of the stars in the above list on any other night in November, as also that of determining the local instant of its transit over the meridian of any other station, will be found on p. 456 of Vol. LXVIII. It must, however, be noted that, as there stated, these rules given are not rigidly accurate as applied to Polaris, nor, in fact, to any close circumpolar star, though in practice they will doubtless be found abundantly so for the regulation of the best ordinary clock or watch.

USES OF ALUMINIUM.*

THE principal uses of aluminium are too many to be enumerated. The properties of the metal are so akin to those of copper and brass that, broadly speaking, aluminium or one of its light alloys should to a large extent replace both copper and tin and also nickel or German silver. Such a change would be followed by various advantages to all concerned. Not only would there be a considerable reduction in the weight of the articles, but they would not tarnish or turn black on exposure to air. The cost should be the same, if not actually lower, inasmuch as, bulk for bulk, aluminium is already cheaper than copper or tin; and its price will continue to fall as the demand increases. One field, however, remains which copper is bound to maintain as its own—namely, the construction of isolated electrical conductors. Experiments have already been made on a large scale with bare conductors of aluminium for telephones, with perfectly satisfactory results, its conductivity, weight for weight, being double that of copper. But when the mains have to be insulated, copper is absolutely unapproachable, on account of its greater conductivity, volume for volume, which is 165 per cent. of that of aluminium.

Besides the advantages set forth above, aluminium is not poisonous, and is pre-eminently adapted for the manufacture of cooking utensils. A steady demand for aluminium is springing up in various kinds of printing processes, as well as in lithography. The metal appears to answer admirably for the construction of rollers used in calico printing; and when its surface is properly prepared, it is also capable of replacing the ordinary lithographic stone. It can easily be imagined that, instead of having cumbrous and heavy stones, which can be printed only on special slow-running "litho" machines, it is far better and cheaper to use thin sheets of a metal which can be bent into a circular form and printed on rotary presses. Bicycles, electric-light fittings, chains, bridles, stirrups, surgical instruments, sextants, and other scientific apparatus, keys, cigar-cases, pen and pencil-holders, toilet articles, plates and dishes, spoons, forks, frames, nameplates, door furniture, hat and coat-pegs, boot-trees, fire-engine fittings, business and visiting cards, and photographic cameras are a few of the things that are being daily made in aluminium by various firms. For motor-cars there should be a large field for aluminium. A further demand for the metal will be brought by its introduction into the military services. All parts of the soldier's equipment have practically been made already in aluminium, such as mess-tins, water bottles, buttons, helmets, parts of rifles, cartridge-cases, fittings for guns, tents, horseshoes, portable bridges, &c., and it is well known that Continental armies, notably the German army, are employing aluminium on a large scale.

The use of aluminium in shipbuilding is growing rapidly, on account of the almost inestimable advantage of its great saving in weight. Four or five years ago a small canoe was made on the Thames of two sheets of aluminium, stamped and riveted together. In 1892 Messrs. Escher, Wyss, and Co., of Zürich, constructed a small launch entirely of aluminium, driven by a naphtha motor, and in the following year they built for Mr. Nobel another larger vessel which has been in use ever since, and is now on one of the Swedish lakes. During 1894 and 1895 the author had a similar vessel on the Thames, between Windsor and Maidenhead. A much more ambitious attempt was made by Messrs. Yarrow in 1894. By request of the French Government they built of aluminium the whole of a second-class torpedo-boat, 60ft. long by 9ft. 3in. beam. This boat weighed in full working order, but exclusive of armament, only 9½ tons, and attained, during a run of two hours, carrying a load of three tons and with engines indicating about 300H.P., a mean speed of 20¼ knots—an advance of 3¼ knots over all previous records.

Several yachts were also constructed at the same time, but they do not seem to have been a real and permanent success, owing probably to the adoption of an unsuitable alloy. As pure aluminium was not strong enough alone, it was thought better to use an alloy containing about 6 per cent. of copper in the construction of some of these boats. This alloy possesses a tensile strength of 14 tons per square inch; but, as already stated, this material is absolutely untrustworthy in sea water, owing to the rapid corrosive action set up between its two ingredients. Moreover, although nobody would dream of employing any other metal than copper for plating sea-going vessels unless it were afterwards painted, aluminium has always been used bare, which the author considers a mistake. If the aluminium had been protected from direct contact with the water, it would have lasted much better.

Unfortunately, this comparative failure has materially discouraged the adoption of aluminium in shipbuilding, and although it is now well recognised that the pure metal, and several of its alloys which do not contain copper, stand the action of salt water better than iron or steel, some time is likely to elapse before these premature tests are forgotten. Eventually, however, when further experiments have been carried out, there is no reason why a suitable alloy should not be adopted which, when properly used and protected from direct contact with sea water, would resist corrosion as effectually as the majority of materials now employed in shipbuilding. These remarks refer only to the keel and other parts of the vessel below water, and chiefly to such craft as are to navigate the open seas.

* By E. Ristori, in *Cassier's Magazine*.

ELECTRIC LIGHTING FROM CAR AXLES.

THE system of lighting railroad cars by electric current generated from the axle, which has been developed by the National Electric Car Lighting Company of New York, has made use of a belt connecting the axle to the generator, and while it has proved to be possible to make this work satisfactorily when camel's-hair belts were used, the elimination of the uncertainty of the life of the belt was seen to be desirable, and this company has recently improved and simplified its apparatus by substituting direct frictional contact between a fibre roller on the end of the generator shaft and a pulley mounted on the axle. The belted connection required a countershaft between the pulley and the generator, the triangular connection of which, together with spring mountings in the countershaft bearings, provided for the vertical motion between the generator and the axle. The slack was adjusted by tightening the springs of the countershaft bearings. The average life of a belt with this arrangement was not above 15,000 miles, and the

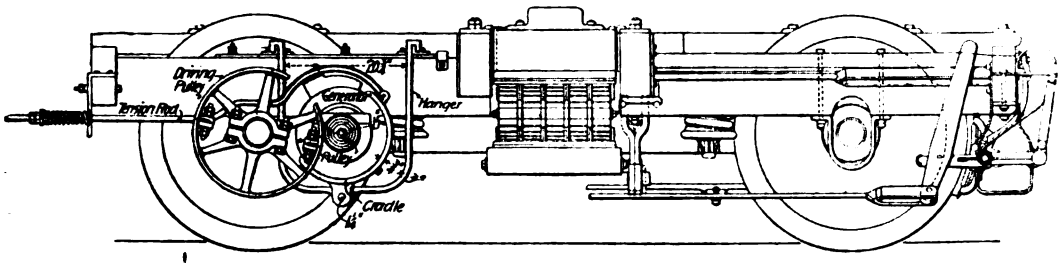

Fig. 1.—Truck with Generator for Axle Lighting: Atchison, Topeka, and Santa Fé Ry.

arrangement shown by the accompanying engravings insures a life of at least 35,000 miles for the transmitting pulley, which, we are told, is a statement based on experience.

The engravings illustrate the new method of mounting the generator and the construction of the fibre roller or pulley. The generator is carried under the frame of the truck, to which it is hung in slings and carried on a hinged support at the bottom, as shown in the elevation. A tension rod urged towards the left by a spring draws the roller to the driving pulley with a pressure which is adjustable. It will be seen at a glance that the vertical motions of the generator with reference to the axle are fully provided for in a very simple manner. In the detail drawing of the driven pulley or roller the method of substituting a new fibre filler for one which may have become worn is seen to be easy. It is stated that this improvement is giving excellent results on the Atchison, Topeka, and Santa Fé, where it has been for some time in service. This road has this lighting system in use on about a hundred cars, and it is understood that it is to be extended.

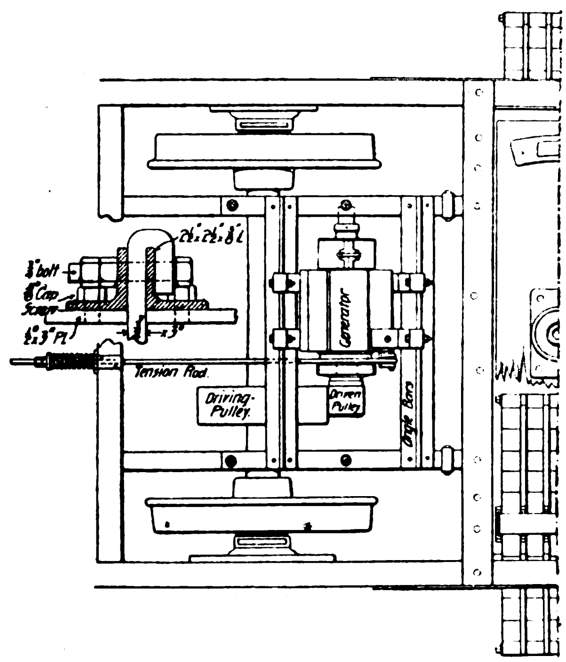

Fig. 2.—Plan of Truck, showing Generating Apparatus.

In addition to a material reduction in the number of parts, the new arrangement renders the generator more accessible and the lubricating problem is greatly simplified. In connection with lubrication, another improvement has been made, whereby the oil is carried in a tank containing about 2½gal., which is connected to the lubricating devices by a sight feed, and the valve regulating the supply of oil is controlled by a solenoid, which is operated by the electric current in such a way as to cut off the supply of lubricant when the generator stops. By the use of these devices cars make trips of 3,000 miles without requiring any attention to the lubricating apparatus. Experiments are now being made to insure a uniform viscosity of oil in summer and winter. The improved method of driving the generators was designed by Mr. Morris Moskowitz, chief electrician of the company, and the improvements in lubrication were devised by Mr. George K. Wheeler, superintendent of the company.

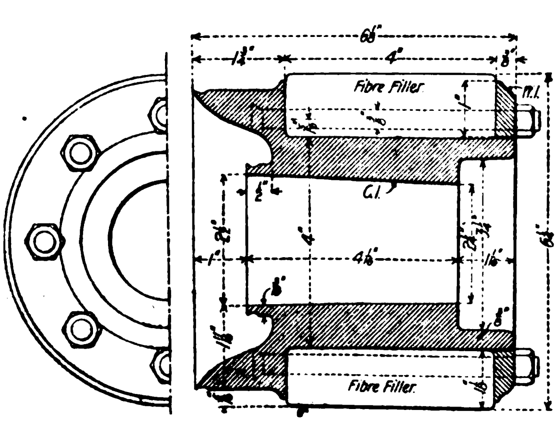

Fig. 3.—Driven Pulley—Showing Method of Holding the Fibre Filler.

The Electric Axle Light and Power Company has recently assumed control of the National Electric Car Lighting Company, the new company being incorporated under the laws of New Jersey with an authorised capital of 25,000,000dols. The introduction of the axle light is to be pushed, and it is understood that the company is also experimenting with a system of car refrigeration, in which the power will be taken from the axles in the same way as it is now taken for electric lighting.—*American Engineer and Railroad Journal.*

ENGINEERING FORMULÆ.

In the spring of this year Mr. Brysson Cunningham read a paper on "Engineering Formulæ" before the Liverpool Engineering Society, and a useful discussion followed. The *Engineer*, commenting on the subject of the paper, says:—It was suggested that the paper was more suitable for students than for grown-up engineers, and then proceeds—"We all go on day after day doing certain things; and we do them on Wednesday simply because we have done them on Tuesday, without asking any questinns, or hearing the suggestion that it might be advantageous to make a change. We use formulæ and make allowances, and postulate conditions, not because this is the best way to arrive at a good bridge, or the discharge of a water main, but because it is the way we have always done it. Mr. Cunningham's paper was intended to wake us up, and this he very effectively does by pulling the house down about our ears. He told his hearers that formulæ were not the special gifts of Providence that some people seem to suppose, and he went on to demolish a number of those in daily use in a fashion leading to the belief that if he only had time he would smash "Molesworth" from cover to cover. It must be submitted that his statements were wholly irrefutable. Nothing worth mentioning was said at the meeting in the defence of formulæ, unless it was the statement of one gentleman, that he had used one concerning a weir in Molesworth, and the result was entirely satisfactory; or the remarks of another, that "what struck him more than anything else was the agreement of results calculated from formulæ under conditions often different to those from which the formulæ were constructed," which, after all, is a very poor compliment to the formulæ.

The substance of the whole matter is that engineers use formulæ, because these represent, or are supposed to represent, the results of experience. The defects of the formulæ are that the author may not have rightly understood the results of his experience, or that that experience was too narrow, or that a false analogy has been drawn between the formula and the new case to which it is being applied. Another feature of most formulæ is the presence of constants, and Mr. Cunningham showed that in important instances there is no agreement whatever between the constants proposed by different authorities. It is not necessary to quote any examples. They will suggest themselves, no doubt, to most of our readers. It will be enough to name hydraulic formulæ, and those relating to wind pressure, and to the strength of columns. This lack of agreement testifies to our ignorance. If we knew all about everything we should have no difficulty in preparing formulæ which would invariably agree, and always be right. As the world goes every formula must be regarded as a bit of information which has to be taken for what it is worth. Thus to cite an example. The formula given by Seaton for proportioning screw-propellers is useful in that it gives us some kind of data on which to start designing a propeller. But it would be foolishness to suppose that by using it we shall of necessity get the best propeller possible for any particular ship. "Formulæ," said Mr. Cunningham, "were primarily intended to be a means of saving time. To solve every problem from first principles would involve an amount of labour which might be more usefully expended in other directions." This is only partly true. Scores of formulæ exist, and are in use simply because there are no first principles to go on. A formula is the condensed essence of an experience. Fairbairn's formulæ for the strength of beams, for example, were all based on an elaborate series of experiments. The shortcomings of formulæ are due in the main to the limited range of the experiments on which they are based. We may test a hundred cast-iron bars transversely and get a certain result. Then comes the hundred-and-first bar, which is very much stronger or very much weaker, and our whole average is upset. It is the characteristic

defect of averages that they can be ruined by big exceptions. When we use a formula for the calculation of the strength of a girder, we assume that it will represent the average within a little. It has often been urged that formulæ need to be used with intelligence. The truth is obvious; the means of applying it obscure. The only intelligence which can be brought to bear appears to be that engineering instinct, which divides the capable man from his fellows, and which is really responsible for the greater part of the best constructive work past and present.

But the use of formulæ is reconcilable with very good practice, because of the beneficent action of the factor of safety. The late Ross Winans, locomotive builder, is said to have told his pupils, "Boys, when you have to make a thing strong, mind that you make it d——d strong." That is the clue to half the success which has been attained in engineering. It is a curious fact that the more accurate a formula is, the less likely is it to be right. If a calculation works out to more than two places of decimals, we may be certain that the results will not be borne out in practice. It is the knowledge of this and kindred truths that has endowed us with the factor of safety. It is noteworthy that this is quite arbitrary. For some unknown reason it is usually taken to mean six to one. The engineer calls in the aid of the specialist calculator, and works out the designs for a great bridge with infinite care and thought, and reams of paper, and when they have arrived at a result, they say, "Ah, ah! that is good! Now, we will put in just six times as much steel as the calculation says will be enough." Why six times? And what is the utility of calculating stresses to five or more places of decimals, if the calculations give us after all no more than a rough approximation to what the bridge will carry with safety? There is incompatibility between the differential calculus and the factor of safety. The higher mathematics seem to be stultified by a brutal insistence that they are not more than fractionally right in the reply they give to our questions. After all, the factor of safety is nothing more than the manifestation of that splendid mixture of ignorance corrected by common sense which has practically solved most of the great engineering problems of the world. The most refined calculations cannot tell us what a bridge really will carry, because there are so many "it's" in the conditions. But they they are competent to keep us safe, provided we allow a large margin. That is the true function of formulæ. They are of use, provided we do not trust them too far. If a man selling pig iron possessed no weight but one which he knew to be somewhere about one-sixth of a ton, he would find his advantage in giving six times its weight as a ton rather than in guessing at the number of pigs which represented twenty hundredweights. It seems a pity, however, that so little is known, or can be known, about this factor of safety. It is of very great importance. In bridge work, for example, the larger the factor of safety the heavier the bridge. A structure with a factor of but three to one might, anomalous as it sounds, be in all respects a better bridge than one with a factor of six. It is probable that large numbers of bridges now exist which are very much stronger than they need be. Anyone looking at the wonderful Boyne Viaduct, for example, must feel that if it is right a great many other bridges are wrong.

Notwithstanding Mr. Cunningham's criticism, the world will go on using formulæ. They are beyond all question extremely serviceable. Whether quite in the right way is another question. Even those who do not understand them, and employ them empirically, just as they do "Bradshaw," may resort to their use without much chance of going far wrong if they will allow a sufficient margin for contingencies. If we calculate that a particular cutting will stand at two to one—Mr. Cunningham was peculiarly severe on earthwork formulæ—we shall probably be safe if we make the slopes four to one. After all, this seems to be what is meant by the intelligent use of formulæ.

TURNING PISTON-RINGS.*

THE turning and facing-up of piston-rings is a job that needs care, or the expense account of the rings will be as bad-looking as the rings themselves. If a job is turned out of the lathe bad, it is a bad job all through. It has to be doctored here and there, and perhaps finds its place in the scrap pile. We cannot, either, say that it is always the poor mechanic that turns out the poor job, for mishaps will occur sometimes with the best of men; but then it is usually caused by matters beyond his control. His machine may need repairs, a matter that he has often reported, but nothing has come out of it, and this one bad job may cost more than to have repaired the tool many times over. There are a great many companies that say it does not pay to use a machine that is either out of date or badly in need of repair, even though the repair might put the tool in shape to do that particular job just as well as a new one, and though, if the repairs had been kept up when required, the tool would have been good for many years. The danger in this direction is that when a concern adopts this line, a great many tools will be taken out and replaced when the difference in cost will not meet the difference in saving. If it costs 2dol. to turn out a piece of work on a machine that is worth 600dol., and it is replaced by one that costs 3,000dol., and the piece may then be produced for 3 per cent. less, the wear and tear of the new tool may more than offset the saving. There are cases where a large amount of money has been used in the purchase of machinery and plant, and where the result has been very wide of what has been expected. Money put into tools

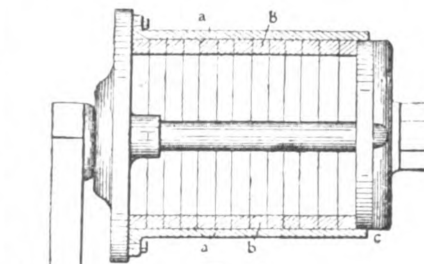

Fig. 1

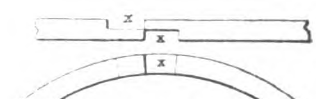

Fig. 2

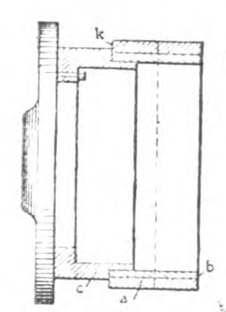

Fig. 3

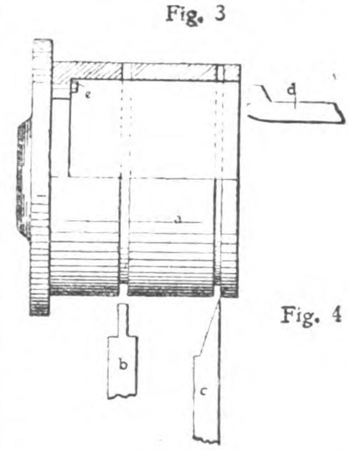

Fig. 4

that are producers, if the tools can be kept at work, is well spent; but when the dollars are put into brick and mortar, care must be used, or the amount so invested will not show at the end of the year. There are other concerns who have made the mistake of thinking that because they had a great amount of floor space they could set machines as far apart as they chose. But when the time came for increase of plant they must go to the expense either of digging out old foundations and putting in new, so as to close up the tools, or of adding new buildings.

Now, in the matter of piston-rings, we might say we will put in a new machine, specially designed, drawings and patterns made, and only one of them built, at great cost, that will take care of these rings all right. But the money might be used to a greater advantage in an increase of the number of regular tools, and some special attachments devised for this job.

The piston-ring that is used very extensively of late years is a single ring turned about $\frac{3}{16}$in. to the foot larger than the bore of the cylinder, sprung together after cutting, and filed to fit the bore. To do this by hand is expensive, and there is danger of spoiling the ring by filing too much, and having the ends stand open in the cylinder. To get over this hand-filing I devised the arrangement shown in Fig. 1. A special face-plate was finished up, with a good, strong bolt screwed into the centre of it, with a plate *c* turned true on the outer end of the bolt and fitted into the ring or sleeve *a*. After cutting the rings, as shown at *x x x*, Fig. 2, we placed a number of them inside of this sleeve, springing them together, and after drawing the plate *c* hard against the rings we could remove the sleeve *a*, and take a light cut over the lot at very slight cost. The bore of the sleeve should be just enough larger than the cylinder bore to allow this cut to be taken. The amount required to be cut out of the ring at *x x x* is about three times the amount that the ring is larger than the bore of the cylinder; or, to be exact, multiply the difference between the bore of the cylinder and the diameter of the ring by 3·1416.

In Fig. 4 is shown the method of preparing the rings for Fig. 1. In the first place we take the ring or sleeve from the foundry, and face the edge where it is bolted against the face-plate, so that the casting may be without spring. It is a bad practice to catch the casting in a chuck to finish the rings, as the chuck jaws will distort the sleeve casting, and when the rings are cut off they will be out of round. To have a still better job, after the rough cuts, inside and out, have been run over the sleeve *a*, it should be loosened and allowed to take its natural shape, after which we tighten up the bolts *e* and proceed. We first cut down the groove with the square-nose tool *b* to within about $\frac{1}{32}$in. of going through. Then with a good sharp side tool *c* take a finish cut inside, and also with the opposite side tool finish the outside. Now we put in a boring-tool *d*, and cut away the stock inside, and the ring will drop off.

Fig. 3 shows the method of finishing up the old-style three-ring packing, one inside and two out. After cutting them off from the sleeve, as at Fig. 4, we drive them together, and by using the short end of the sleeve *c*, Fig. 3, as a mandrel, we may take a cut over the outside and face up the outer edge. In turning this mandrel care should be used in squaring the edge *k*, so that the rings may run true at this point, and not require facing.

* By H. S. Brown, in the *American Machinist*.

THE DUKE OF ARGYLL ON FLYING MACHINES.

THE Duke of Argyll, commenting on Major Baden-Powell's letter in the *Times* on the "aërial ship" now being prepared in Germany, says:—One objection to the probability of its success strikes me very greatly, and that objection is that it is constructed on a principle directly the reverse of that on which nature solves the problem when she has to deal with it. This ship is constructed entirely on the principle of buoyancy. The whole ship is to be lighter than the air it will displace. This is the principle of all balloons, and Major Powell very correctly refers to it as "a buoyant balloon such as this." Now, nothing can be more certain than that no flying animal is constructed on this principle. Every one of them is constructed on the opposite principle of weight lifted and guided by mechanical energy. There is not a flying animal in the world, from the smallest midge to the largest bird like the condor, which is not always heavier than the air in which we stupidly describe it as "floating." If you wound the organs of mechanical energy every flying animal falls like a stone. I do not think that man can overcome the natural laws that condemn all buoyant bodies to an inertia that makes them useless. They must go with the medium in which they float. They cannot resist it, seeing that they have no fulcrum to act upon. My own belief has long been that if we ever are to navigate the air it must be on the mechanical principles which nature has adopted in her glorious and exquisite mechanism of avian flight.

The letter of Major Baden-Powell referred to by the Duke of Argyll reads:—Having lately had the opportunity of inspecting the vast contrivance now being "made in Germany" which is expected shortly to plough its way through the realms of the air even as the Atlantic liner glides over the waters, I may perhaps be allowed once more to call attention to the great importance of the advent of such an innovation. Through the kindness of General Count Zeppelin, I was allowed to visit the "dockyard" wherein this wonderful ship is being constructed, and was immensely impressed on entering the great wooden building erected on a floating raft to see what appeared to be the slender skeleton of some huge vessel, as big as one of our most powerful battleships, but of such delicate material as rather to suggest a stupendous birdcage. This, made entirely of aluminium, is the framework on which the outer skin is to be stretched. Inside a number of large balloons will be placed. Underneath are the gallery and the cars, all of aluminium, and here are the engines with which to drive the vessel, it is hoped,

at the rate of 22 miles an hour through the air. The total lifting capacity will be about ten tons, which should enable the vessel to carry sufficient stores and ballast to remain in the air for some days. All this may sound like some dream, but it is stern reality. It is said that altogether something like £70,000 has been spent upon it, and a commission including many of the leading scientific experts in Germany have approved the plans. In a few weeks' time all should be ready for a start, and though accidents and delays may, of course, happen in connection with such a novel undertaking, much is expected from this event, since such an amount of money and skill has never before been expended on such an enterprise, and all the calculations have been so accurately made, every contingency so carefully considered, each possibility of failure so cautiously guarded against, that we can but hope that success will follow. A buoyant balloon such as this, it may be pointed out, has the great advantage over a purely mechanical flying-machine (such as that of Maxim or Langley) of being able to rise with certainty off the ground, and of preserving its balance when suspended in mid-air. We have just recently had an unfortunate instance of the extreme difficulty of preserving this balance even in a small flying-machine (I myself having been a witness of this most regrettable event). In the case of a machine lighter than the displaced air these uncertainties are done away with, and the whole question becomes one of speed. Twenty-two miles an hour is perhaps no great rate as compared to that of the winds which have to be surmounted, but it is sufficient to accomplish a great deal. Given a practical airship, and improvements are bound to follow. And what then? Notwithstanding what peace conferences may decide, wars in the future will without doubt be decided in the air. The plateaus of the Pamirs, the defiles of the North-West Frontier, the swamps of the Upper Nile—even Mafeking and the tablelands of the Transvaal—will become as accessible as New York. The exploration of the North and South Poles—but I will no further speculate. Those wishing for visions of the future can refer to Jules Verne. Those that desire technical details of this latest scheme to utilise the highway of the air may find them in the *Aëronautical Journal* for this month. I will here only direct attention to what we may call the political aspect of the question, in the hope that we in England may not be long in following in the lead of our energetic cousins in making a bold and unsparing attempt to conquer this element, which has hitherto baffled our ingenuity.

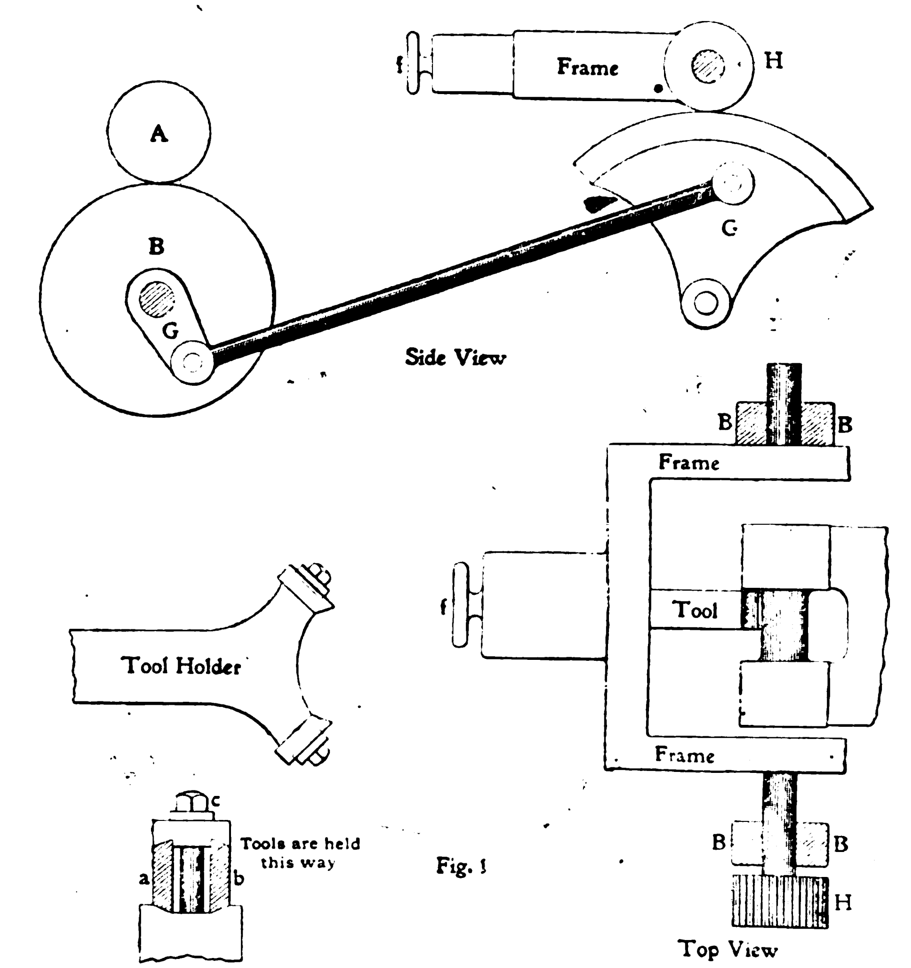

Fig. 1

TURNING SOLID CROSS-HEAD PINS.

As solid cross-head pins are being used to considerable extent in some localities, it may be interesting to see how they are turned in some shops, and it must be admitted they have some advantages as well as disadvantages, when compared with the loose pin.

There are several methods used in various shops, from the hand machine to the special tools shown in outline here, not forgetting the cross-head lathe attachment which has been patented from time to time, and which usually turns the cross-head in about two-thirds of a revolution and back again. This arrangement either uses two tools—one back and one front—or shifts the cross-head so as to complete the turning. This idea was probably the foundation of the machine shown in Fig. 1, which was found in the Manchester Locomotive Works recently. The sketches shown give an idea as to its method of working, but are, of course, only an outline and not all in correct proportions, but the idea is there.

In this the cross-head is fastened solidly to the machine in a vertical position, so that the centre of the cross-head pin is in line with the main shaft, as shown in the top view.

Taking the side view of the machine, A is the main driving pinion, which drives the gear B, also crank C, which is fastened to same shaft. This is connected by the rod shown to the segment G, which gives motion to gear H, shown in both views. This turns gear H and carries the frame with it about two-thirds of a revolution, so that the tools in the tool-holder (shown in small sketch) cover the entire surface at each complete sweep. The frame is fed along by a rachet feed, similar to a planer, and moves in the bearings, as shown. The gear H is wide face to allow for this. It would seem better to feed the cross-head; but there may have been difficulties in the way of design which were not apparent at a hasty glance. The tool-holder and method of holding tools are shown, so that little more need be said, the tools being fed in, of course, by the hand-wheel shown at back of frame.

The machine at the Rhode Island Locomotive Works is built on the lines of some of the hand and portable power machines which have been used at various times for the last fifty years, and though only a sketch is shown, the working will be clear (Fig. 2). The top view shows the gears, or rather gear *a b*, for it is one gear, with about a third of its face turned down in the centre for a bearing in the frame or box shown in the detail. This is driven by the double-face pinion *c d*, which in turn derives its motion from the pulleys shown through gear *e* and pinion *f*. This view also shows the crosshead in place.—*Locomotive Engineering*, N.Y.

THE HARVEIAN ORATION.

THE Harveian Oration was delivered at the Royal College of Physicians by Dr. George Vivian Poore, F.R.C.P. After alluding to the benefactors of the past year, Dr. Poore reminded his audience that they met upon St. Luke's Day, and after comparing the high state of medical knowledge and education in the first century with its almost total eclipse in the Dark and Middle Ages, he arrived at the conclusion that the "beloved Physician," the companion of St. Paul, had probably a more extended and more scientific grasp of medicine than the immediate predecessors of Vesalius and Harvey. But if science in the Middle Ages stood still,

The Handicrafts Progressed,

and found ultimate expression in buildings marvellous for their engineering skill and matchless beauty, which enshrined all that the most cunning hands, impelled by artistic imagination and devotional enthusiasm, could produce. Science can never know what it owes to the handicrafts. Not only has it been largely recruited from their ranks, but it is obvious that science cannot progress without the craftsman to furnish it with instruments of precision. Chemistry could not exist without the glassblowery; astronomy and microscopy owe their very existence to the optician; while medicine and physiology have advanced *pari passu* with the power of recording and measuring. All branches of science must unite in doing homage to the printer who made the Renaissance possible. Further, it should not be forgotten that the Middle Ages were not without their high ideals, and that the Mediæval priests were indefatigable in preaching charity. Many of our asylums and hospitals owe their existence to the exhortations and piety of ecclesiastics. To take only one example, let us not forget that St. Bartholomew's Hospital owes its existence to a Mediæval prebend of St. Paul's, and that Rahere, by providing a place in which our Harvey subsequently observed disease, must be allowed to have some share in Harvey's great discovery. Dr. Poore said Harvey was a born naturalist. He could not help observing. He was in this respect like Aristotle or Pliny, Nehemiah Grew, White of Selborne, John Hunter, and Charles Darwin. In the pursuit of natural knowledge never tired, because "the labour we delight in physics pain." He seems to have risen superior to the political violence of the time, and to have felt that the establishment of the

Facts of Nature

was of more importance than the ephemeral questions by which professional politicians seek ascendency. No man can successfully interrogate nature unless he his constitutionally honest, and it is not, therefore, surprising that Harvey should have earned the entire confidence of the King and Lord Arundel. It must be admitted that, considering the rancour of the times, he suffered singularly little at the hands of the Parliamentary party. His papers appear to have been destroyed by a mob which visited Whitehall, but no harsh treatment was ever meted out to Harvey by Cromwell or his subordinates. This fact is probably due not only to the guileless simplicity of Harvey's character, but to the sanity of the reformers. Cromwell could recognise a wise man when he met one, and, although he knew the uses of fanaticism, he was not one to tolerate the mastery of a mob. One cannot but contrast the safety of Harvey with the fate of Lavoisier, who, one hundred and fifty years later, was hurried to execution with the cry that "The Republic has no need of *savants*." Dr. Poore exhorted his brethren to search out the secrets of nature by way of experiment. If knowledge is to advance investigation, is a necessity. Not only is it true that, as Aristotle pointed out, the greatest pleasure in life is contemplation, but the philosophic mind is never dull, and the joys of the successful investigator are probably the greatest which this world has to give. The modern investigator, who by infinite pains turns a disease from a word into a fact, and who, by careful isolation, cultivation, and inoculation, draws back the veil of mystery, and points the way towards the prevention and cure of a pestilence, surely experiences an unsullied joy such as the victorious general, the idolised plutocrat, the lucky gambler, and the adroitest of Parliamentary hands have no knowledge of. The

Soul is Invulnerable.

The well-stored mind soars above the whips and scorns of time. When, after a period of civil strife, unequalled in the history of this country, Ent sought out Harvey in 1650, and asked, "If all were well with him," "How can it be?" was Harvey's reply, "when the Commonwealth is full of distractions, and I myself am still in the open sea. And truly," he continued, "did I not find a solace in my studies, and a balm for my spirit in the memory of my observations of former years, I should feel very little desire for longer life. But so it has been, that this life of obscurity, this vacation from public business, which causes tedium and disgust to so many, has proved a sovereign remedy to me." Here we have from Harvey's own lips precious testimony to the content which is to be found in searching out the secrets of nature. "Happy is the man that findeth wisdom; her ways are ways of pleasantness, and all her paths are peace." Nature is omnipresent, and the study of her affords the best discipline for the mind, for she only yields her secrets to the man of truthful spirit who works with patience. The great advance of the latter half of this century has been the discovery of microscopic parasites in the blood and tissues. It is but fifty years since Davaine demonstrated the Bacillus anthracis in the blood, and the facts of a similar order since accumulated have bewildered us by their number and variety. To take only one example:—We have attained to a certain knowledge of the physical cause of the plague, which in times past has numbered its victims by millions. This disease has been isolated and cultivated. It has been sent half round the world in a tube, and has been reinoculated in animals. Some of these animals accidently transmitted the disease to their keeper, who, in turn, infected his medical attendant and nurses. The disease manifested all its ancient virulence, but a knowledge of the cause enabled the plague to be stayed. The much-honoured and lamented victims of Vienna have demonstrated to the world at large how the pestilence which walketh in darkness has been illuminated by the full light of science. We are full of hope as to the good which will follow on the discovery of the malaria parasites in the blood, and their transference by means of mosquitoes. There can be no doubt that the rational and methodical observation of disease, assisted by experiment, has had an enormous influence for good on manners and morals. It is to the leaders of medicine that we owe the recognition of the fact that conduct which we once regarded as sin, calling for cruel and revengeful punishments, is in reality disease, which must indeed be controlled with firmness, but firmness tempered with mercy rather than vengeance. There can be no doubt that one of the causes which has led to the decrease of our prison population and the increase of our asylum population has been the gradual appreciation by the educated public that much disorderly conduct is, in reality, disease. We are more ready now than heretofore to "forgive those that trespass against us." There can be no doubt that our increased power of recognising the early stages of brain disease, a power which we largely owe to those who have sought out the

Secrets of Nature

by way of experiment, has made for mercy. The average man regards medicine as merely the art of curing disease, and judges of its progress by the degree to which it enables him to enjoy life, often in defiance of common sense and morality. The higher aim of medicine, however, is to point out man's true relationship to his surroundings in this world. Our relationship to our fellow men, the lower animals, vegetation, the atmosphere, sunlight, water, and earth can only be determined by the study of "the things which are," and by searching out the secrets of Nature by every means which human ingenuity can devise. There have always been two schools of thought in regard to scientific inquiry. One school, fearful lest inquiry into proximate causes should lessen our reverence for the ultimate cause, protests that "all is vanity," and "he that increaseth knowledge increaseth sorrow"; while the other school finds in wisdom "an effulgence from everlasting light and an unspotted mirror of the working of God." It is quite impossible not to admit that our increased knowledge of the laws which regulate the visible universe has increased our living faith and added to the glory of God, while it has made it more difficult for men to make gods after their own image, and use them for their own purposes.

Modern Medicine

is teaching us that much bodily suffering is due to man's wilful neglect of the beneficent laws of nature. That diseases are due to ignorance and disregard of law, and are not "sent" as scourges by a petulant and capricious Deity, is clearly a doctrine which in no way dims the glory of God. After alluding to the opposition which science occasionally has met with at the hands of fanatical and emotional persons, Dr. Poore concluded:—In this country we have always wisely recognised the uses of opposition. The stability of our political organisation has been largely due to the fact that the party in power is subjected to the ruthless criticism of the Opposition—"the toad ugly and venomous" which "wears yet a precious jewel in its head." So it has been in medicine, where scientific advance has been checked not only by the criticism of the learned, but occasionally by the clamour of the prejudiced and ignorant. We have seemed at times to lag behind our neighbours, but our advance, if occasionally slow, has generally been sure. The party of scientific advance is necessarily always a small one, and it is possible that the relatively ignorant may cause some temporary discomfort to the learned few. But this is the extent of their power. The true spirit of inquiry, like the divine afflatus of the poet, is not subject to human control, and the laws of Nature are more permanent than Acts of Parliament.

MOUNTANTS AND MOUNTING.

IT may seem almost an act of supererogation to many to devote an article to the above simple subject, yet amongst the most frequent queries we have to reply to in the answers column are those relating to mountants and mounting. Scarcely a week passes without our being asked by one correspondent or another how to mount photographs without the mounts cockling, or how to mount them on the leaves of an album without the same thing occurring. Now, there is no question that a cockled mount is a very unsightly thing, whether it is framed or unframed; also, that an album with its leaves so buckled that the book will not close flat is very ugly. The avoidance of these evils, without the aid of a rolling press large enough to take the mounts is, however, no easy matter to overcome; and even with that aid at command, unless certain precautions are taken in the first instance, it is sometimes difficult.

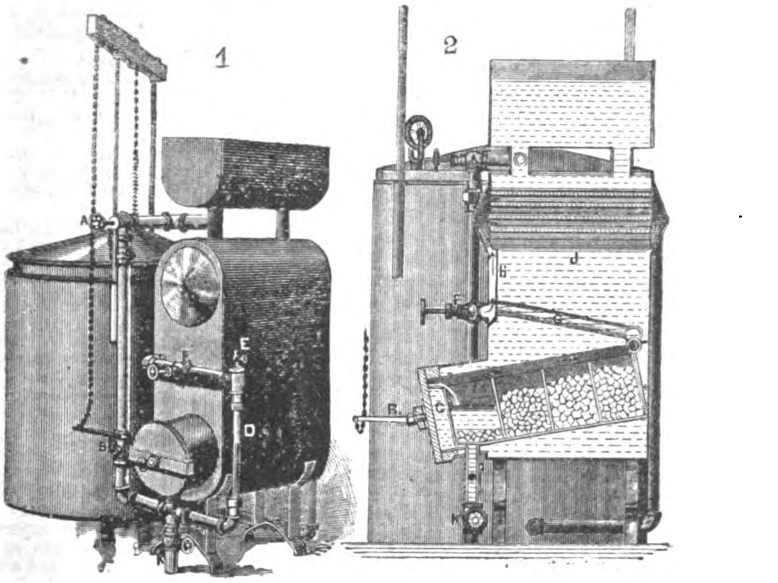
In the case of the prints having to be mounted in an album, the rolling of the pictures is, of course, out of the question, unless, indeed, the album is first taken to pieces, and that is really the proper course to pursue when the best result is imperative. A bookbinder will, however, take the album to pieces and rebind it, after the prints have been mounted and rolled, for a very small sum, and it is somewhat surprising that this is not more often done than it is. We shall here assume, however, that this cannot be done, and see how the best results are to be secured without it.

In the first place, it will be well to consider what it is that brings about the cockling, so that, when that is fully recognised, the conditions for its avoidance, or at least reducing it to a minimum, will be better understood. When paper, whether in the form of a print or a mount, is moistened with water, however slightly, it has a tendency to expand, and it contracts again as it dries. Hence, when an aqueous mountant is applied to the back of a print, it expands, and, if much water is present, greatly. If, while in this expanded state, it be put upon the mount, it is larger than it was when dry; then, as it dries, it contracts again, and in doing so draws the mount with it, and so produces buckling. This is not all, for the moisture in the print also causes the centre of the mount to expand, and thus further increases the evil.

Now, a little consideration will show that the drier the print and the mount can be kept during the operation the less will be the expansion, and, consequently, the less will be the cockling. Conversely, the wetter the print is made the more will the difficulty be increased. Many photographers are in the habit of having their prints mounted wet. Now, it will be obvious that this condition, whatever mountant be used, is fatal in the avoidance of cockling with thin mounts without rolling, because the pictures are put on the mounts in their most expanded condition. Even after rolling they often cannot be made perfectly flat if the mounts are very thin.

After what has been said, it will be seen that, if the print be dry and the mountant contain no water, there would be no cockling. Have we such a mountant? Yes; in a solution of indiarubber in benzole. When that is employed, the pictures and the mounts remain perfectly flat. This mountant, unfortunately, however, is not at all satisfactory, as it is found, after a time, that the rubber is liable to perish—becomes resinised—and the picture peels off. Alcoholic solutions of different resins would cause no expansion of the paper, but, in practice, they have not been satisfactory for mounting purposes; therefore we have to rely upon aqueous mountants. There are ways, however, in which these may be utilised in what may be termed almost a dry state.

Some years ago Mr. A. Cowan published a dry method of mounting. It was this: the back of the print was coated with starch paste and allowed to dry; the surface of the mount was then slightly moistened with a damp sponge, and the two passed through a rolling press, when perfect adhesion was secured. Here is another method we saw in use in a large Continental publishing house, where the pictures were issued on plate-paper mounts with India tint and titled. The method was this: the back of the print was coated with a thin solution of gelatine, dried, and then trimmed; the India paper was slightly damped between blotting-paper. Next a copper-plate, with the title engraved upon it, was heated and inked in, after the usual manner of copper-plate printing. It was then placed on the bed of the copper-plate press, the print put upon it, then the damp India paper, and on that the plate paper, after its surface had been brushed, as is usual with printing on India paper; the whole was then passed through the press. The damp India paper caused



the gelatine to adhere to it, and it adhered to the plate paper by virtue of the brushing it had received. In this way the mounting, titling, and plate-marking are done in a single operation. These mounted prints were as flat as if they were copper-plate prints instead of mounted photographs.

As, however, the above methods are not applicable to mounting photographs in albums, other means must be adopted, and, from what has been said, it will be manifest that the object must be to reduce the water in the mountant to the smallest possible quantity, and, at the same time, to get the print into position on the mount before the paper has time to expand to any great extent. The great thing to be avoided is the expansion of the paper. It will be obvious, for this reason, that if, say, starch-paste be used, a thick solution, thinly and quickly applied, will cause less expansion than will a thin solution applied thickly. Starch, however, is not to be recommended for our present purpose, because, however thickly the paste be made, it must necessarily contain a large proportion of water.—*British Journal of Photography.*

AN AUTOMATIC ACETYLENE GENERATOR.

THE improved acetylene apparatus, which we illustrate in perspective and in section, consists essentially of two parts—a gasometer and a generator connected by pipes. The gasometer comprises the usual water-sealed bell rising and falling in a tank. The generator comprises a case located alongside of the gasometer and provided with a superposed tank, from which water is supplied to the carbide-chamber. This carbide-chamber, C (Fig. 2), consists of an inclined cylinder inserted in the lower portion of the case, and projecting outwardly for a short distance. The cylinder contains a drawer divided into a number of carbide compartments. The drawer being inclined, it follows that when the carbide is all decomposed the compartments will all be filled with water, and, consequently, little gas will be lost when the chamber is opened to be cleaned. From the upper end of the carbide-chamber a pipe G extends to the cooler, and thence to the gasometer. Water is conducted to the carbide by means of a pipe connected with the lowermost chamber. The carbide-chamber receives its supply of water from the superposed tank through the medium of a pipe having a valve, A, the seat of which is provided with a small by-pass, through which the water can always flow, so as to prevent the possibility of an inrush of water through the feeding-pipe, and, hence, an over-production of gas. Between this valve and the generator a controlling-valve B is inserted, by means of which the flow of water can be entirely cut off. The valve B is automatically operated by means of a lever connected by a chain with the gasometer-bell. When the bell has reached its lowermost position, the chain is pulled, the lever raised, and the valve B opened to admit water to the generator. The water-pipe, provided with the valves A and B, is connected with the generating-chamber by means of a four-way fitting, with which is also connected a valved drain-pipe K. The fitting is provided with a by-pass pipe extending upwards, and connecting with a T-valve, F, controlling the pipe C leading to the carbide-chamber. The by-pass is fitted with a water-gauge D showing the level of the water in the carbide-chamber, and is provided with a vent-valve E. When the carbide-chamber is filled with water and the valve F is closed, the by-pass allows the water to run off for the renewal of the carbide. The valve F also controls the passage H leading to the cooler L, consisting of pipes, the ends of which are covered by caps. The gas flows through the passage H between the first cap and the side of the case, thence to the space between the opposite cap and side of the case down through a pipe into the gasometer. The inventor of the apparatus is Leonard F. Rose, of New London, Iowa.—*Scientific American.*

SCIENTIFIC SOCIETIES.

QUEKETT MICROSCOPICAL CLUB.

THE 371st ordinary meeting of this Club was held on Friday, Oct. 20, at 20, Hanover-square, Dr. John Tatham, M.A., F.R.C.P., president, in the chair. After the usual formal business, Mr. R. T Lewis presented a series of preparations of cattle ticks he had mounted from material sent by Mr. C. J. Pound, of New South Wales, and on which he made a communication at the April meeting. Mr. Curties exhibited a number of photo-micrographs of low-power objects with the Kromscope. Messrs. Watson exhibited their new educational or school microscope, with a well-made coarse, but no fine, adjustment, and their "Holoscopic" eyepieces with an adjustment to render them either under or over-corrected for use with achromatic or apochromatic objectives. Mr. Nelson was afraid that in inexperienced hands, at least, these eyepieces would introduced greater aberrations than those they were intended to correct, as it was a difficult and delicate matter to adjust an eyepiece to varying objectives.

Mr. Nelson made some remarks on a series of Reichert's microscopes shown in the room, with improvements in the fine and other adjustments. Also a new form of double-rack coarse movement, which he had devised to obviate loss of time or backlash in focussing, fitted for him by Messrs. Watson to one of their student's microscopes, and a fine adjustment to the substage of the same instrument. In reply to a question by the President, Mr. Nelson said he considered this latter adjustment almost indispensable when immersion condensers of high aperture were employed.

Mr. J. G. Waller read a paper on "An Undescribed British Sponge of the Genus Raphiodesma Bowerbank," illustrated by figures and drawings on the board.

Votes of thanks were passed for these several exhibits and communications, and the proceedings terminated. The next meeting will be held on Friday, Nov. 17.

A VEIN of coal has been discovered 1½ mile from Bessemer, Alabama. It is 7ft. thick, and is said to be of good quality.

THE "London University Guide," issued by the Univ. Corr. Coll. Press, is a very useful work for students, as it not only gives them all the information they need for matriculating or graduating at the London University, but furnishes lists of books which will help candidates in their studies. The work is published at Burlington House, Cambridge, and at 32, Red Lion-square, London, W.C. A copy of this work should be in all the schools where science classes are held, and in all public libraries, especially as those who have any right to ask for it can, we believe, have it gratis.

SCIENTIFIC NEWS.

IT appears that the special committee of the Russian Astronomical Society appointed to revise the Julian Calendar and bring it into agreement with the Gregorian have been unable to accomplish the task, owing to the difficulty (impossibility, it is said) of reconciling the dates of the religious festivals as they are given in the two calendars. The committee have, however, decided to recommend that the dates according to the old and new style should be indicated on public and private documents. That is to say, the matter remains as it was.

The American *Nautical Almanac* for 1902 contains some alterations in the details, notably in the constants assigned for precession, nutation, aberration, and mean obliquity of the ecliptic; but these, pending an agreement amongst astronomers, are merely temporary. The three partial eclipses of the sun will be invisible at Washington, but one of the two total eclipses of the moon will be visible in America. The "Ephemeris" has been published under the editorship of Prof. Harkness.

Those who would like to have a history of Greenwich Observatory, with portraits of the Astronomers-Royal from the time of Flamsteed, will find their desire satisfied in the October number of the *Observatory*. The article is by Mr. H. P. Hollis, B.A., F.R.A.S., one of the editors, who has succeeded in obtaining a portrait of Pond, the predecessor of Airy.

The *Journal* of the British Astronomical Association (Oct. 18) contains the report of the council, the revenue account, and the balance-sheet for the past year, some reports from branches and the meteoric section, and a number of interesting notes on astronomical subjects gathered from various sources. There are also several letters which will attract attention. Members who wish to take part in the photographic observation of the November meteors are requested to send (without delay) their names, with full particulars of their photographic equipment, to the Director of the Section, Mr. R. Wilding, F.R.A.S., Swillbrook House, Bartle, near Preston, Lancs.

The death is announced of Mr. James Carpenter, F.R.A.S. (1867), of Lewisham, in his sixtieth year. He was formerly on the staff at Greenwich, and was joint author with the late Mr. Nasmyth, of "The Moon, considered as a Planet, a World, and a Satellite."

The Council of the London Mathematical Society have selected the president (Lord Kelvin), the vice-presidents, and the secretaries to serve in the same capacity on the council during the ensuing session. Prof. W. Burnside, Mr. H. M. Macdonald, and Mr. E. T. Whittaker have been nominated to fill the vacancies on the council. At the annual meeting, which will be held on Nov. 9, the De Morgan Medal will be presented to the sixth medallist, Prof. Burnside. The council have sanctioned the issue by the secretaries of an index to the first thirty volumes of the *Proceedings*. This index will be drawn up on the lines of the similar index to the first fifty volumes of the *Mathematische Annalen*. They have also authorised Mr. Tucker to draw up a list of all the members elected since the foundation of the society in 1865.

It is stated that a circular has been issued to all Catholic missionaries by the Sacred Congregation of the Propagation of the Faith, urging them to use such opportunities as the locality of their mission work affords for the collection of natural history specimens, to be given to scientific societies and institutions. The intention is not only to interest and encourage such missionaries as are keen naturalists, but also to remove the reproach that the Church does not look with favour upon science, and especially biological science.

Mr. P. L. Sclater, F.R.S., the secretary of the Zoological Society, is at Cape Town, where his son is director of the South African Museum. Mr. Sclater is, says the *Chronicle*, anxious to bring back examples of the Gemsbok antelope, which is not represented in the Regent's Park Gardens. The species is found in Namaqualand and Bechuanaland, but is rare.

At a recent meeting of the Paris Academy of Sciences, M. Tsvett presented a memoir on the reversible liquefaction of albuminoids. The solution of those bodies is assisted by some acids, alkalies, and salts; and M. Tsvett has found

that some organic bodies also possesses the liquefying power to a remarkable extent—e.g., resorcinol, phenol, pyrocatechol, chloral hydrate. He finds that a solution of gelatine treated with an 80 per cent. aqueous solution of resorcinol forms two liquid layers, the upper of which is a solution of gelatine in aqueous resorcinol, and the lower a solution of aqueous resorcinol in gelatine, the solubilities varying with the concentration of the resorcinol and the temperature.

It has been decided by the Royal Agricultural Society of England and the Highland and Agricultural Society of Scotland that the societies should hold conjointly, under the management of the board, an annual examination in the science and practice of agriculture at a convenient centre. Candidates who may pass the examination and obtain a certain percentage of maximum number of marks will receive a diploma, and those who obtain a higher percentage of marks the diploma with honours, a gold medal being awarded to the best candidate on the honours list. The examination will be divided into two parts, to be taken, as a rule, in two successive years. The scheme now only awaits the formal approval of the councils of the two societies before being publicly issued, and it is contemplated that the first examination will be held in the month of May, 1900.

The council of the Royal Photographic Society have decided to hold a series of monthly meetings at which lantern lectures will be given. The first Tuesday in the month is the day selected, and the lectures will be delivered from Nov. to April, the first being given on Nov. 7. The second Traill Taylor memorial lecture will be delivered on Nov. 14, at the rooms of the Royal Photographic Society by Major-General Waterhouse, who will take for a subject "The Teachings of the Daguerreotype."

The third International Congress of Photography will be held in Paris July 23-28, 1900. Those who desire to be present are requested to communicate with the secretary, M. S. Pictor, Rue Lincoln 9, Paris.

Prof. Watts, of Mason University College, lecturing at the Midland Institute Scientific Society on "Coral Reefs," said that Darwin's theory was that the reefs had grown round islands which had subsided; Murray's theory supposed the level of the ocean bed to remain stationary while the reefs grew outwards like fairy rings on their own débris. Instances of rings formed, according to both methods, were quoted, and the arguments, on the whole, were considered by the lecturer to show that subsidence was the main mechanism in the majority of cases. Darwin had suggested that a millionaire might enable the problem to be solved by arranging for a boring through a coral island. The Royal Society, with the co-operation of the Admiralty and the Government of New South Wales, have adopted that method of investigation. A boring to a depth of about 1,100ft. had been carried out on the island of Funafuti in the South Pacific, while the Admiralty had surveyed the island and sounded the ocean round its shores. The result had been to give a clearer picture than had ever been obtained before; but sufficient details had not been made known yet to justify an absolute conclusion. Summing up, Prof. Watts said that if the subsidence theory were correct, the fact that the reefs were spread over a large area of the Pacific and Indian Oceans would indicate that large areas of land—vast continents, indeed—must have disappeared, and that the subsidence must have been going on for an enormous length of time.

A patent has been obtained in the United States by Mr. C. T. E. Zimmerman, of Cumberland, Wisconsin, for an improved pendulum escapement. An ordinary clock does not keep correct time because of the varying tension of the spring, but the invention is designed to overcome that by a peculiar construction and arrangement of the parts of an escapement, so combined with the pendulum and an escapement-wheel that the pendulum is not actuated by the escapement-wheel and the variable power of the mainspring, but by an intermediate weight set into action by the escapement-wheel and falling with a constant force to actuate the pendulum uniformly.

A locomotive driven by a rotary engine forms the subject of a patent granted to Mr. A. Given, of Ellensburg, Washington, U.S.A. It is stated that the locomotive is "considerably simplified," since the usual cylinders and parts thereon depending are dispensed with. It is safe to say that when this locomotive is built and put to actual work its performances will be watched by every locomotive engineer in the world.

An International Congress will meet at Paris on July 19, and will sit for three days, to discuss subjects connected with naval architecture—not necessarily connected with warships. Lord Hopetoun, Sir W. White, and Dr. Elgar are on the committee, and those who desire to take part in the discussions should communicate with M. Borja de Mozota, Place de la Bourse 8, Paris, and those who wish to read papers with M. Hauser, the secretary, Rue Meissonier 4, Paris.

According to M. Henri Coupin, in a memoir presented to the Paris Academy of Sciences, the vitality of seeds is affected, when under the influence of anæsthetics, by the hygrometric condition. If the seeds are dry, they are unaffected, so far as their vitality is concerned, by atmospheres saturated with chloroform or ether; but if the seeds are moist, the presence of even a small quantity of ether in the atmosphere surrounding them is sufficient to destroy their vitality.

The old question about the poisonous effects of yew on cattle and horses has cropped up again. Mr. G. R. Ryder gives a case of a carthorse, four years-old, supposed to be poisoned by yew, because in the stomach shoots of yew were found. The time of year is this month, and these are the statements:—"All the organs were healthy—no trace of any poison was to be found—but in the stomach there were from 12 to 20 shoots of yew, about 3in. long apiece, unchewed, lying on the surface of the stomach. No one connected with the place was aware that there was any yew tree accessible from the field; but, after minute research, there was found to be one stunted specimen of an Irish yew under a beech tree, almost merged in other little shrubs, and from this it was evident some shoots had been recently torn off. The nearest could not have been less than from 2ft. to 3ft. distant on the inside of the fence, and the horse could only reach them by straining his neck over the iron fence, which had a barbed wire running along the top bar, and tearing them off, for they bore signs of being torn rather than bitten off, and were so undamaged in the stomach that some of them were afterwards fitted to the branch from which they were taken. The horse seems to have died within 10 or 15 minutes of the first shoot having been eaten. It seems extraordinary that the virus of the undigested shoot should have been so powerful as to destroy vitality so completely and in so short a time. I may add that calves and horses and a donkey have been in the field throughout the summer with absolute impunity." It is well known that there is a deep-rooted belief in the poisonous character of the yew, especially the young shoots; but some hold it is the leaves, particularly the dead leaves, that are poisonous. The subject is one that might well occupy the attention of experts, for it is not proven that the yew has any deleterious properties.

The continuous brakes return laid before Parliament for the half-year ended December 31 last shows that the number of vehicles fitted with brakes complying with some, or all, of the conditions laid down in the requirements of the Board of Trade amounted, at that date, to 95 per cent. of the number in use, and that the number of vehicles fitted only with pipes and connections amounted to 4 per cent.

Iodine in Articles of Diet.—Iodine has not hitherto been presumed to be present in any important quantity in alimentary materials; but according to recent researches which have opened up a very delicate process for the detection and estimation of iodine, this element occurs certainly in the flesh of fish and shell-fish in not a negligible quantity. It is true that traces of iodine have been found in cod-liver oil, which with other elements such as bromine and phosphorus probably exert a slight specific action, and possibly a favourable influence, on the absorption of the oil, thus contributing in some measure to its tonic effects. The flesh of fish is peculiarly nutritive, though less satisfying, and perhaps less stimulating, than ordinary kinds of meat. It is able to be digested more easily and rapidly than is animal flesh, and on these considerations affords a useful food for invalids. But (says the *Lancet*) most fishes contain iodine, and thus the occurrence of this element may be a factor of importance in the suitability of a fish diet for invalids.

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no moe than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

VEGA AND ε LYRÆ—REDUCING INTENSITY OF LIGHT—COLOUR OF RIGEL, &c.

[42948.]—LET me thank Mr. Espin for his information and diagrams of α and ε Lyræ. Being in Dublin last week, I took the opportunity of visiting Dunsink once more, with the special object of having another look at Vega, and a few more stars in which I am interested, with the South equatorial. The night was a lovely one, and the air fairly steady; but not a trace of the second companion to Vega could be seen. There must have been something wrong with my observations last time. The star, or ghost of a star, was distinctly visible then—not only to me, but also to my brother, who was with me. I also paid special attention to ε Lyræ, and could see not only those stars figured by Mr. Espin, but also one or two more extremely faint points of light in the group. May I say also, in reply to another correspondent who inquires about the visibility of the companion to Vega in a 3⅞in. or 4in. Gregorian, that on the evening of Wednesday, Oct. 11, observing from the window of a house in the suburbs of Dublin, about 9.30 p.m., I saw the companion distinctly with a 2¾in. Tulley refractor, power 66.

I thank Mr. Stielow for his much too flattering remarks regarding my humble self. My experience *re* visibility of faint companions to bright stars is slightly misrepresented in the way he puts it. I should not recommend low, but *moderately* low, powers for such objects. Thus, of the eyepieces of my telescope, 86 shows the companion to Vega best, 40 next best. I can always see it easily with 86; not quite so well with 40. It is often difficult with 150, or anything higher. This cannot be owing to different thicknesses of lenses, as my 86 power has the thickest lenses of the whole set. It is a great thing to be theoretically correct, and I am duly grateful to "H." for his criticisms on my various proposed devices for reducing the intensity of the sun's light and heat for telescopic purposes. But what I wanted to get at was not theoretical correctness, but a practical working device which would be safe, cheap, and would not materially impair definition. This I think would be attained by placing a piece of coloured glass in the inside end of the draw-tube about 10in. within the solar focus of the object-glass. With the purpose of ascertaining how much such a device would affect definition, I cut out a circular piece of ordinary good plate-glass, and fixed it in the draw-tube of my 4in. telescope, and then tried the instrument on some stellar test-objects. Result: a slight loss of light, and a slight lengthening of the focus (about $\frac{1}{10}$in.) Effect on definition almost *nil*. Star discs still sharp and round; perhaps a trace of scattered light round bright ones. π Aquilæ still separated, nearly as sharply as before. For the purposes of nine amateur observers out of ten, this amount of disturbance of definition, in solar observations, would be quite immaterial.

"H." suggests that the coloured glass would need to be figured to certain curves which should be calculated by mathematical process. It does not require much mathematics after all. The curves required to give least possible disturbance of rays from the object-glass would evidently be spherical curves, having their common centre at the solar focus of the o.g. Thus, if the dark-glass were to be 10in. within the solar focus and ⅛in. thick, it should be a meniscus having its convex surface of 10in. radius, and its concave surface 9⅞in. radius. Then all rays from the o.g. would be perfectly normal to both surfaces, and would suffer no change whatever, neither refraction nor dispersion, in passing through the glass, save only reduction in intensity.

Such a lens need be only about 1in. in diameter and could not cost many shillings. Of course, I agree with Mr. Calver that a solar diagonal is the proper thing; but a diagonal costs about thirty shillings, while my device would not cost five, and would be good enough for those who only want to see, not to observe with minute accuracy. "H." also recommended a perforated stop as improving

the view of double stars. I have already recorded my effects as applied to solar work: it was not encouraging. But, as "H" advocated its use on stars so strongly, I thought I would try it. I used a piece of perforated zinc, dead-blacked, and mounted in the dew-cap, about ½in. in front of the object-glass. I pointed the instrument to Vega, and looked through the eyepiece with great expectations. The result was magnificent, but it was not astronomy. In the centre of the field shone a feeble ghost of Vega; surrounding it were six brilliant diffraction spectra arranged in radial streaks of colour: outside of these, again, were multitudes—millions, it seemed—of similar spectra, fading away through infinite gradations of faintness, to the extreme edge of the field of view. I turned the telescope to γ Delphini; same result, only doubled. I shall not make "H." my guide, philosopher, and friend in matters astronomical any more.

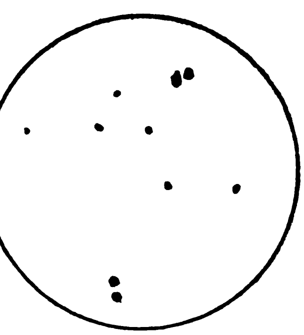
What different eyes we all must have as regards colour perception (see letter 42841)! To me Rigel, Sirius, Vega, Altair, and α Cygni are all alike, blue-white, the colour of an arc lamp. I should think the spectroscope would be the court of final appeal on this point. Have not these five stars spectra practically identical—i.e., hydrogen lines strong, all other lines faint or absent? That is, they differ little from a continuous spectrum like that of the electric light.

Wm. F. A. Ellison.

Monkwearmouth, Oct. 18.

EPSILON LYRÆ.

[42949.]—I beg to send you copy of the sketch of this group by the late Major T. A. Skelton (letter 42873, p. 208), as seen in his 15in. With reflector,



power 240, Sept. 8, 1891. The sketch appeared in Vol. LIV. p. 349, where it is mentioned he thought it probable that a higher power eyepiece on a very fine night would have shown him additional stars.

W. M. P.

CRATER NEAR TIMOCHARIS.

[42950.]—"R. P." (letter 42839) apparently seeks information about what Elger describes as "a bright little crater on the N.W. connected with the foot of the glacis," and it is drawn as such in his map. In Vol. XXIII., *Ast. Register*, Elger describes it as a crater, or rather crater-cone, on N.W. near the foot of the wall, adding, "Mädler and Neison omit it."

"F.R.A.S." seems to have seen Timocharis *a* and *b*, which are very much more distant. These are figured by Neison, but I cannot find them in Elger's map; while the crater close to the wall is not given by Neison, nor have I seen it.

The suggestion as to incorrect orientation is probably the true explanation of "R. P.'s" difficulty.

E. D.

61 CYGNI—LIGHTNING.

[42951.]—Can "F.R.A.S." or any other of your astronomical contributors inform me whether the star which he refers to as *a*, in his letter in your issue of Oct. 20, has been used as a comparison star in any previous determination of the parallax of 61 Cygni? It is evident that its use for such a purpose by an astronomer who was unaware of its peculiarities, might derange his figures altogether.

I can hardly believe in a very faint star with small proper motion possessing the large parallax ascribed to this star by Dr. Schur. It seems to me much more likely that its proper motion is disturbed by a large invisible companion—which occurred long ago to Sirius and more recently to Procyon. The description of a small orbit in a period not differing much from a year might under certain conditions be easily mistaken for a large parallax, provided that the companion star was invisible.

The meteorology referred to in my letter (42933) was that of Kaenitz, of which an English translation was published many years ago. The author investigated the cases of heat-lightning which he noticed, and found that the date always corresponded with (so-called) forked lightning at considerable distances—sometimes I think 300 miles.

W. H. S. Monck.

BABBAGE'S CALCULATING MACHINE.

[42952.]—I have a copy of the "Vestiges of Natural History of Creation," published in 1844, and, as your readers know, this book contains an account of the above machine. The import of this book contains, as I understand it, this remarkable feature—that there is a natural classification of the animal creation, the typical—i.e., the main, or principal family; the sub-typical, or first and next offspring of that family, consisting of the beasts and birds of prey. The police, so to speak, to keep the excessive breeding of the first down; the natatorial—i.e., the aquatic, the sub-aquatic, such as sharks; the suctorial and the rasorial. Now, this deduction is apparently made to be the working out of a natural law, which is exemplified even in mathematics and logarithms. In order to prove this the author, Hugh Miller, instanced Babbage's Calculating Machine, and mentions the fact that in the revolutions of the wheels, to use his own words, "True to the vast induction which has been made, the next succeeding term will be one hundred million and one (viz., 100,000,001); but the next number, presented by the rim of wheel, instead of being one hundred million and two (100,000,002), is one hundred million, ten thousand and two (100,010,002). The law which seemed at first to govern this series failed at the one hundred million and second term; *x x s* being, in fact, the series of *tri*-angular numbers 1, 4, 6, 10, 15, 21, 28, &c.

$$1 = 1$$
$$1 + 2 = 3$$
$$1 + 2 + 3 = 6$$
$$1 + 2 + 3 + 4 = 10$$

&c., each multiplied by 10,000. In the "Vestiges" there is no illustration given of machines. In your issue of the 13th inst. there is, and it must have been of the greatest possible interest to your scientific readers to peruse the description of the same.

It often happens that, however great the human intellect may be in dealing with such matters, some simple feature is missed, which becomes at once apparent to another mind, which has not been so wrapped up in particular detail.

Without being dogmatic, it appears to me that there is a view to be taken of Babbage's calculating machine which is an intelligible explanation of the action of his machine, which Mr. Babbage admitted that he himself did not understand, because he jumped to the conclusion that there was some mysterious law in the succession of numbers, without suspecting that the cause was in the imperfect construction of his machine.

It is, as you say, a great pity that the Government did not afford the inventor the necessary means to have completed his investigations and machinery, because we are face to face with the fact that it misled Hugh Miller into fancying that the deductions he drew therefrom in the animated world were correct. "The Vestiges of Creation" was the stepping-stone in Hugh Miller's mind to the "Testimony of the Rocks."

Now, both works are full of the defective reasoning of the generation in which they were written, and the false conclusions, the dissolving views extraordinary of the exploded ideas of the Pentateuch, misled the author into supposing that he had made a discovery beyond which nothing could be discovered, and, eager to anticipate its truth, he *blew his silly brains out*.

The moment I saw your illustration of the mysterious world-famous machine I said: There is the cause of its mysterious action in producing the term 100,010,002 instead of 100,000,002, in having three columns of wheels instead of four, and in the number of barrels of numbers—the machine in short being triangularly constructed, the progression of numbers can only go on to a given point, at which point it must skip numbers in accordance with triangular, or odd, law, instead of progressing in an even manner, which it would have done had the columns been even and the barrels containing the numbers and the cogs of the wheels even also. As far as I can see, it cannot possibly be otherwise, because reason is against it.

The inference is that Hugh Miller supposed that after a species of animal—that is, the typical, had propagated a given number, it followed that some mysterious law of numbers leaped out of the regular routine and produced a beast or bird of prey.

Now, when you begin an argument the first thing to be sure of is whether both sides agree upon the meaning of the terms which they use, otherwise it is arguing on false premisses. In the instance before us it is not a question whether Babbage's or Hugh Miller's deductions were right, but whether their first premisses were correct; because if they were not the superstructure which these authors or scientists raise, falls down.

I think I have pointed out sufficient to show that there is nothing in any such idea, and that beyond the salient features of the different orders of animated life there is no such classification of species possible in the sense suggested by Hugh Miller in his celebrated work of the "Vestiges."

A. Subscriber.

[42953.]—In your issue for Oct. 13, you give an account of Babbage's calculating machines sufficient to whet our appetites for a more detailed explanation accompanied with illustrations of the various parts and movements. Apart from illustrations, it is next to impossible to understand such complex machinery. Could you not provide us with a few articles on this subject? I am sure they would be very acceptable to many of your readers as well as to

An Old Subscriber.

AERIAL NAVIGATION.

[42954.]—Kindly allow me to assure "Aviator that in my letter of the 13th inst. I had not the remotest idea of attacking the late Mr. Pilcher, or, indeed, anyone else. My sole object in writing that letter was not to air any ideas of my own or to sneer at the incompetency of others (we are all incompetent on this subject, including "Aviator" himself), but to warn any man, no matter who he may be, that to experiment in the air with any kind of contrivance that has large flat surfaces contained in it—will be, and ever must be, extremely dangerous. This fact will be brought home to any man by a little study. I think even "Aviator" will own to this hard fact if he only takes the trouble to study well over the subject. Nothing can possibly be more dangerous than a machine in the air containing large unbroken flat surfaces. It will be at the mercy of the wind, and no power contained in the machine itself can ever make it safe, and as a matter of course the larger the flat surfaces contained in the machine the greater will be the danger. In fact, in a rough wind such a machine would be certain of destruction. Will "Aviator" or any other man be bold enough to deny this? "Aviator" takes upon himself the task of defending those who have never been attacked. This, I opine, may be a thinly-veiled excuse to deliver a thrust at my humble self. "Aviator," in letter 42941, says I make two other mistakes: first to sneer at the use of gas-bags for aërial navigation, and secondly by asserting that the perfect flying-machine can be produced only by himself. Now, allow me to point out that it is "Aviator" himself who has made the greatest mistake here. I never said gas could not be used for aërial navigation, but that a flying-machine which depended upon gas-bags for support in the air would not be a flying-machine, but a balloon. Secondly, if "Aviator" will kindly point out any passage in my letters to this journal or any other wherein I stated that the flying-machine which would safely fly the air could only be produced by myself, I will most willingly withdraw the assertion. I am not aware I ever made the statement; but I have said, and say it again here, that the practical flying-machine, wherever made, and whenever made, and by whomsoever made, will be—in fact, must be—made on the general lines, on the general principles, which I have chosen for the foundation of my own design. This I have stated many times; but this is not saying that the practical flying-machine can only be produced by myself. One word more. I don't quite understand "Aviator's" meaning when he remarks that competent men like Langley, Maxim, Lilienthal, and Pilcher direct their efforts not to fly, but to prove plane support by various devices. Competent, what in? Does "Aviator" mean these men are competent in inventing or making flying-machines, or competent in only trying to do so? If the latter, why exclude your humble servant, the writer? The fact is, there is no particular class of men that can claim any real knowledge on this subject. The man of science knows no more than it is open to any humble mechanic to know, and, for all anyone can tell, the unlearned may see that which the most learned man of science failed to recognise: It is the unlikely that sometimes happens? Thomas George Challis.

THE WIMSHURST FOR X-RAYS.

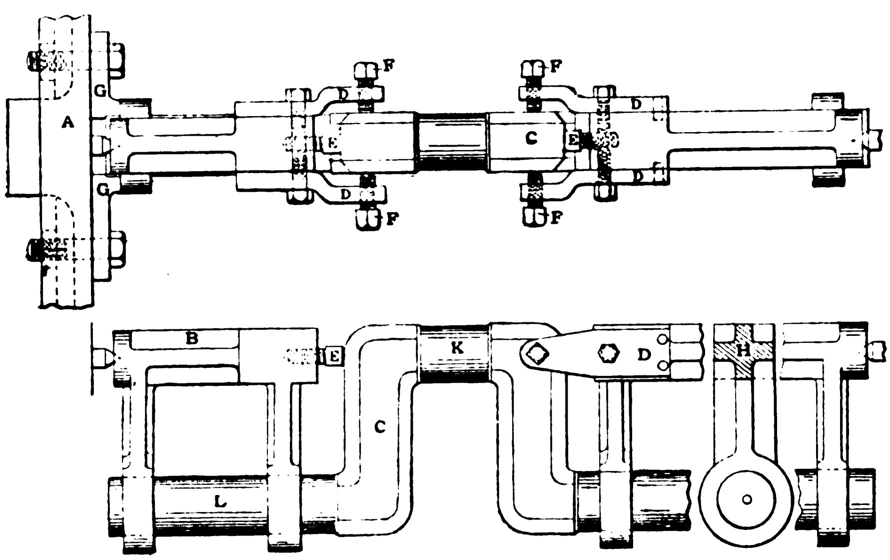
[42955.]—My attention has been directed to an article in the *Daily News* of Oct. 18, 1899, entitled, "The X-Rays in the War," in which credit is given to Mr. Pidgeon and to Major Beevor—to the former for inventing a new form of machine for generating electricity, and to the latter for the "first practical trial of the Wimshurst machine for the production of X-ray results." In justice to myself, I would point out that I was the first to practise and to advocate the use of the Wimshurst machine for this purpose. (See English Mechanic, April 3, 1896, reply 88031.) That I published in Jan. 7, 1897, a little work having for its scope full elucidation of the constructional modifications demanded by the application of the Wimshurst to this particular end, as also for the mode of using when constructed; and that in Jan. 3, 1898, I dedicated in my book "Radiography," a whole chapter to the construction and use of a specially devised form of Wimshurst adapted to this purpose; and, lastly, for the last three years I have manufactured and sent out from

my works several hundreds of these special X-ray Wimshursts to officers, medical men, and hospitals, and have succeeded in placing the Wimshurst in its proper position as being *facile princeps*, as compared to the coil, for X-ray purposes.

Wallington, Surrey. **S. Bottone.**

TURNING CRANKS.

[42956.]—As I have often seen inquiries in the "E. M." about methods of turning cranks, I send the following, which Mr. O. C. Crane contributed recently to the *American Machinist*:—The accompanying sketch shows a rig for turning cranks, used



with marked success on a number having a long throw in proportion to the size of the shaft. The castings B are bored to fit the straight turned part of shaft L, and centred for the lathe the same distance from the shaft centre as the required length of the crank, which, if they are properly set, insures the turning of the crank-wrist K parallel with the shaft. The straps D on the sides of casting B are for adjusting the side position of the crank by means of the set-screws F, thereby making the adjustment a very simple operation. The screws E are for resisting the pressure of the lathe centres. This combination makes the whole quite rigid for the turning of the wrist K. The time necessary for perfect adjustment with this arrangement is too insignificant to make any account of. The centre holes should be quite large, with three oil grooves cut in them to insure perfect lubrication. The casting B is square at D. The section of the arms is shown at H. A represents the face-plate of the lathe, with angles G, bolted on to lock and to drive the end of the shaft. The usual counterbalance, not shown, is bolted on the opposite side of the plate.

The tools for such turning have to be as stiff as possible, on account of the reach from the tool-post to the cutting point. The roughing tool has a single small round point, and feeds both ways, and is set to cut at or below the centre to prevent the digging-in, so liable to occur in such cases. The finishing tools should be square-ended, with a small round for the corners, one to feed right hand, and one left; these also set at or below the centre. By using soda water, a very fine finish can be made, without using file or emery-cloth.

This rig would not pay unless there were a considerable number to be made exactly alike. There are simple ways for centring arms clamped on the ends of a crank-shaft, when only one is to be turned, which the wide-awake mechanic will use without having to guess and try again.

Cincinnati, Ohio. **T. L. P.**

DODGES IN ARITHMETIC.

[42957.]—Referring to Mr. Schooling's article in last week's issue of your paper, it seems to me that he has omitted the simplest of all the methods of multiplying by 11. I mean by adding the original number to the same number multiplied by 10. Thus:—

763942 × 11
= 7639420
+ 763942
——— 8403362

Julian. V. Jameson.

St. Minver, Liss, Hants, Oct. 17.

MOTOR CARS.

[42958.]—As another reader waiting for the promised articles on a motor car, I would like to endorse the suggestion made in your last week's issue by E. H. Micklewood (letter 42940). If the castings and parts of the car and motor to be described could be obtained early, it would be possible to keep pace with the instructions, which I hope will not be long in making their appearance.

W. S. Miller.

MOTOR CYCLES.

[42959.]—Mr. E. H. Micklewood, in his letter (42940), exactly describes my position, and, I feel sure, that of many others.

Like him, I had made up my mind to start on a motor cycle; but I should much prefer to try the motor car, and I am sure if the writer of the articles could kindly arrange with a firm to supply the necessary parts at once, it would be a great boon to many, and would enable the work to be carried on as described in the "E.M.

R. M. G.

[42960.]—Referring to "Monty's" letter in a recent issue, your correspondent finds the bearings in the De Dion to be 9sq.in., and only 9·6sq.in. in the Components Dion motor, as fitted to "Ariel" and other cycles. He is incorrect in his measurements. The actual figures are as under:—

De Dion, 51 by 25mm. = 76mm.; diam., 20mm.; surface, 76 by 20mm. = 1,520mm. Components Dion, 39 by 31mm. = 70mm.; diam., 22·2mm.; surface, 70 by 22·2mm. = 1,554mm. Connecting rod: De Dion, 25·6mm.; diam., 16mm.; surface = 25·6 by 16mm. = 409·6mm. Components Dion, 26mm.; diam., 22·2mm.; surface, 26 by 22·2mm. = 577·2mm.

Your correspondent writes: "You will wonder how I am so familiar with internal economy of engine," and "though I am not in the motor-tricycle business," &c. "Monty" was in the employ of my firm, first as an engine-driver, and then in various capacities, ultimately finding his way in the early days into our motor department, where he was employed for some little time, eventually leaving—not of his own accord. He is now in the employ of a gentleman in this city who is engaged wholly in the motor business! I will content myself by asking your readers to compare and investigate for themselves the figures given above with the totally unreliable statements made in "Monty's" letter. I decline to continue further a correspondence with a former employé writing anonymously, especially as he does not confine himself to possible mechanical improvements, and, further, writes on a motor made 12 months ago, when we were admittedly new to the business.

Selly Oak, Birmingham. **Chas. Sangster.**

GARDEN CITY.

[42961.]—Mr. Steere and Mr. Howard both say, on p. 233, that enlargement beyond 32,000 inhabitants in one city is "eminently undesirable." That entirely alters the problem, and should rather be called "Garden Town." If mankind in future are to be scattered in towns of this moderate size, unenlargeable, the objections to more than 32,000 ought first to be stated and discussed.

However, Mr. Steere's next objection is that "parks are not visible" in my plan. Now, as I provide *six*, of unlimited size, all within half a mile of every dwelling, however large the city may grow, it is inconceivable how Mr. Howard's *one* of 145 acres can be preferred. All my dwellings are as near to factories, to gardens and allotments as any of his, and nearer the public buildings, which he put more than two furlongs from any other buildings. Railways might be carried round, more distant from the town hall, if they are pronounced "an annoyance." Howard's streets, all crossing at right angles, make every passage from house to house as wasteful of steps as in present cities. His blocks are of ten acres and more; mine less than five. The wide streets are sheer waste and delusive. The chief are 120ft., the width of Portland-place, Marylebone, which ought to have a central avenue of trees, if without railway or canal. But the grand fault is that, in contradiction to his term "Garden City," he really plans no gardens. Every dwelling has another to face it, while mine all look out on an opposite garden of more than half an acre. If the city were cut down to the infallible 32,000, mine alone, I contend, could be called *Garden* city. I would allow him the term *Crescent* city or *Circus* city. Anyone who has dwelt in Finsbury-circus, or Burton-crescent, knows how awkward the wedge-like rooms are.

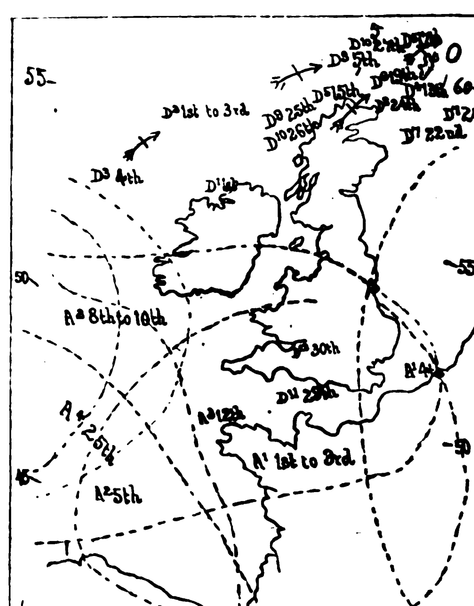
E. L. Garbett.

THE WEATHER OF THE BRITISH ISLES IN SEPTEMBER—REMARKABLE MOCK-SUN PHENOMENA.

[42962.]—

Date.	Cause.	Effect.
Sept. 1 to 3	Anticyclone to southward. Depression on the N.W.	Fine and warm, except in the N. and N.W.
4	High pressure to S.E., low-pressure area still N.W.	Fine everywhere, except in the N.W.
5	Anticyclone moving in from Atlantic.	Fine; very warm in central and south districts. Rain in extreme north.
6 and 7	Shallow depressions in the neighbourhood of the English Channel.	Heavy thunderstorms on the 6th in London, and on the South Coast. Fine, and very warm elsewhere.
8 to 12	Atlantic anticyclone.	Fine and warm as a whole.
12 to 14	Central anticyclone.	Fair generally.
15 to 26	A continuous series of depressions to N.	Persistent westerly winds of varying force, and unsettled weather.
27 to 29	Central depressions, crossing our islands from W. to E.	Unsettled, rainy weather throughout our entire area.
30	Deep depression over the Bristol Channel.	N.W. gale and much rain in the West of England.

Throughout the second half of the month a continued procession of low-pressure systems passed to the northward of our islands, gradually working



southward, and causing the very broken weather experienced towards the end of the month.

The rainfall during the heavy thunderstorm in London on the 6th amounted to the following values in the various districts of the Metropolis named:—Wandsworth Common, 1·09in.; Brixton,

1·00in.; Westminster, 0 90in.; Clapham Park, 0·53in.; Camden-square, 0·50in.; and Greenwich, 0·42in. We may add that at Bournemouth the fall was 1·49in.

On Oct. 11 a curious phenomenon occurred at about 1.30 p.m., and continued with variations for over an hour. The curious part of this "solar halo" was that it did not appear *as* a simple *circle* or semicircle, but as a series of ever-changing wavy lines, above which was an upright and inverted rainbow of brilliant colour. I should be pleased if any of your correspondents would say if this phenomenon is rare. D. W. Horner.

THE TELECTROSCOPE.

[42963.]—In opening this short note, I beg to wish Jan Szczepanik and his invention, the telectroscope, the best of success, and at the same time to make a few remarks on the same; also to mention an invention of my own. To begin with, the telectroscope is, on the whole, a simple instrument, and at the same time (according to an article "Seeing by Telegraph") it is ingenious. But the point is, Will it work? According to *Pearson's*, the experiments (private) so far made have been a success, the principles—i e., the blending of millions of points of light of different colours together—are well known in scientific circles. But here is the vital point: "Can those different points of light be dissected, transmitted, and then united or blended together again, and shown upon the screen sufficiently rapid as to form a similar picture as the one taken by the lens, and dissected by the prisms at the other end of the wires?" The first difficulty, if there be any difficulty at all; would be, I am inclined to think, in the fact that the selenium would not be sufficiently sensitive to register every dissected point of light, and at the same time to register them sufficiently rapid; and then, again, can those points of light be transmitted over the wires rapidly enough to be brought almost simultaneously upon the screen (I have my doubts); and if not, then the thing is a dead failure. We cannot overlook the fact of the rapidity with which the retina of our eyes are impressed by different points of light (and that almost simultaneously) which form the pictures that we see.

My invention, by the way, I have worked out without the slightest knowledge of what Jan Szczepanik was doing, and I did not know that he was the inventor of such a thing until I saw a short notice of the same in the "E. M." on the Monday of Oct. 16, 1899. However, though we have been working at a somewhat similar subject, yet we differ in many ways, as Szczepanik's invention is to show the object upon a screen, and mine is to take it down in black and white; and while his instrument will have to work at a great speed, mine will work much slower; but I will not say that my invention will be a success as yet. It is by criticising each other that we are better able to see where our faults lie. But Szczepanik is an inventor of no mean order.

The reader must bear in mind that my invention is not a telectroscope, and that I place it under another name, which I think is more appropriate.

Huddersfield. H. Mather.

PERPETUAL MOTION.

[42964]—Re letters 42938 and 42939, I beg to point out to "W. J. G. F.," and Webster Michelson, that I have not attempted "to obtain power from nothing"; but, as I before stated, I have tried to generate with a small amount of energy a greater amount than I first used. This may seem the same thing to many, but to my mind it is entirely different. For instance, the weight I represents the small amount of energy first used. In displacing the balanced weights C^1 and C^2 it generates power several times greater than itself. This I have proved by actual experiment. F. W. B.

MORE PERPETUAL MOTION.

[42965.]—Inclosed please find diagrams illustrating a machine designed to overcome the hitherto insuperable difficulties connected with the solving of the problem of perpetual motion.

The main object (as it must be with any machine designed for this purpose) I had in view was to generate with a small amount of energy a greater amount of power than I first used. This I have accomplished by balancing the weights c^1 and c^2 so that although the pendulum weight c^2 is sufficient to keep c^1 in the position described in Fig. 1, yet a very slight additional weight drives it down to the position assumed in Fig. 2. This additional weight is furnished by weight *i*. It will better aid you to understand the apparatus if I describe the actual working.

At the commencement the machine is as in Fig. 1. The weights c^1 and c^2 are, as I have stated, almost equally balanced, so that the weight *i* releasing itself from the spring *j* drives it down to position shown in Fig. 2. The access of power derived from the leverage exerted brings case *a* down as shown in Fig. 2.

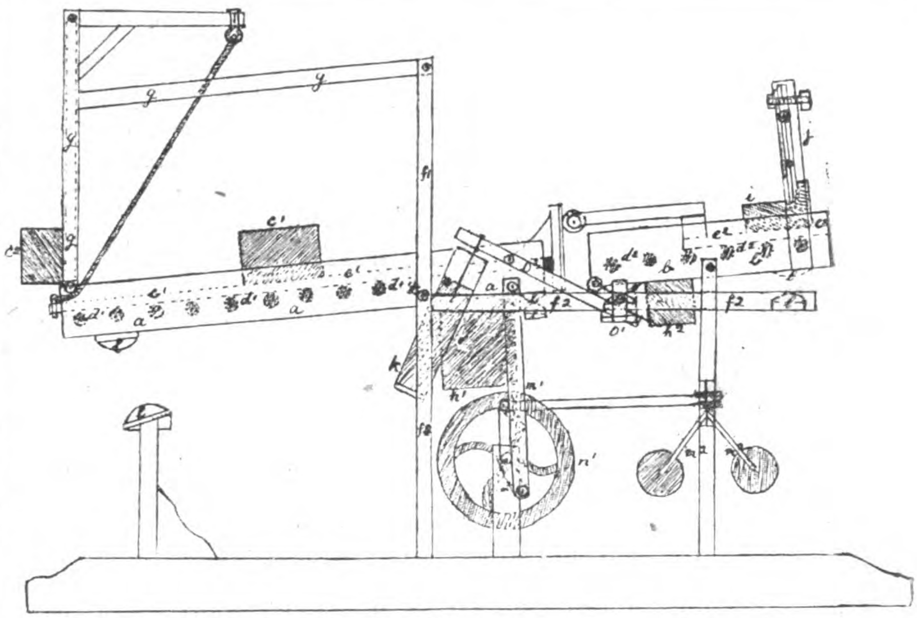


FIG. 1.

a, case; *b*, smaller ditto; c^1, lead weight; c^2, weight on pendulum counterbalancing c^1; d^1 and d^2, rollers; e^1 and e^2, pieces carrying weights c^1 and c^2 moving on rollers; f^1 and f^2 standards and support; *g*, supports for pendulum; h^1 weight counterbalancing, and slightly heavier than c^1 and c^2; h^2, weight counterbalancing, and slightly heavier than weight *i*; *j*, spring checking weight *i*; *k*, weight raising smaller case; *l*, pads; m^1 and m^2, crank-shafts; n^1 and n^2, flywheel and governors; o^1, shaft raising case *b*; o^2, catch holding o^1.

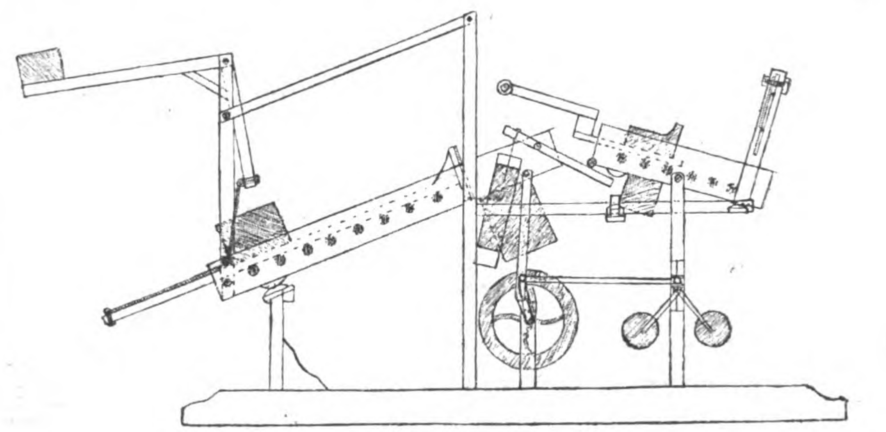

FIG. 2.

Case *a* being depressed, releases the shaft o^2 from the catch o^1 (shown in Figs. 3 and 4). The weight attached to shaft o^1 suffices to raise case *b*, as shown in Fig. 2. This takes the additional weight off c^1 and c^2. Fig. 2 shows the machine just at this

FIG. 3.

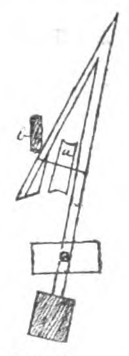

FIG. 4.

a, Grooved wheel; *b*, shaft; *c*, case; *d*, support; *e*, weight holding catch in position.

juncture before the pendulum weight c^2 has had time to drive back c^1 to its original position, and before weight *i* has run back to position shown in Fig. 1. This being done, the apparatus assumes its first position. The use of the spring *j* is to prevent weight *i* running down till case *b* is in its proper position, being adjusted by the screw, so that directly the case is at the right angle the force of the weight itself is sufficient to release it. The process, of course, would be continued *ad infinitum*.

From experiments I have carried out I have every reason to believe that the machine will attain the object for which it was designed, and I submit it to the criticism of your readers, hoping that they will be kind enough, through the medium of your valuable paper, to point out any defects they may notice either in its construction or the principle on which it is designed.

Swiss-road, Weston-super-Mare.

LIQUID AIR AS A COMPANY LEVER.

[42966.]—In America, since the death of Keeley, great efforts have been made to boom liquid air, and all sorts of statements have been made as to its (prospective) capabilities—that is, in the prospectus of the company. Liquid air has its uses—only some have been found out as yet—but it will not do all that is claimed for it. Here is a very good exposure, which emanates from one company criticising the statements of another:—

"The refrigerating power of any substance is measured by its capacity of absorbing heat from the surrounding atmosphere and objects near at hand. And when we wish to express heat in terms of quantity we take as our standard what is known as the British thermal unit; that is to say, the amount of heat sufficient to raise the temperature of one pound of water by 1° Fahr. Now, it has been found by experiment that one pound of ice requires 144 heat-units in order to become completely melted. It is then in the form of one pound of water at 32°, and can absorb 18 additional units in rising to 50° Fahr. Consequently, when ice is used to cool the the interior of a refrigerator to 50° Fahr. it has a cooling power of 162 units per pound. In comparison with this let us see what cooling power is possessed by a pound of liquid air. The best scientific authorities are agreed that the heat absorbed in converting one pound of liquid air into ordinary gaseous air is 144 units; and the

product then has a temperature of about 312° below zero. A pound of gaseous air, however, takes very much less heat to raise it 1° than does a pound of water, the proportion being only 238 to 1,000. If, then, we desire to know how much heat a pound of air will absorb in rising from 312° below zero to 50° above, we have to multiply 362 by 0·238. This gives 86·156 units, which, added to 144, makes 230 as the entire cooling power of one pound of liquid air. Accordingly, one pound of liquid air, considered as a refrigerant, is theoretically equal to 230÷162, or 1·42lb. of ice. But as the loss by evaporation in moving and handling liquid air is very great compared with the analogous loss sustained by ice, we are bound to regard the two substances as being practically equal in refrigerating power, weight for weight. A pint of liquid air weighs somewhat less than a pound, and is thus not more effective than a pound of ice in cooling power. A tumblerful is the equivalent of about ½lb. of ice. Yet, the before quoted prospectus says it will maintain a temperature of zero in a refrigerator for twenty-hours!

"A house of moderate size contains about 1,000lb. of air. To reduce its temperature by 1° Fahr. requires the absorption of 238 heat units. A quart of liquid air is rather less than 2lb. in weight, and if used to reduce temperature to 60°. has a total theoretical cooling power of about 450 units. It, therefore, would not lower the temperature of a house full of air by even 2°, and if we consider that the air in a house is being continually changed, the effect of a single quart of liquid air gradually evaporated would be altogether inappreciable. Yet the precious prospectus tells us that 'a quart of it placed in the ventilating apparatus will keep the temperature of the whole house at 60° during the hottest summer day'!

"Heat, as everyone knows nowadays, is transformable into mechanical power. The force exerted by a steam-engine is derived from the heat in the furnace under the boiler. One heat unit if entirely converted into mechanical power will raise a weight of 772lb. through the space of a foot. Now, liquid air has no power in itself. It is merely a vehicle or mechanism by means of which heat may be converted into mechanical power, and its value in this respect is measured by the quantity of heat it can thus transform. It accomplishes the conversion by expanding against a piston in a cylinder, and a gallon of liquid air in thus expanding to 800gal. of gaseous air at ordinary atmospheric pressure and temperature, will develop a mechanical power of 1,500,000ft.-lb. One horse-power is 33,000ft.-lb. per minute. We see, therefore, that a gallon of liquid air is a mechanism by which we may exert a force of 1H.P. for 45 minutes, if we have a corresponding supply of heat available. We must find some way of warming the air, so as to gasify it and raise it to atmospheric temperature, and we must also supply it with a quantity of heat equivalent to 1,500,000ft.-lb. of work. In a steam-engine it is not the steam itself that does the work. The steam is a mere carrier for the heat generated in the furnace. In like manner liquid air used for power purposes is a mere carrier of heat. It has, however, an advantage over steam. It does not necessarily require a special supply of heat. Owing to its low initial temperature, the vessel that contains it and the surrounding atmosphere, together with all contiguous bodies, are very hot by comparison, and thus serve as a costless furnace. But this furnace is of very slow operation; so slow, indeed, as to be unavailable for practical purposes. A thousand candles may perhaps be capable of generating as much heat as 100lb. of coal; but a steam engine driven by the flame of a single candle would not be of much use, even though the flame might be kept burning from year's end to year's end. Assume, however, that this difficulty does not stand in the way, and that by some ingenious method the atmospheric heat is transmitted with practical celerity to the liquid air. Five and one-half pints —i.e., a gallon after deduction of a tumblerful and a quart—of liquid air used in a motor with full theoretical 100 per cent. efficiency will only give us a force of 1H.P. exerted for thirty-one minutes, or, say, one-tenth of a horse-power for five hours. And yet we are told by the prospectus Munchausen that it 'will generate enough heat to do the cooking, run the electric lights, warm the water for the bath, and in winter heat the entire house by electric radiators'!"

There are, it appears, several companies prepared to do wonders with liquid air, if only the public will supply them with funds; but after some recent exposures, it can scarcely be expected that the American public will seek after perpetual motion to the extent of diving deeply into their pockets.

M. E. V.

LIGHT AND DARKNESS IN A NEBULA.

[42967.]—The "F.R.A.S." is quite mistaken about the Nebula in Andromeda, which he tells us in p. 184 appeared in 1884. I have asked Mr. W. H. Maw, who says, "The temporary star you refer to did not appear in 1884, but in 1885 (August). Its position was slightly preceding and very slightly south of the centre of the nucleus." This was what I remembered, when saying that if it rotated, every place thereon would have evenings and mornings, like our world in the first three periods described in Genesis. Of course we know not whether it rotates, like the majority of heavenly bodies, or whether it exists. I only profess to take the most probable position.

The days must have been understood originally to be long periods. The traditions of the Hindoos prove this. They believe in six before the Deluge, and that we are now in the seventh. The Hebrews were to rest a day after six of labour, because God rests after six of his great days, which the Hindoos call "Days of Brahma." Their account of seven men and their wives in the Ark is not the oldest, but plainly arose from the earlier story of the patriarch having but seven saints with him. The word for "saints" became masculine instead of epicene as at first, and then seven wives were added. The story of his building the Ark was lost, and then it was said to be miraculously provided for him. The approaching comet is described as a fish that at first was no longer than his finger; in three days it was doubled, the next day tripled, and so on till the seventh day, when its train extended a million leagues. In a latter edition these days are turned into years.

E. L. Garbett.

WHEN WERE YOU BORN?

[42968.]—In your last issue a contributor to your valuable paper called attention to a formula of his, showing that this question could be answered, and inviting other readers of "E M.," if they had any other like formulæ, and would be pleased if you could insert them; but his formulæ is scarcely correct after all. Put into form thus, born 2/2/54; age 45. Example:—

Day of month born	2
Multiply by	2
	4
Add	4
	8
Multiply	50
	400
Add No. of month	2
	402
Multiply	100
	40200
Subtract age − 1	44
	40156

And then tell you the remainder.

You then add	100
	40256
Then subtract	20002
	20254

He then says you were born 2/2/54, but it is really 20/2/54, as shown.

I think I can furnish him with about six easier solutions of same with a little over half the figures. The last but one is this. Example:—

Day of month	2
Multiply	1000
	2000
Add No. of month in hundreds	200
	2200
Subtract age + 1	46
	2154

These tell you remainder.

You then add	100
	2254

Which is 2/2/54, as above. Or this—

Day of month	2
Multiply by	1000
	2000
Add No. of month + 1 in hundreds	300
	2300
Subtract age + 1	46
	2/2/54

Which is identical with the above.

R. A. Lawson.

READJUSTING GREGORIANS.

[42969.]—My thanks are due to your distinguished contributor "H." for his full and careful directions for cleaning and adjusting the specula of my old Gregorian. By following his directions, I put the old instrument in excellent working order in about three-quarters of an hour. When I began, the specula were about of the same brilliancy as the end of an old tin can; but in less than fifteen minutes I had them as bright as a piece of new plate mirror, then about half an hour's work adjusting put the instrument in perfect order. I have not had an opportunity of giving it a thorough test yet; but from the trials I have made of it, I think it will prove a very good one for its size and power. I am both surprised and delighted to be able to get it in such good condition so easily.

But "H." is not right in his conjecture as to the proper position of the lenses of my "dialyte," which, by the way, he admits is not at all a certainty. I tried the position he mentions, as well as all other possible relative positions for the two lenses of the corrector, and found that for *these particular lenses* the positions I mentioned in 42842 was the only correct one, and gave excellent results as far as I was able to test it, while all the other positions, including the one mentioned by "H.," gave most miserable definitions, although I could easily correct it for colour. I should certainly write to Mr. Ingall if I knew his address; but "A Mr. Ingall, of London," is a trifle indefinite—to me at least.

This whole subject of the dialyte seems to be very uncertain, and I suppose the best way to find out the facts in the case is to build the telescope and try it. This I shall do as soon as I can spare the time, and will try to give you the result when finished. I am an experienced mechanic, and shall take great care to make all mountings perfect, so the results will depend upon the lenses.

I intend to so mount the lenses of the corrector that they can be separated to any desired amount up to, say, 1½in., while kept rigidly parallel to each other and to the object-glass.

The tube of telescope I shall make of sheet steel, which will insure rigidity, which must be very important in such an instrument.

If any reader can offer any further advice or suggestions I should be glad to hear from them. Again I thank "H." for his valuable and explicit directions regarding the Gregorian.

E. P. Clark.

245, West 18th-street, New York, U.S.A.

CLEANER FOR TOBACCO-PIPE BOWLS.

[42970.]—The sketch represents a little tool numerous readers of "Ours" doubtless feel the want of; it is only necessary to explain that the scraper is of pliant "trough-shaped" steel, so each arm has two cutting edges, and the free upper ends

contract when inserted into a pipe. A turn or two of the appliance "evenly" removes the scale, and without the risk of breaking the bowl as when a "rigid" tool is used.

161, Albion-road, N. A. Clarke.

SEEING BY WIRE.

[42971.]—There seems to be rather more fiction than fact in that paragraph on p. 230, quoted from *Pearson's*. Statements of that genus may suit readers of the American papers (in the backwoods); but in this country, thanks to the science classes, boys of twelve to fourteen, say, are grounded in principles, and ask awkward questions when you speak to them about the possibility of seeing round a corner by means of electricity. "Almost as far back as he can remember, Szczepanik had it in mind to invent a machine for seeing at a distance." Just so: he had it in mind; but has he succeeded in inventing that machine? I think not; but I do not say it is impossible—only that it is improbable. We are becoming quite "acclimatised," so to speak, to these yarns, mostly emanating from American sources; but it would be interesting to have at least a small portion of fact to go with the fiction, so as to have something to digest. Can anyone tell me whether anything whatever has been done towards seeing by wire, or by electricity? I think not, but I preserve an "open mind." These tales may do in a novel on the Jules Verne plan, but they "won't wash." You can telegraph writing and therefore drawings, as witness Cowper's writing telegraph, and more recently Elisha Gray's method, but are they useful as well as practical? The latest device of the kind is practical, but so far as I can learn it is not a practical success in the sense of being commercially useful. The "electroscope" may be

"beautifully simple in its underlying principle," but where is it—where can it be seen? The writer of the article quoted says, "when we see a man or a house, we really receive in the eye perhaps a million, perhaps ten million, distinct pictures of distinct points on the surface of that man or house." It would certainly be interesting to learn what that means. It will be noted that the "time" is not stated. Writers of fiction are apt to take hold of anything they see in the papers of a "startling" character; but we have not arrived at the stage of "seeing by wire." Why "wire," when we already have "wireless telegraphy," as it is called? The question I would ask is simply, Has that "peck of pepper" been found? S. R.

GILBERT'S NEW POWER MACHINE.

[42972.]—Would that the problem of perpetual motion were forsaken for ever. Mr. Gilbert says that he has overcome friction; in that case, why not get an ordinary wheel cast at the nearest foundry, fit it with his anti-friction idea, start it, and if frictional resistance by the air be got rid of, it will run on for ever; but neither Mr. Gilbert nor anyone else has overcome friction so far, because two surfaces can't be produced which are really smooth, for even the most microscopical protuberances on the one surface fit into hollows on the other, and consequently require some force to make them slide over one another. Now where is this force going to be got? In machine No. 1 there are six weights tending to lift eight besides working the lifting gear, so that it is evident that we need not look to the weights for this force, and so far as I can see they constitute the only peculiarities of an otherwise respectable wheel. Those holes look a bit out of place in the weights: if the weights are going to drive the thing, why weaken it by taking away its motive power? Mr. Gilbert says that the principle is there—about as much as in any other perpetual-motion machine. I do not know what Nos. 3 and 4 will be like; but they should be carefully secured with ropes while being built, in case they start of their own accord; failing which, you are as far from perpetual motion as ever; for if you have to start them, then the work put in = the work given out + lost work, so that you can never even get as much work out of the machine as you put into it, and friction in this case will be no negligible quantity, as Mr. Gilbert can prove by having a weight cast similar to those on No. 2, say, and screwing it in and out of a piece of iron and noting the effort required.

If would-be perpetual motion inventors would only take a few lessons in elementary applied mechanics, they would save themselves a lot of trouble, because they would see the futility of their ideas, and would grasp more fully what they in their ignorance were trying to do—namely, to create energy out of nothing. Knowing what we do of mechanics, those perpetual-motion fads, Keeley motors, and liquid-air motors constitute particularly nauseous reading, and cause one to sigh, and exclaim "So much more brainwork thrown away."

W. Ewart Gibson.

The First Iron Boat.—The county of Lancaster is entitled to the honour of having produced the first iron boat, which was made by John Wilkinson, at Cartmel, about 1750. John Wilkinson was in partnership with his father and brother, and they, having engaged in smelting the rich hematite ores then known as Furness iron, used the peat and turf of the district for fuel. To get a proper supply of this for the furnace, John Wilkinson designed a short canal which was cut through the turbary, and the iron boat was constructed. The country was then keen on canal enterprise, and Wilkinson constructed other iron boats for the purpose of this inland navigation. These iron boats caused great astonishment, and, according to a letter written by Wilkinson, the unbelievers in their capacity for swimming were 999 in 1,000. The boats were a nine days' wonder, and were then like Columbus's egg.

Casting Iron Columns.—At a meeting of the German Iron Founders' Association, Direktor Pusch made a communication as to the vertical casting of iron pipes and columns, and eventually the following conclusions were adopted:—1. The vertical casting of columns affords no greater guarantee of uniform thickness and sound metal than does horizontal casting; and a column moulded and cast horizontally with the same care is not inferior in quality to one cast vertically. 2. Uniformity of thickness secured by boring, and a compression test to double the maximum load, afford a sufficient guarantee of strength and quality. 3. The superiority of columns cast vertically cannot be admitted; but for producing pipes vertical casting is quite suitable, because they must be smooth inside and outside, with a uniform diameter, and there can be no support for the cores; while, during the vertical casting of plain pipes, the impurities in the cast iron rise to the top, and may without disadvantage form part of the runner.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[96555.]—**Equation.**—"M.I.C.E." has evaded my remarks. I simply questioned the legitimacy of introducing certain integral assumptions into a problem. When, for example, we are asked to find x in $x^2 + 3x = 5$, we have no right to begin by making restrictions, such as "M.I.C.E." does—viz., that the sum of a rational and surd cannot be a whole number, and therefore x must be exact or the equation absurd. "M.I.C E." stated that there were only two values of x^2 which could divide 34,445¼ exactly—viz., ¼ and 2¼, and I pointed out that there were certainly twenty values which could do this. He now says that x cannot be a surd, that its extreme value is only a little over three, and a number of other things which have nothing to do with the subject or his method of solution. So far as we could know, x, y, z might have been surds without disturbing the conditions of the equation. Thus, if $x = \sqrt{\frac{2}{3}}$, $y = \sqrt{\frac{3}{2}}$, $z = \sqrt{6}$, then $x^2, y^2, z^2, xy, xz, yz$, are all rationals. Again, how can we be sure that one of the three unknowns is not negative? Of course, trials may convince us one way or the other; but this is not algebra. I admit, however, that the device employed by "M.I.C.E." is a useful suggestion, and may frequently lead to a quick solution of cubic and biquadratic equations when x is *not* a surd. I simply object to unlimited assumption as an algebraical process—nothing more. Suppose we have the following cubic to solve:—

$$x^3 - 18x^2 + 87x - 70 = 0.$$

Here the usual formula fails, and the trigonometrical method is laborious and clumsy. But, dividing by x, and making the assumption that x must be exact, we have—

$$x^2 + 87 = 18x + \frac{70}{x}$$

where x must be one or more of the factors of 70—viz., 1, 2, 5, 7, 10, 35. We see at once that 35 is too great, and that 1 and 10 satisfy the equation. We also find that 2 and 5 are too great for the left-hand branch, and that 7 exactly balances both. Hence x=1, 7, 10. Lastly, in the biquadratic—

$$x^4 - 25x^2 + 60x - 36 = 0.$$

Dividing by x^2 and assuming x to be exact, we have—

$$x^2 + \frac{60}{x} = \frac{36}{x^2} + 25.$$

But x^2 can only be 1, 4, 9, 36, and therefore x, 1, 2, 3, 6. The first three values satisfy the equation, and taking 6 negatively, we obtain a fourth—i.e., x = 1, 2, 3 − 6.

West Norwood. Henry T. Burgess.

[96555.]—**Equation**—(Correction).—See my reply, p. 234 (near the middle). In the equation $m = \frac{8}{3} n \pm \ldots$, the fraction $\frac{8}{3}$ should be $\frac{8}{5}$.

Bath. M.I.C.E.

[96633.]—**Green Water.**—I think Mr. J. Sinel is right in attributing the greenness to infusoria. The water not only turns green, but the surface becomes covered with myriads of minute bubbles, which go on increasing till in a few weeks the whole surface is covered with an inch of yellowish foam. Assuming it to be caused by Euglena viridis, is there any cure or prevention? The bath is 40ft. long, and contains over 9,000 gallons. The water is pumped from a well 37ft. deep in chalk, and is perfectly clear and drinkable when first pumped up. With a fair breeze the mill takes four days to fill the bath, and it begins immediately to get green.

Quex.

[96641.]—**Grinding-in Valves.**—If the valves have worn so very badly, it might be advisable to run over them with a dead-smooth file. The best "mud" for doing the fine grinding—that is, the grinding into the seat—is the stuff found in the grindstone trough. Very fine emery, such as is used for finishing telescope mirrors might do, but that is too valuable for other purposes, and ordinary emery, even if fine, should never be used for grinding metal surfaces to one another. Grindstone mud is the best stuff, and if a very close fit is required finish with jeweller's crocus or rouge. Mix the powders or "mud" with oil, and grind in with a circular motion, shifting from time to time.

M. T.

[96654.]—**Turret Clocks.**—The question asked is as to the best illustrated work on turret clocks, which is best answered by asking another question: Is there any illustrated work on turret clocks? The best work on such a subject that I know of is Lord Grimthorpe's (Sir E. Beckett's) "Clocks, Watches, and Bells," published by Crosby Lockwood and Son. All requisite information can be found in that. The Westminster clock commonly called Big Ben (which name refers to the bell) is a "turret" clock in a sense—possibly the best in the world.

S. R.

[96655.]—**Silvering Glass.**—Methods of silvering glass have been given many times, but as to a "perfectly opaque coating of silver on any polished glass surface" that is another matter. To be "perfectly opaque" the coat of silver would have to be rather thick. The querist will find the usual recipes in the back volumes, and in the manuals which treat on such subjects; but I expect he will have to experiment for some time before he obtains a "perfectly opaque" coating. Metops.

[96658.] — **Rheumatism.** — "Adams" asks (p. 188) what is meant by "kerosine oil," which may be spelt kerosene. It means, or should mean, the burning-oil obtained from petroleum after the lighter oils down to benzoline have been taken away by distillation, and the heavy oils removed by freezing or any approved method. It is the name used in America for the "safe" burning oil. I do not know what kerosene has to do with rheumatism; but possibly if the system is saturated with it the hydrocarbon will drive out the poison of the rheumatism. S. M.

[96668.] — **Mirror-Back Show-cards.** — This query is not quite definite; but if it means only how is bronze powder affixed to glass, that is easily done by making the glass perfectly clean, floating it with pure size or a clear varnish (Canada balsam if necessary), and then dusting on the powder. The bronze powder may be mixed with varnish and painted on, but the important point is that the glass must be quite clean—chemically clean. Essar.

[96719.]—**Gauging Cylindrical Tanks.**—As I read the query of "Chemicus," the tanks lie in a horizontal position, therefore the formula of "Regent's Park" is not applicable, as that applies to the vertical position. Perhaps "The Park" was a little misty just then. It is so sometimes at this season of the year. In all probability "Chemicus" will not get exactly what he wants; we rarely do. I think he will have to work out each wet inch separately. The transverse section of the fluid is, of course, a segment of a sphere, the area of which can be found by the help of the tables in Chambers's "Mathematical Tables" or Peddie's "Practical Measurer." The area being found and multiplied by the length, and then by "Regent's Park's" multipliers, would give the contents in gallons. The wet inches would, of course, correspond to the versed sine or rise of the arc. I think if "Chemicus" applied to a maker of slide-rules, he would get a rule probably made for the purpose—such as are used for gauging boilers. T. J. Lenny.

[96729.]—**Grindstone.**—I am much obliged to your correspondent "Regent's Park" for his suggestion as to a solution to my query; but it is not a solution. The problem should be capable of being dealt with in a useful form, which I feel sure "Regent's Park" or some other of your readers could devise. Grindstone.

[96759.]—**Bikes and Prams.**—What I want to know is where and when it was decided in a court of law that bicycles are carriages within the meaning of the Act. I fail to see how a cycle can be a "carriage" when it is not carrying anything, but is being merely wheeled on the path—to be removed as soon as possible. Please quote the case in which the point has been settled. I believe town councils, corporations, &c., can make by-laws within certain lines, and decide what shall be considered an "obstruction"; but if they can permit perambulators (which are certainly carriages) on the foot-path, they can also allow a bicycle to be wheeled on the path for the temporary convenience of the man who would prefer to ride it. I will promise not to use the word "bike" (which has come into universal use) when the makers of bicycles spell tire instead of tyre. Rota.

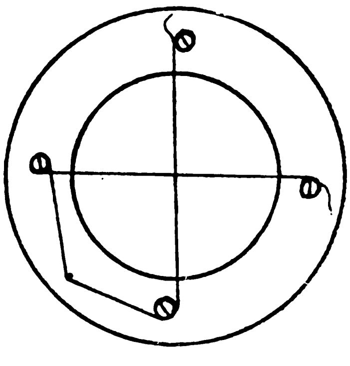
[96803.] — **Equatorial Adjustment.** — It appears to me as if the declination vernier is simply out of adjustment. Halve the difference between the two readings with the telescope E. and W. of the pillar, and set the vernier to this reading. Repeat the operation—using a star as nearly on the meridian as possible—until both read alike. The difference of reading indicated (three or four minutes) certainly appear a long way out—impossible in some instruments; but I have worked with an excellent equatorial of Wray's in which the vernier was a separate circle, which could be turned completely round on the declination axis.

H. Wadsworth.

[96808.]—**Dynamo Switchboard.**—Also practically the same in my little handbook "How to Manage the Dynamo," at pp. 36 to 39.—In replies over my name, 96830 and 96865, two errors occur. In the first, the power required to drive dynamo should be 48 to 50H.P.; and in the latter, in the last line but one, the word smaller should be substituted for "similar." S. Bottone.

[96810.]—**Finder.**—Mr. N. Maclachlan will find that a long piece of human hair (the finer the better) will make capital cross-lines for his finder. if applied in the following way:—Take the brass frame which carries the cross-lines, and drill and tap four holes in it, at opposite ends of two diameters accurately at right angles to each other.

In these holes insert four brass screws, which must fit friction tight. Twist the hair round the screws, having previously screwed them nearly home. When the cross is complete, screw the screws up tight; but not too tight, or the hair may cut. The hair should be twisted round the screws in such a way that when they are screwed home it may tighten, not loosen. With this arrangement it is easy to renew the lines at any time. If the querist lives in the country he may find it possible to use spider-web instead of hair. The elasticity of either the hair or web makes it possible to tighten up without breaking. The diagram will help to make



my directions clearer. It is a good plan to make a single hair form the entire cross, as there is less chance of its coming looce, and to do this it may be necessary to insert a small stud between two of the screws to keep that portion of the hair from crossing the field of view, as indicated in the figure; or the screws my be set further back from the edge of the aperture. W. F. A. Ellison.

[96837.]—**Phonograph.**—To give a full explanation of the difference between the Edison and Bettini reproducer would, I am afraid, take up too much space in this column. Briefly, it is this: In the recorders and reproducer of the phonograph and graphophone the style is attached to the centre of the glass diaphragm, whereas in the Bettini recorder and reproducer (in the case of a single diaphragm) it is attached by means of small arms on branches to various parts of its surface; but in the complex form, which consists of several diaphragms, the branches are attached to the centre of each diaphragm, so that each diaphragm will vibrate to some special characteristic in the sounds received. The Bettini improvements cover several forms of diaphragms, one or two of which have already appeared on the English market. In reply to your other question, there is practically no difference between the phonograph and graphophone records as now supplied. If by graphophone you mean the machines now being sold in this country under such names as phonograph-graphophone, Columbia phonograph, &c., though cheap, well-finished, and reliable machines, are not to compare with such machines as the genuine Edison and the better class of Edison-Bell phonographs. F. F.

[96837.]—**Phonograph.**—As "F. F." has not responded, I will endeavour to answer this query. The Bettini has a mellower, fuller, and more musical tone than the ordinary glass reproducer. This arises from three causes. 1. Its size. A big drum has a richer, mellower note than a small drum, and the Bettini has double the vibration area of the other. 2. The composition of the tympanum. If a metal plate be struck it emits a "singy" musical note, due to the number of overtones which it emits —a glass one on the contrary has a sharper and thinner tone with fewer overtones. My Bettini has apparently an aluminium diaphragm which I should think would be very much better replaced by a bellmetal or silver one. 3. The mechanism which forms the subject of Bettini's two patents, August 1889 and December 1892. When a stone is dropped into a still pond a circle is immediately formed, followed by another circle until the whole pond is covered by concentric circles. If a section of the pond could be obtained, the surface would be seen to consist of a regular series of troughs and crests like the waves of the sea—this being the way sound-waves are always projected. When in motion the diaphragm of the reproducer resembles the surface of the pond, and Bettini considered that he might utilise more than one wave; so I find mine has a sort of wire spider with nine legs fixed at different distances from the "body" which supports the sapphire stylus, thus utilising the whole vibratory surface. In addition it has a much larger area of tube to the horn projector. I presume by his second query, "C.E.O." means "Gramophone" which has a flat horizontal record. These are, I believe, made of celluloid, which is harder and has a more piercing tone than the wax ones of the phonograph; but the possessor cannot make his own records. Fred. Davis.

[96840.]—**Microscope.**—To "Optician."—My lenses are all convex. Micro Amateur.

[96848.]—**Failure of Dynamo.**—"Brewed Ginger" should look to his mode of connecting the lamps to the cables. Arrange the lamps in "parallel" instead of in "series," and then the failure will cease. In other words, instead of the lamps being connected all along the cables like beads on a string, they must be placed across the cables like the several rungs on a ladder. When this alteration has been effected, you may put back your 60-volt lamps, and your machine will then run fifteen or any less number of 16c.p. lamps, as it was originally intended to. Q. I. E.

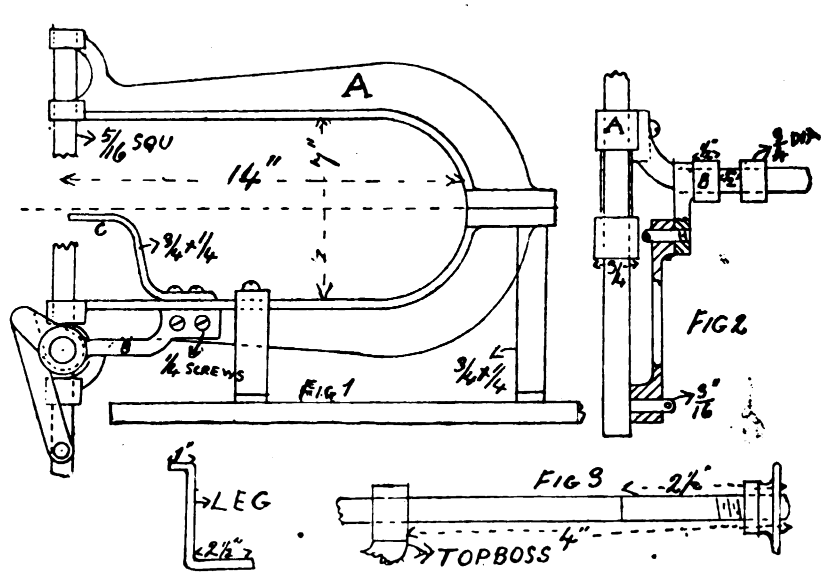
[96849.]—**Board of Trade Exam.**—Get afloat as engineer; you will have to serve about eighteen months at sea before allowed to sit for a second engineer's ticket. No certificate is required to commence with. Engineer.

[96849.]—**Board of Trade Exam.**—The Board of Trade regulations for a candidate for second-class certificate are: He must be twenty-one years of age, must have served an apprenticeship to an engineer for three years at least (no period of service in a drawing office can be allowed to count for more than six months' workshop time); he must have served one year at sea in the engine-room as an engineer on regular watch. "No Name's" best plan will be to try and get employment at a marine-engine works, or the repairing shops of a large steamship company (preferably the latter), for at least eighteen months; he will then have ample opportunity to persuade the owners or managers to give him a berth as junior engineer on one of the boats.
Niton, I.W. S. C.

[96859.]—**To "Monty."**—Ignition-lamp described is essentially a gravity-feed lamp, and is not intended to work with supply tank below or pressure in tank above ½lb. If tank was below, vaporising arrangement would have to be added similar to

frequently remedy by wiping points with piece fine emery-cloth, and perhaps slight adjustment of screw is all that is needed. The ignition plug, too, has been a fruitful source of worry, with cracks and loose stems through which high-tension current passes and is lost. A simple plug which is not a patent, having been used to my knowledge fifteen years ago, may be made from an old plug, centre china having been taken out and filled with mica washers, also top and bottom with mica ⅛in. thick, and whole screwed up solid by means of a centre bolt, which is tipped at bottom with platinum points. They are practically indestructible, and if a tight fit on centre bolt and screwed up hot, will give satisfaction in use. You can, if you like, fix platinum tube inside combustion chamber, and another outside for lamp. After engine has started lamp may be put out, and inside tube, becoming red-hot, will make engine self-firing, and it will keep running if not cut out too frequently or long at one time. The Daimler Co., who first introduced present tube system for oil motors, are now moving towards electric ignition on their latest cars. Monty.

[96862.]—**Fret-Saw Machine.**—I send a rough sketch of a machine I built some time ago. Its cost is under five shillings, and it cuts ⅜in. wood easily. "Terf-Was" should buy an old Singer sewing-machine of the kind that have two small mitre wheels in them. Mine cost me 1s. 6d. The parts to save for the fret-cutter are the flywheel with its spindle, the small crank underneath, and the largest of the screws. Then procure two casting, like A, Fig. 1, and bolt them together with ¼in. bolts (not shown), not forgetting to put a piece of leather in between, as that saves the trouble of filing up the joint-faces. Drill holes in the bosses where the bars work up and down, and file out square afterwards. A milled nut is fitted to the top bar, which bar is rounded and screwed for about 2¼in., as shown in



Actua, which consists simply in passing flame through a coil of tube through which oil is forced up. These lamps have sometimes 15lb. to 20lb. on them when forced. Why do you want to add vaporiser when you can buy petrol ready refined, which saves all paraphernalia, and also objectionable smell from heating heavy oil such as paraffin, which I presume you are thinking of doing? It is a far more difficult problem to produce a satisfactory heavy oil-engine for many reasons I can't give here —all tried so far are simply not in it with petrol. The Longuemare type of vaporiser as described for saturating air is one of the best going, though it has endless modifications. At risk of being tedious, I will again repeat warning: "Don't throttle your engine by making inlet and exhaust and all connections too small." Gauze box should have a diameter at least three times that of inlet pipe, as it retards vapour greatly. It is a great deal easier to choke high-speed petrol engines than most people are aware of. Platinum gives better results than anything else, though first cost is greater, present rate being about 34s. for a tube, half of which you will be allowed in changing for a new one. Platinum being thinner, heats us and fires much quicker, and lasts a very long time with care. There is a good imitation known as Hecnum metal, which may be bought for 7s. each. They seem to work well, though I have not given them lengthy trial on road. In spite of all drawbacks to electric ignition, it is infinitely superior to lamp, and some form of magneto will undoubtedly survive over troublesome batteries. The Dion form of contact-breaker is not certain when covered with oil on platinum points; hence faults sometimes, which user could

Fig. 3. When at its highest point, the top of the bar should be about 4in. above the top boss of machine. Slip a rather stiff spiral spring over bar, so that it rests on boss, and regulate stiffness by the nut on top. Make a full-sized drawing of machine before building it. A pattern must be made for the bracket B, Figs. 1 and 2. The worktable (now tilting) is screwed to the bent iron bracket C. Fig. 2 is an enlarged view of driving gear A, boss on frame B, bracket from pattern D, crank from old machine E, spindle from same, cut to length required. Driving-wheel from old machine goes on end of spindle E. Connecting-rod can be a little forging, or can be converted from rods about the sewing-machine. Cut a hole in bench for bottom bar to sink into. The back legs are held by two of the bolts, which hold the two halves of the machine together. This machine has a true vertical stroke, which is not the case with those that have two long arms to them. I have said nothing about the saw clamps on the ends of bars, as they can be copied from a hand-frame. In conclusion, if "Terf-Was" cares to advertise his address, I will lend him a pattern of A, Fig. 1, gratis. E. W. Fraser.

[96877.]—**Electric Light.**—The average consumption of units per hour for 16c.p. incandescents is ·056. For a 500c.p. arc on a 50v. circuit ·25 unit, and for a 1,000c.p. arc ·5 unit.
A. H. Avery, A.I.E.E.
Fulmen Works, Tunbridge Wells.

[96877.]—**Electric Light.**—Reckoning that a fairly efficient incandescent lamp takes 3½ watts to work it, then a 16c.p. will take 56 watts, or nearly one-eighteenth of a unit per hour. A 200c.p. will

take just about one unit. A 500c.p. arc lamp will take about one-third, and a 1,000c.p. about two-thirds of a unit. S. BOTTONE.

[96877.]—**Electric Light.**—The consumption in units per hour of a 16, 32, and 100c.p. incandescent lamps, and 500 and 1,000c.p. arcs, will be approximately $\frac{1}{16}$th, $\frac{1}{8}$th, and $\frac{1}{3}$rd of a unit, and $\frac{1}{6}$th and $\frac{1}{3}$rd of one unit respectively.

WEBSTER MICHELSON AND CO.,
Dudley. Electrical Engineers.

[96873.]—**Whole-Meal Bread.**—The reply of "Regent's Park" to the above query states: "Dissolve 1oz. of bicarbonate of soda in boiling water." He has apparently overlooked the fact that under these conditions the greater part of the bicarbonate $NaHCO_3$ would be converted to the sodium carbonate Na_2CO_3, the equation being, $2\ NaHCO_3 = NaCO_3 + CO_2 + H_2O$. On the decomposition of the bicarbonate by heat depends the aëration of soda cakes. It should be dissolved in cold water.

T. J. LENEY.

[96873.]—**Whole-Meal Bread.**—In making the above with yeast, there is a difficulty in getting sufficient porosity, as the yeast does not propagate so freely in wholemeal, owing, no doubt, to the white portion comprising the gluten and starch in which the yeast cells thrive being considerably separated, by reason of the presence of the bran. The remedy is to add a small portion of white flour, which will counteract this defect. Take, say, about one quartern of wholemeal and half a quartern of white. Use the pressed or German yeast—about 2oz. See that it is fresh. It should not crumble too readily. Dissolve this yeast in warm water that is of about the same temperature as the hand; add about a saltspoon of salt to the flour, and stir in the yeast water. Make the dough slack at first, and knead in more dry flour till of the right consistency. Have ready your baking-tins, grease them inside, and around the sides tie some paper. Put in each a piece of dough of a size sufficient to about one-third fill the tin. Place these somewhere near the fire, where they will be kept at about blood-heat, bearing in mind that yeast is a vegetable growth, and will easily be killed with too much heat. In about an hour it will have risen to nearly three times its bulk; then put in the oven, which should be brisk at first, and slower after. About one hour is the usual time of baking. The reason for having the oven brisk at first is that it will cause an expansion of the carbon dioxide set free by the yeast cells, and this tends towards greater porosity.

T. J. LENEY.

[96881.]—**Malting Wheat.**—H. Stopes on "Malt and Malting," of *Brewers' Journal* Office, London, E.C., gives difficulty of growing it with the acrospire outside the husk. Its excess of gluten and other nitrogenous constituents give much trouble. It is rarely made and little known. Differs in itself from barley, and is much more difficult to make. In 1834 wheat was cheaper than barley, and a considerable quantity made into malt. Owing to great difficulty of working up a flour without damage to the growing acrospire, many maltsters mixed wheat and barley together. At that time 13 bushels of barley produced same quantity of beer of standard gravity as 9 bushels of wheat, 10 of rye, or 10 of oats. J. E. Thausing and W. J. Braunt on Malt, and Low and Co., speaking of wheat malt:—It gives light colour better than barley, but more difficult because of its nakedness, and partly because in germinating the cotyledon appears on same point of grain shortly after radicle has made its appearance. The gaining of wort from wheat is difficult, on account of tenacious layer of grains. Wort is frequently cloudy, difficult to clarify, beer is said not to keep well—probably, as to latter, caused by the larger quantities of proteine substances dissolved in mashing. Mealy wheat better than glassy wheat for beer fabrication. As to rye, it appears to have same defects, as when the worts are cloudy mucous, does not clarify, has disagreeable, sharp taste—this sharpness caused by formation of butyric acid in rye mashes. Much the same processes as with barley.

REGENT'S PARK.

[96882.]—**Vinegar Plant.**—Vinegar by means of vinegar fungus:—In 1862 a new method of making, devised by Pasteur. Vinegar fungus (*Mycoderma aceti*) is agent, is first propagated and cultivated in fluid composed of water with two per cent. of alcohol, one per cent of vinegar, and a small quantity of the phosphate of potash, magnesia, and lime. The surface of fluid soon becomes covered with fungus, part of alcohol at same time acetified. When half of alcohol has become acetified, small quantities of wine and beer are added to fluid every day, and the process carried on until all alcohol has become oxidised. Vinegar then removed from containing vessel and fungus employed in manufacture of a second batch. Vinegar prepared thus is said to possess aroma of wine vinegar. Vessels are made of wood, and in form round or rectangular shallow tanks. The prepared liquid, contained in a vessel having an area of about $10\frac{3}{4}$ square feet, and a capacity of from 90 to 100 pints, yields about 9 to 10 pints of vinegar daily. Tanks are covered by lids, air admitted to contents through holes bored at end of vessel; whilst alcohol is conveyed to bottom of fluid through perforated guttapercha tubes—an arrangement which gets rid of the necessity of opening the lids. When alcohol alone is employed, Pasteur makes the addition to the fluid of about $\frac{1}{10000}$th of its weight of sulphate of ammonia and phosphate of potash and magnesia, as well as some vinegar. The above salts constitute the food of the fungus, and as they are contained in beer and wine, they are dispensed with when these fluids are employed instead of alcohol, and successful result can only be obtained by paying great attention to the healthy development and growth of the mycoderma at starting. REGENT'S PARK.

[96883.]—**Diamond.**—Unchanged by heating out of contact with air to 1,300° or 1,400°; but, placed between carbon poles of powerful battery, it glows brilliantly, swells up, splits, and after cooling the surface resembles coke from bituminous coal. Unchanged when heated to whiteness in water vapour. Strongly heated in a stream of O, diamond is completely burnt to CO_2, &c. (Watts's "Chemical Dictionary.") REGENT'S PARK.

[96887.]—**Clocks.**—Perhaps secretary of the Horological Society, Northampton-square, E.C., may have data. Have not seen it in Britten's works on clocks and watches. REGENT'S PARK.

[96890.]—**Lahmeyer Dynamo.**—TO MR. AVERY.—In the first place quadripolar armatures never give very good results. A tripolar, or, better still, cogged drum, would effect a vast improvement. Then, again, a finer gauge of wire is required on the armature; the querist does not mention what output he requires; but as a guide I may say that with a machine of these dimensions, I use 3oz. No. 24 on the armature, and 12oz. No. 22 on the fields, getting 15 volts 2 ampères at 2,800 revs.

A. H. AVERY, A.Inst.E.E.
Fulmen Works, Tunbridge Wells.

[96891.]—**Sun-Views by Projection.**—I have just obtained a Slade micrometer for this purpose, which I think will answer very well. But it will be advisable to stop down the o.g. or mirror, as too great heat might injure the photographic film. A ruled glass reticule will be somewhat expensive. I am using my Slade for direct vision, with my $8\frac{1}{2}$in. mirror largely stopped down. H. WADSWORTH.

[96894.]—**Crickets.**—Make a paste of some (one part) powdered chloride of lime and half a part of some fatty matter, and spread on pieces of bread to lay in or about infested places. Expect they will clear out. Or sprinkle a little quicklime near to cracks at which you expect they enter room. Laid down at night, it can be swept away in the morning; but keep the children from fingering chloride of lime. Or put chloride of lime and powdered tobacco in their holes. REGENT'S PARK.

[96899.]—**Tides.**—Roughly speaking, it may be said that high-water at any port occurs daily a certain number of hours and minutes after the moon crosses the meridian of the place; of course, the sun's influence makes this only very roughly true. Now, on the day of change or full, the moon must cross the meridian (above horizon in former case, below it in latter), very nearly at noon. For, since the moon's motion in its orbit alters the time of crossing meridian by only about 50min. per day, it is evident that although new or full moon may occur at any time of the day, the moon must cross the meridian on that day within a few minutes before or after the sun. Therefore, the time of high-water must be at nearly a fixed interval after noon on day of full or change—i.e., it occurs at almost a fixed time of day. It is the average time, of course, which is given in the tide-tables. It need hardly be said that whether the moon crosses the meridian at noon above the horizon (as at change), or below (as at full), is immaterial, as the theory of the tides shows that the moon's tidal influence is similar when it is on opposite sides of the earth.

ARCTURUS.

[96900.]—**Grammaphone.**—Yes, I should think the diaphragm ought to be "as thin as you can get it." Perhaps (if the querist uses talc) glass might answer better in his case. Possibly he may not have secured the edges of the diaphragm as tightly as they should be held. Again, the screeching may be the result of some fault in the record or needle. The latter, if not sharp enough, sometimes slips over the edge of the groove. I am afraid I cannot help him with the latter part of his query.

R. A. R. BENNETT.

[96901.]—**Wimshurst.**—TO MR. BOTTONE.—Do not use wood—you will utterly spoil your machine. Procure two discs of ebonite, reaching nearly to the brushes, and cut them into stars, the rays of which reach between the sectors. Cement these on with very thick shellac varnish. S. BOTTONE.

[96902.]—**Gas Explosions.**—The hydrogen alone requires less air mixed with it to form an explosive mixture than the compound gas from the ordinary jet; besides, there is a great difference between a bottle and a room. Very near all gases containing hydrogen require a fixed quantity of air to be at the most explosive point, and an excess of gas or air from this point reduces its explosive character in comparison until it burns quietly.

D. T. W.

[96905.]—**Negatives of Diagrams.**—For this class of work I always use Ilford isochromatic plates. There are "process" plates specially made by the same firm for this work. Give a short exposure in a good light. Use some pyro developer with plenty of sulphite of soda in it, or else hydroquinone. To fasten the diagram opposite window may cause a shadow of the camera on it. I fasten them sideways to the window. If above system is carefully carried out, it is almost impossible to tell the print (if in platinotype, &c.) from the original.

R. A. R. BENNETT.

[96905.]—**Negatives of Diagrams.**—Use less accelerator in the developer than you would in ordinary work; also look to exposure, which must not be over-long. If you have many to do, you had better begin by exposing three or four plates on a diagram, giving different times. The result will give you the best indication as to exposure. The black lines should be nearly clear glass on the negative, so that they will print out black almost at once, and before any light has got through the dense part. DIAGRAMS.

[96905.]—**Negatives of Diagrams.**—Bromide paper offers a ready method of getting a soot and whitewash print. Use a slow plate, backed to prevent halation; and with a small stop, minimum exposure, and plenty of pyro, there ought not to be much difficulty, if the diagrams are in a good black ink and cannot be used as negatives. I have somewhere seen recommended duplicate isochromatic film negatives, printed superposed, but have not tried this. J. D.

[96906.]—**Arc Lamp.**—(1) Yes, with close attention. (2) On a continuous-current circuit the carbons are arranged in pairs—one solid, connected to the negative wire, and the other cored, and connected to the positive. (3) For a current of 13 ampères, the positive carbon should be 20mm. cored, and the negative 13mm. solid. Sputtering is chiefly due to imperfections in the carbons; use only the best obtainable.

A. H. AVERY, A.I.E.E.
Fulmen Works, Tunbridge Wells.

[96907.]—**Wireless Telegraphy.**—TO MR. BOTTONE.—(1) The relay spring is apparently too stiff, and perhaps the iron of the relay retains magnetism, hence the failure in decohering. The core of relay should be a bundle of well-annealed No. 22 soft iron wire. (2) You do not say how your decoherer is made or how it works; but in all probability it does not strike the coherer at the right spot to decohere the filling. (3) One wire can be horizontal, provided it touches nothing but the coherer. The other can be taken to earth. This "vertical" wire may take the form of a strip. (4) Yes, a fourth ball increases the effect. (5) Probably due to the stiffness of the relay spring.

S. BOTTONE.

[96908.]—**To Mr. J. Dormer.**—Contact prints of antiquarian extent are beyond my experience, and bromide paper, though obtainable of this size and printable by gaslight, is, I suppose, not suitable. Some other reader may be able to give the information required. Again, I know nothing about parchment as a substratum; but to palliate this disappointing agnosticism, I append a cyanotype recipe. Take about 80gr. red prussiate of potash and about the same quantity of ammonio-citrate of iron, dissolve each in an ounce of water, mix and apply to well-sized paper; dry quickly, and do not keep too long before use. If you treat paper with iron alone, the ferrocyanide will act as a developer. Clear the whites, if necessary, with a little citric acid. J. D.

[96909.]—**Gilding.**—Put book into press straight and on level with cheeks of press between cutting boards, boards of book thrown back. Screw up tightly, any projection of cutting-board taken away with chisel. If paper unsized or at all spongy, edge should be sized and left to dry. This may be ascertained by wetting a leaf with tongue; if spongy, the moisture sinks right through as in blotting paper. Scrape quite flat edge, and even all equally. When quite smooth, mixture of black lead and thin glair water painted over edge, and with hard brush well brushed till dry. Now cut gold on the cushion. Lift leaf out of book with gold knife, lay on cushion, breath gently on centre of leaf to lay it flat, then cut to size. Edge glaired evenly, gold taken up with piece of paper previously greased by drawing it over the head. Gold then laid gently on edge previously glaired. Whole edge or end being done, it is allowed to get perfectly dry, say, in two hours. Before burnishing lay a piece of fine paper on gold, and gently flatten with burnisher; it then becomes dull gilt. When intended to be bright a waxed cloth should be gently rubbed over the surface two or three times before using burnisher. To peruse J. W. Zaehns-

dorff's "Bookbinding" would well repay—of G. Bell and Sons. REGENT'S PARK.

[96910.]—**Belt-Lacing.**—See "Leather Manufacture," by A. Watt, 1885 (Crosby Lockwood and Co.) Cowhide almost invariably used for belts; lacing-thongs commonly made of leather or good clean cowhide, softened and stretched somewhat to render it firm and even; vary in width from ¼in. to ⅜in., and in thickness from $\frac{1}{32}$in. to nearly ⅛in., according to width. REGENT'S PARK.

[96911.]—**Accumulators.**—Pasted plates are better, insomuch as the active material bears a much greater proportion to the surface exposed than with the Planté.

A. H. AVERY, A.Inst.E E.

Fulmen Works, Tunbridge Wells.

[96914.]—**Astronomical.**—If "Novice" means by the time of rising of a star the time at which its true altitude is 0°, a star which rises exactly in the east must be situated on the celestial equator, and will be 12 sidereal hours above the horizon, or 11h. 58m. 2s. of mean time. But as refraction causes a star to appear on the horizon when it is actually 35′ below it, such a star will appear above the horizon for a slightly longer period, depending on the latitude. In latitude 52°, for example, the time would be about 12h. 6m. of mean time. ARCTURUS.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered, are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

The German Beer Industry.—The German beer industry has grown year by year, and the increasing capacity of the establishments has made it necessary for the brewers to search for new markets where their overproduction could be disposed of. In the year 1885 the export of German beer reached its maximum, amounting in that year to 1,318,000 hectolitres (28,996,000gal.), representing a value of 24,000,000 marks (£1,200,000). The next year, however, showed a decrease, and since then the export has gone down to about one-half of what it was in 1885. According to the United States Consul at Kehl, the reason given for this decline is that the countries which were Germany's best customers—France, Belgium, and the Netherlands—have increased their output sufficiently to nearly meet the home demand. The high duty placed on foreign beers by France has also had the effect of considerably reducing the import of German beers into that country. In all those years the export of German beer in bulk (barrels) has been greater, contrary to general belief, than in bottles. German beer once had nearly a monopoly of the beer trade of South America; but there also, it is stated, the demand has decreased, while at the same time, according to trade reports, the demand for the United States has increased. The decline of the German beer trade in Brazil alone, during the year 1896 and 1897, is given as amounting to fully three-fourths of what the German brewers had exported to that country in former years. It is a noticeable fact that while the export has declined year by year, the production of beer in Germany has advanced steadily, showing that the home consumption has greatly increased. At present the United States is the best foreign customer for German beer, importing in 1895 522,138gal., and in 1896 689,456gal. The export of beer from Germany to Venezuela, Japan, and China together did not in the years given amount to one-half the exports to the United States alone. Brazil and British India, as consumers of German beer, come next to the United States. The German brewing industry has strong hopes of entirely supplanting the English in Australia and other British colonies.

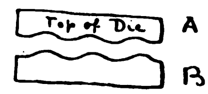
QUERIES.

[96918.]—**Scrap Arc Lamp Carbon.**—Can any reader of "Ours" tell of any use to which the short, burnt ends of arc carbons may be put?—Q. I. E.

[96919.]—**Floating Body in the Air.**—Will some reader please explain how Maskelyne's floating human body is done? Can anyone produce it in public?—TRIXIE.

[96920.]—**Electroid Gas.**—Can anyone please give me information concerning a new gas called "electroid" gas? A daily paper stated that it was used to light a village, but gave no particulars.—J. H.

[96921.]—**Thin Sheet Steel.**—Can I corrugate the above by heating to red heat and fixing between a metal die like the accompanying diagram, A, B, so that it will



be permanently corrugated when taken out of die, and yet retain the spring when tempered?—JASMINE.

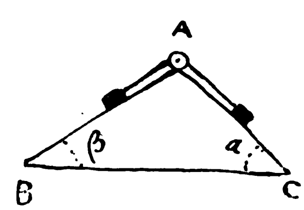
[96922.]—**Stylographic Ink.**—Can any reader kindly recommend a really good ink for stylo. pens, as I find that most of the inks sold for the purpose are unsatisfactory? My idea of a good ink is one that will run freely, have a dense black colour, absolutely free from sediment, dry quickly, and will not smear or run if the writing should happen to get wet. The latter is the greatest fault of nearly all stylo. inks.—S. C.

[96923.]—**Heating Tank.**—Can any reader tell me the amount of heating surface of tubing required to raise the water in a tank containing 1,000gal. of salt water, from a temperature of 80° Fahr. to 160° Fahr., the steam entering the copper coil in the bottom of the tank at 50lb. pressure? The tank is cylindrical in shape, lying on its side, the coil being composed of 1in. bore copper tube.—HEAT.

[96924.]—**Artificial Diamonds.**—I find it stated that some years ago a London firm produced artificial diamonds made of a "composition of glass, lead, and carbon, and tipped with platinum." They were guaranteed to last twenty years, and are said to "have become the rage." I am acquainted with paste "diamonds" made mainly of strass, but in what form would that "carbon" be, and what is meant by "tipped" with platinum?—DOUBLET.

[96925.]—**Panama Hats.**—Are Panama hats made of the fibre of pineapple, and where are they principally made? Are they difficult to make. One London dealer is stated to have sold three in one day at £25 each. These hats (some of them, I presume) are said to be as soft as silk, and can be folded up and put into a waistcoat pocket. Is that true?—C. E. GREEN.

[96926.]—**Velocity of Centre of Gravity.**—Will some reader kindly give me the solution of the following? Two heavy particles of masses, m and m^1, rest upon the frictionless inclined planes A B and A C, and are connected by a string passing over a pulley at A. When the



particles are in motion. it is required to determine the velocity of the centre of gravity of the particles resolved parallel to the two inclined planes after a time, t, from the commencement of the motion.—Q.

[96927.]—**Mercury Gilding.**—Can any reader tell me what is the best way to get mercury out of the system? I have a friend engaged in the trade, and now and then he appears to have a surfeit of the mercury in his body: his hands shake like a palsied man, and he complains of neuralgic pains in the head, but he does not appear sufficiently ill to go to a doctor; in fact, he will not go. Perhaps someone can tell me what will counteract the effects.—GILDER.

[96928.]—**Electro-Magnet.**—The two limbs of a horseshoe electro-magnet may either be wound in series or shunt. Compare results for purposes of motor.—NEW CENTURY.

[96929.]—**Electric Ignition.**—Can any of "ours" give particulars of electric ignition for 2¼H.P. oil launch engine? Tube at present, but would like to experiment. What length of spark, and which is best—accumulators or small dynamo driven by engine? Also hints as to volts, amps., &c., required; also size, speed, &c., of dynamo, if considered best.—SPEED.

[96930.]—**Sound.**—I believe there is an instrument constructed by which it is possible to hear through a glass window or a wooden door, &c. Will any of the readers please instruct me how to make a simple one?—C. G.

[96931.]—**Dry Batteries.**—I have a quantity of No. 6 E.C.C. dry batteries, but cannot get any current from them. Will some of our readers kindly state whether it is possible to recharge them? If so, how? I may say they have lain aside for some time.—A. H. R.

[96932.]—**Polycistina.**—Will any reader kindly give me information where I can procure a small quantity of polycistina, say about ¼oz., unmounted? If I can get it ready cleaned for mounting it would be more convenient, as after attempting to clean some myself by boiling &c., I can only find a specimen here and there.—VERINDER.

[96933.]—**Asbestos Fire.**—When I had the gas-pipes laid on in my house I had them continued to the fire-places in the drawing and sitting room; I am now wondering as to the best method of heating the room by gas, of which I am desirous. Is the asbestos fire cheaper, and does it give out as much heat as the asbestos stove? Although the local gas company hire out gas kitcheners at a very moderate sum per quarter, they do not hire the gas-heating stoves, but only sell them. Perhaps one of "ours" might know, and be able to enlighten me on the subject? I should be glad if so, with probable cost.—SAM.

[A definite question would have more chance of a definite reply. We have Verity's gas fires in library, bathroom, and billiard room, and like them. They are dearer than Fletcher's (first cost), but we like them better. They are dearer than coal fires. We don't like them in a dining or drawing room. They must have plenty of gas behind them. They are of no use with the ordinary ⅜in. pipe. They often disappoint in foggy or frosty weather, thanks to the Gas Companies and clogged pipes!—ED. "E.M."]

[96934.]—**Motor Tricycle.**—I am an owner of a motor tricycle, Beeston make; the same goes well, but after I have ridden about 15 miles at a fair speed the cylinder seems to heat, and the engine makes a grinding noise, and will not drive, though amply lubricated; I have to get off and wait 15 to 20 minutes before I can proceed. This happens frequently, and specially in hot weather, and I understand that most air-cooled motors do the same. I have heard lately that Mr. Stocks, of the Ariel Cycle Company, in his long-distance rides, and also Mr. Edge, use on their machines water-cooled motors; that they have a tank carrying one gallon of water between frame, which boils away and has occasionally to be renewed. I should like to know what there is against adopting this plan, and why it is not generally adopted instead of air cooling. Does the sediment inside the jacket prove troublesome?—W. ATTKINSON.

[96935.]—**Motor Cylinder.**—Will any reader kindly tell me how to bore a steel tube 3in. diameter for a motor cylinder? I have been told it cannot be turned, but must be ground true. If this is correct, how must I proceed? I have a 6in. lathe and plenty of tools.—SENLAC.

[96936.]—**Locus.**—A point moves so that the sum of the distances from two angles of an equilateral triangle is equal to its distance from the other angle. Show that the locus of the point is the circle circumscribing the triangle. I can prove that if any point is taken on the circle the two distances mentioned are equal to the third.—EUCLID.

[96937.]—**Electric Light.**—We use about one million cubic feet of gas per year, the cost being 3s. 8d. per thousand feet. Could we have electric light as cheaply? What power would be required, and what would be cost of engines and accumulators?—ELECTRIC.

[96938.]—**Question in Arithmetic.**—A square field is surrounded by a wall. The part immediately within the wall, all round the field, is covered with gravel, and two straight gravel walks 13ft. in width run across the field, joining the middle parts of the opposite sides. The ungravelled part of the field contains 2¼ acres. What is length in yards of the boundary wall?—CORNUBIA.

[96939.]—**Ebbing Well and Burning Cliff.**—Is the ebbing and flowing well at Brixham (the "Laywell") still in existence? At what period did the "Burning Cliff" near Weymouth cease to justify its name, and of what was the burning mass composed? One often sees the waste-heaps at collieries smouldering, owing to the presence of sulphur; but this would hardly be the case at Weymouth, where the conditions are so different.—A. S. L.

[96940.]—**To Mr Bottone.**—I wish to establish a wireless telegraph (merely to ring a bell) with a house about a quarter of a mile away, but with no need for any reply. Will you please tell me what height of pole is necessary, whether a coil or Wimshurst machine is least expensive for the same efficiency, and, generally, give me an idea of the cost, exclusive of poles (which I could get locally)? Must the pole carry a strip of wire netting, or is a simple wire sufficient? I know the arrangement necessary, but do not know all the details of actual instruments as now constructed.—A. W. L. T.

[96941.]—**Mean Time Dial.**—To "E. L. G." AND "F.R.A.S."—Some time ago "E. L. G." promised to tell us how to construct a "mean time" dial. Unfortunately, he has never done so, and I therefore hope he will not mind my now calling his attention to the matter. I have also coupled "F.R.A.S." with "E. L. G." as another authority on such matters whose help I would ask for. Suppose, instead of a bar, we consider the gnomon to consist merely of its extreme point, or of a small ball in the place of such point. Then, assuming the plate of the dial to have no lines on it, let the hourly positions of the shadow of the ball be marked on the plate, according to a mean time clock, on the shortest day, and weekly thereafter till the longest day. Evidently we shall have, so far, obtained a dial of the required description. Can what has been thus done mechanically be done geometrically, and to what errors would a dial so made be subject, annual or otherwise? I know the dial with the "figure of eight" gnomon, to give mean time, but it is better in theory than practice, as the shadow of the gnomon is too indefinite. I fear the same objection would apply to the ball, but my question is rather one to elicit an opinion on the geometry of the problem than to describe an actual dial.—A. S. L.

[96942.]—**Motor Tricycle.**—Should be thankful for advice from "The Writer of the Articles" or other. I have a Beeston motor tricycle, tube ignition, and have had it running every day for a year. It continues to run well, but I find the oil leaks very much from crank chamber (which is of aluminium), no matter how much I tighten bolts; the leak takes place right at the top, both in front of and behind cylinder, and there is quite a spurt of oil on pushing machinery along. I have had cylinder off, and taken a cutting in lathe off outside where it fits into recess on top of crank chamber, and now it is an easy fit, but still leak takes place. What is best to be done? Shall I "pack" between the two halves of crank chamber, and if so, what with? Or shall I file surface flat? What is cause of surfaces not coming into contact as they did when new? Bolts are all tight as I can make them. I thought perhaps the cylinder, on getting hot and expanding, forced apart the upper part of crank chamber, but I

still cannot bring it together properly, although I have taken cutting off cylinder. Chamber gets very oily, and covered with dirt, and requires fresh supply of oil every six miles.—Cranky.

[96943.]—**Diving.**—Will any reader please inform me to what distance a diver is able to see clearly under the surface of the sea, and whether the use of a powerful electric light would increase the distance?—Enquirer.

[96944.]—**To Mr. Bottone.**—Thanks for information; and would you please oblige me further? Could I put this laminated armature of 3in. diam. 4in. long to any useful purpose as a dynamo, as it is so well made that I do not like to put it on one side if I could possibly turn it to account? There are 24 winding spaces, the ends are slotted to take wood wedges, also a 24-part commutator. —J. Ellis.

[96945.]—**Jointing Machine.**—Will some reader kindly inform me if I can make a machine for making quickly half-round joints on 1in. round beechwood for making furniture?—Yonge.

[96946.]—**Navy.**—Will any reader tell me how I can become an assistant probationary engineer for permanent service in the Royal Navy? I have served 4½ years in the engine works in a large shipyard. Would going to sea for a year or two and getting first and second-class certificates be any help? I have not yet been to sea. Could I go to sea with 4½ years' apprenticeship? I am 20 years of age. Must I serve twelve months at sea (on watch), or will twelve months at sea in the engine-room as fourth or fifth engineer allow me to sit for second-class B.T. certificate?—Apprentice Engineer.

[96947.]—**To "F.R.A.S."**—Many thanks to "F.R.A.S." for answer to query 96834 about lighting wires in a transit instrument. There is no lens over the aperture of the pivot. Should it be convex or concave, and about what length of focus?—R. A.

[96948.]—**Launch.**—Will some kind reader oblige me by giving the leading dimensions of a steam launch for river use? Length over all, 35ft.; B.P., 31ft.; mean draught, 2ft. I want to go up to 15 miles per hour if possible. I should like to know the least practical beam; horse-power required at that speed; approximate weights of triple-expansion engine running about 600 revs. and water-tube boiler working at 200lb.—Rocque.

[96949.]—**Mutoscope Pictures.**—Will any reader kindly tell me how the pictures in the mutoscope are printed? I imagine they are originally taken on films, which I presume would be the negative; but how are they enlarged and made positive? I am desirous of trying my hand at it, so should be glad of all information possible to start with as to apparatus required and probable cost, &c.—Amature, Dudley.

[96950.]—**Slade Micrometer.**—Can it be used for finding position-angle as well as distance? In what respect does it differ from the ordinary filling micrometer? Describe a cheap way of illuminating. Can it be easily arranged by electricity?—Enquirer.

[96951.]—**Inflammation of the Parotid Glands.**—Can any reader help with hints? Age 57, occupation sedentary, temperament bilious, mode of life regular. Fairly good health till twelve months since, when, supervening on a bad attack of influenza, the parotid glands on each cheek began to swell, and remain so, making the face unsightly. No pain, but general feeling of stiffness and unpleasantness, and apparent interference with secretion of saliva so that mouth is always dry. Have seen seven specialists, who confess inability to treat; one would have been inclined to suggest surgical treatment, if on one side of face only, but hesitated on both sides. Have spent some time at the South of France by another's orders, but am no better.—Y.

[96952.]—**Model Boiler.**—Will any kind reader of "Ours" give particulars of model vertical boiler, to work a cylinder ⅞in. bore 1in. stroke? What size, shape, and material should the boiler be made of? Also pressure, and if any tubes and riveting.—Amateur Engineer.

[96953.]—**Steam Exhaust.**—I have a 3H.P. steam-engine, the exhaust from which is carried away through 30ft. of 1¼in. iron pipe, but being in an awkward place, the steam from exhaust-pipe creates a nuisance. Is there any possible way in which I can stop this, by condensing steam or placing some kind of fitting on end of exhaust pipe, which will not cause any back pressure on the engine?—Exhaust.

[96954.]—**Motor for Car.**—Would "Monty" please help me by answering the following question? I am building a 3H.P. Endurance horizontal motor for car, with electric ignition, and what would the simplest and best carburetter be to make? I also have an 8-volt dynamo, with plenty of power to drive it. Would it be suitable for charging accumulators, 4 volt 30 ampère hours, and how long would it take it to charge them? Also how to make an effective silencer for exhaust, and cooler for the water from cylinder jacket? Any other information re Endurance motor would oblige.—Harry.

[96955.]—**Stage Thunder.**—Will some reader give instructions for producing stage thunder, also stage lightning?—No. 7.

[96956.]—**Glass Silvering.**—There are many formulæ given in back numbers. Which is most suitable for use in a workshop? I mixed a lot some years ago from instructions in the "E M.," and did not get a deposit on glass plate. I poured the fluid into a glass beaker, intending to recover the silver. Next morning I found a beautiful coat of silver, so hard that it had to be scraped off with a knife; but I do not know what the formula was.—M. C.

[96957.]—**Quill Pens.**—Will some reader tell me how the fine, clean slit is made in the quill pens sold in boxes ready for use? I like to make my own pens, but seldom succeed in getting a slit that is quite satisfactory. —An Old Subscriber.

[96958.]—**Negatives on Celluloid.**—(1) What is the most expeditious way of making negatives on stiff celluloid supports (such as Frears negatives)? (2) Can a lot be developed together in a large dish, or should a grooved trough be used? (3) Is any modification of developer required? (4) Would the above methods be considered slipshod?—Optical L.

[96959.]—**Moulding Slag.**—Can any reader tell me at what heat the above melts, and if it is possible to mould it into rough bricks or slabs, and if there are any of these at present manufactured, and where? I would also be glad to know if the ordinary limestone slag, from iron blast furnaces, has any injurious chemical effect on lead water-pipes in roadways? Also if it is possible to add anything to the slag in its molten state to make it less brittle? Any information will be acceptable to—A Constant Reader.

[96960.]—**Carbide.**—How much calcium carbide can be kept without a license, and what precautions are legally required to be taken?—Optical L.

[96961.]—**Electrical.**—What is the voltage of a cell of zinc and copper plate one each in dilute acid? Also, if two zinc and three copper plates in one cell? Do the zincs need to be amalgamated?—M. C.

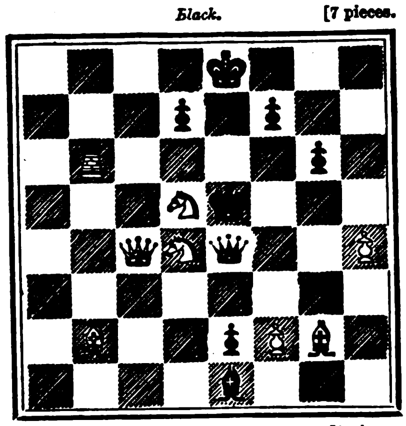
[96962.]—**Multiple Wimshurst.**—To Mr. Bottone and "J. W."—I am constructing one of these machines, and shall be much obliged if you can suggest any reasons for it not exciting. The machine has eight plates, 24in. in diam., made of ebonite $^1/_{16}$in. thick, to which is fixed with knotting another disc of ebonite 15in. in diam. and $^1/_{16}$in. thick, and reaching to the inside (small) end of the sectors, put on to stiffen the plates. Each plate is furnished with 16 sectors, 6½in. long by ⅞in. wide at wide end by ⅜in. wide at small end, and having a boss ⅜in. diam. projecting ⅛in. from face. The sectors are covered with a piece of ebonite extending from the small end against the edge of smaller disc to half-way up, leaving only about 2in. or so of the sectors exposed. The neutralising rods are arranged as shown in Mr. Wimshurst's machine. They are of $^3/_{16}$in. brass wire, with brushes of about 40-gauge brass wire wedged in hole in the end of the rod with clean cooper wire. Each set of rods is connected together, with brass wire passed through a hole in the other end of the rods and soldered. Each two sets, top and bottom, are connected together with a strip of sheet brass soldered to the connecting wires, the top and bottom strips being connected by a brass rod ⅜in. diameter. I have fixed up the machine temporarily, with the neutralising brushes in position, without collecting combs, but on rotation cannot get the slightest signs of excitement; reversing the rotation makes no difference, altering the position of the brushes as much as I can no better. I have put a charge into the machine from a smaller one, but without the slightest result. It is not the weather, although that is not altogether favourable, for I have a smaller machine at work in the same room. Does it matter which way the new brushes are connected so long as they are all connected together, or is it better to connect the top left with the bottom right set, and the top right with the bottom left? I have tried warming the machine as much as I dared, but with no effect. The distance between each pair of plates is 1⅜in. Is this likely to affect the working of the machine? Would a machine work at all if the ebonite is not of the very best quality? I have tried pieces that I have left, and when using a Leyden jar charged at the tension of a 1in. spark (holding the jar by the outside coating in one hand and the piece of ebonite in the other), I get a small discharge, which is dissipated on the face of the ebonite (which is polished), when the knob is $^1/_{32}$in. away, but do not feel the slightest shock. When the jar is charged with ½in. spark I get no discharge at all, or when the ebonite is warmed, so that it appears to be of fairly good quality. Would matters be improved by cleaning the plates with carbonate of magnesia and varnishing with shellac varnish? Even if the ebonite was not of the best quality, I should think it would show some signs, however slight, of excitement. I cannot make it out, as the work has been carefully done. Any information as to the probable cause of failure will be thankfully received.—F. W.

CHESS.

All communications for this column to be addressed to The Chess Editor, at the Office, 332, Strand.

PROBLEM No. 1698.—By F. Schindler.

Black. [7 pieces.



White. [9 pieces.

White to play and mate in two moves.

(*Solutions should reach us not later than Nov. 6.*)

Solution of Problem No. 1696.—By F. G. Tucker.

Key-move, R-Q 8.

NOTICES TO CORRESPONDENTS.

Problem No. 1696.—Correct solution has been received from Richard Inwards, G. W. U., Rev. Dr. Quilter, Quizco, A. Tupman, J. E. Gore, The Boer, F. B. (Oldham), J. Mason, W. Peters, T. Clark.

W-H. and The O., F. B. L., F. A.—Only solution as above.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries, put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Oct. 25, and unacknowledged elsewhere:—

W. T. N.—E. G. Woodhouse.—A Cornishman.—E. L. G. —A Fellow of the Royal Astronomical Society.—Trip. —D. C. G.—H. Brand.—Factorial.—Typewriter.— Veritas.—Invention.—Sixteen Years Subscriber.— T. E. Espin.—Rolande.—Experiment.—Equatorial.— E. N. W. Hume.—Col. Markwick.—Thorn and Hoddle.

J. H., Dublin.—See "Astronomical Notes" and the "Scientific News." The Leonids are expected on Nov. 14, 15, but they may be a little later. They do not arrive with "Greenwich" accuracy, and the best way is to observe on every suggested, or calculated, date.

J. Turner.—You would probably find works of the kind desired in one of the free libraries in your district of London. Culpepers's "Herbal" is a well-known work, and Wesley's "Primitive Medicine" has much to do with herbal remedies, though he was also much too wise a man to use the herbs when other remedies were at hand.

Enquirer.—An analysis of potatoes gives water 75, albuminous compounds 2·3, starch, &c., 18·7, woody fibre 3, and mineral matter 1. Analysis of the ash gives approximately potash 50, carbonic acid 13, phosphoric acid 11, sulphuric acid 7, silica and magnesia about 5 each, chlorine, 2 (more or less), and lime 1 to 2. The figures are percentages, and they vary with the varieties of potatoes and the kind of soil on which they are grown,

A. F. C., Calcutta.—The Fifteen School Girls Problem has often been mentioned in our columns. There is a letter by the late R. A. Proctor, on p. 507, No. 378, in which he gives a method, but says "I have no clear idea why this method succeeds." That letter was followed by others in Vol. XIV., pp. 559, 584, 616. Since then the problem has been referred to at intervals, and it is discussed in several of the mathematical textbooks. See "Mathematical Recreations and Problems," by W. W. Rouse Ball, published by Macmillan. The work is no doubt in one of the libraries at Calcutta.

J. Carlisle.—What is meant by a model? There are plenty of illustrations of battleships to be obtained, but if you want to make a "model" with all the internal fittings to scale, it is scarcely likely that you will obtain the information. You could make a "model" of the exterior by simply copying the illustrations. As to the other questions, please see Hints to Correspondents above.

O. A.—If by "magic" lantern you mean the optical lantern you will find the fullest instructions for making in Vols. LIII. to LVI., commencing in No. 1377, Aug. 14, 1891. There are many hints about the construction of lanterns in back volumes, but it is not quite clear what you mean by "opaque slides." Look through the articles in the volumes mentioned, and you will find all the available information.

W. J. Thomas.—There are several recipes for making writing ink in the back numbers, but it is doubtful if it is profitable to make in small quantities. As to neuritis a medical man should be consulted.

In Type.—M. C.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, post free to any part of the United Kingdom. For the United States, 13s., or 3dol. 25c. gold; to France or Belgium, 13s. or 16f. 50c.; to India, New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-Office Order. Back numbers can also be sent out by the ordinary newspaper post at the rate of 3d. each.

Vols. XXIV., XXX., XXXII., XXXVI., XXXIX., XL., XLII., XLIII., XLIV., XLV., XLVI., XLVIII., L., LI., LII., LIII., LIV., LV., LVI., LVII., LVIII., LIX., LX., LXI., LXII., LXIII., LXIV., LXV., LXVI., LXVII., and LXVIII., bound in cloth, 7s. each. Post free, 7s. 7d.

Indexes to Vol. LI., and to subsequent Vols., except Vols. LIII., LV., LVI., LVII., LIX., LXI., 3d. each, or post free 3½d. Cases for binding 1s. 6d. each.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 3d. each, through any bookseller or newsagent, or 3½d. each post free from the office (except index numbers, which are 3d. each, or post free 3½d.)

ADVERTISEMENT CHARGES.

The Charge for Advertisements in the Columns headed:—

For Exchange.
For Sale.
Wanted.
Addresses.
Situations.

is Sixpence for the first Sixteen Words, and Sixpence for every succeeding Eight or part of Eight, which must be prepaid. *No* reduction on repeated insertions. Advertisers should state under which heading they wish their announcements to appear.

The address is included as part of the Advertisement and charged for. No displayed Advertisements can appear in above columns. Rates fer Displayed Advertisements are as follows:—

For advertisements on inside pages, except page facing leader, for less than a quarter-page; per inch single column—

1	6	13	26	52 insertions.
7s. 0d. ..	6s. 6d. ..	6s. 0d. ..	5s. 6d. ..	5s. 0d. each.

Per Column.—

1	6	13	26	52 insertions.
£3 0s. ..	£2 15s. ..	£2 10s. ..	£2 5s. ..	£2 0s. each.

	1	6	13	26	52 insertions.
	£ s.	£ s.	£ s.	£ s.	£ s.
Per Page....	8 8 ..	7 0 ..	6 0 ..	5 5 ..	5 0 each.
Half-page ..	4 10 ..	3 15 ..	3 10 ..	3 0 ..	2 10 "
Quarter-page	2 10 ..	2 5 ..	2 0 ..	1 15 ..	1 10 "

Back Page, £10 10s. A few dates open during 1899.

ORDINARY ADVERTISEMENTS.

	£ s.
Thirty Words	2 6
Every Additional Eight Words	0 6

Front Page, Five Shillings for the first 40 words, afterwards 9d. per line. Displayed Advertisements, 10s. 6d. per inch. Paragraph Advertisements, One Shilling per line. No Front Page or Paragraph Advertisement inserted for less than Five Shillings.

All Advertisements must be prepaid, and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O. could be sent, and not stamps. Stamps, however (preferably half-penny stamps), may be sent where it is inconvenient to obtain P.O.'s.

Advertisements *must* reach the Office by 1 p.m. on Wednesday to insure insertion in the following Friday's number.

For the convenience of advertisers, replies to advertisements (except those in the Exchange and Sale Columns) may be addressed to "——," care of the ENGLISH MECHANIC Office, and will be forwarded by post to the advertiser, for an extra fee of Sixpence per insertion over and above the cost of the advertisement.

All Cheques and Post-Office Orders to be made payable to THE STRAND NEWSPAPER COMPANY, LIMITED, and all communications respecting Advertisements should be distinctly addressed to:—

THE PUBLISHER,
THE "ENGLISH MECHANIC,"
332, STRAND, LONDON, W.C.

This is necessary, as there are several papers published at the same address, and unless letters are fully directed, it is impossible to tell for which paper they are intended.

For Exchange.

The charge for Advertisements in this column is 6d. for the first 16 words, and 6d. every succeeding Eight, which must be prepaid.

SPECIAL NOTICE. — *Correspondents are strongly recommended not to send money or goods to strangers. The safest way when dealing with unknown advertisers is to send a Post Office Order made payable —— days after date, when in case of non-arrival of goods, or dissatisfaction, payment can be stopped.*

Wanted, **Harp**, exchange Back-geared Lathe, 4in. centre, 50in. bed, compound slide-rest, treadle motion, sundry fittings. —8, Stuart-street, Luton, Beds.

Exchange **Gas-Engine**, drive sewing machine, or small dynamo, 880 revolutions, for Castings, Forgings, &c., of 1B.H.P. Launch Oil Engine.—EDMONDS, Heavitree, Exeter.

Two Series **Arc Lamps**, with copper corona, and wired for globes, as new. Wanted, No. 4 Kodak, or other high-class hand camera, or 1-1 plate R.R. lens, good make, with Thornton-Pickard shutter.—WHEAT, 27, Stewart-place, Nottingham.

Eight Volumes of "**English Mechanic**" for old Sporting Books.—D. T. WILLIAMS, Gwyn - street, Alltwen, Pontardawe, R.S.O.

For Sale.

The charge for Advertisements in this column is 6d. for the first 16 words, and 6d. every succeeding Eight, which must be prepaid.

New Illustrated Price List of **Screws, Bolts**, and NUTS for model work, drawn to actual size, sent on receipt of stamp. —MORRIS COHEN, 132, Kirkgate, Leeds.

Watch and Clock Tools and Materials. Catalogue, over 1,000 Illustrations, post free, 6d.—MORRIS COHEN, 132, Kirkgate, Leeds.

Wheel-cutting and Dividing in Brass or Iron to 12in. diameter.—CLEGG, Belinda-street, Hunslet, Leeds.

Lathes and Machined Parts, Wheels, Chucks, Fans, Angle-plates. Illustrated list, 2d.—JARRATT, Queen-street, Leicester.

Carving. — Brass, Iron, Burnt Wood, Bamboo, Leather, Fretwork, and Picture Framing. Catalogue free.—HARGERS, Settle, Yorks.

Books.—All out-of-print books speedily procured, any subject. State wants.—BAKER'S GREAT BOOKSHOP, Birmingham.

50,000 Choicest Microscopical Objects.— Bargains. Catalogues free. Microscopes, cabinets. Collections purchased.—SUTER, 10, Highweek-road, Tottenham.

Rubber Outer Covers, 3s. 6d. Prepared Canvas, 90 by 9, 1s. 3d.; rubber solution, best quality, 1lb. tins, 1s. 6d.—PEMBERTON.

Air Tubes, all sizes, best quality, 2s. 9d. each. Air tubes with Dunlop valves fixed, 3s. 9d.—PEMBERTON.

Cushion Tires, 3s., 4s., 5s. Solid Tires, 3s. All sizes stocked.—PEMBERTON.

Detachable Outer Covers (Licensed), 12s. 6d. each; all cycle accessories and cycle rubber goods stocked.—PEMBERTON and Co., 1, Cardwell-place, Blackburn.

Nuts and Bolts for Model Work. Illustrated List, 2,800 varieties, 3d.—BUTLER BROS., Haggerston, London.

Screws, Screw-plates, Taps, round and hexagon special steel brass and iron rods. See list.—BUTLER.

"**Simplex**" **Gas and Oil-Engines**, new series, "Otto" principle, ½B.H.P. to 2B.H.P., from £9. Guaranteed.— Below.

"**Demon**" **Gas-Engines**, awarded prize medal, ¼B.H.P. to 12B.H.P., low price, high efficiency, economical. Guaranteed.—Below.

"**Demon**" **Gas and Oil-Engines** are thoroughly reliable. First-class workmanship.—PASLEY and Co, Sherborne, Dorset.

New **Engine Castings**, ¼-horse, 5s. 6d.; half-horse, 11s. per set. Catalogue two stamps.—TOMLIN, Ironfounder, Oldham.

Rubber Outer Covers, average 16oz., Para rubber 5s. each.—FRANKLANDS.

Rubber Outer Covers, 3s. 6d. each, 36s. per dozen. —FRANKLANDS.

Cushion Tires, 3s., 4s., 5s. Solid Tires, 2s. 6d., 3s. All sizes stocked.—FRANKLANDS.

Air Tubes, best quality rubber, 2s. 9d. each. Fitted with Dunlop valve, 3s. 9d.—FRANKLANDS.

Air Tube, Para rubber. Marvellous value. Large stock to clear. Perfectly air-tight., 2s. each.; 21s. per dozen.— FRANKLANDS.

Cycle Capes, 3s. 6d., 4s. 6d., 5s. 6d. Also a few cycle Capes, guaranteed waterproof, 2s. 6d. each.—FRANKLANDS.

Detachable Outer Covers, licensed, 12s. 6d. each. —FRANKLANDS.

Saddles.—A clearing line in ladies' and gents' saddles, 2s. 6d. each, 24s. per dozen.—FRANKLANDS.

Inflators, 18in., 1s. 6d. each, 15s. dozen. — FRANKLANDS.

Bells.—Special line, double gong, usual price, 12s. dozen, will clear 5s. per dozen.—FRANKLANDS.

Prepared Canvas, 90 by 9, 1s. 3d. each, 12s. per dozen.—FRANKLANDS.

Pedal Rubbers, 6d. per set of four, 4s. 6d. per dozen sets; no rubbish.—FRANKLANDS.

Spanners, nickel, usual price, 13s. per dozen. Will clear a few dozen at 7s. 6d. per dozen.—FRANKLANDS.

Cycle Accessories and Cycle Rubber Goods. We hold the largest stock in the North.—FRANKLANDS, Astley Gate, Blackburn.

Stereoscopic Views, 1s. doz., list 4,000. Sample 1d. stamp.—PUMPHREY, Stanhope-street, Birmingham.

Brass and Gunmetal Castings of finest quality. Prices on application.—DANIEL YOUNG, Witney, Oxfordshire.

Booker Brothers' Engines and Motors, oil or gas, ½H P. upwards, also castings.—Tyrrell-road, East Dulwich.

W. Probert and Son, Brassfounders, Whateley-road, Handsworth, Birmingham,

Manufacture Brass Fittings in quantity to sample or drawing.

Brass Tubes, Sheet, Rods, Wire or Strip.

Brass Castings to Pattern.

W. Probert and Son, Whateley-road, Handsworth, Birmingham. Works: Tower-road, Aston.

Calver's **Complete Equatorial,** best ever designed, revolving eye-end, set any latitude by screw and vernier at once. Second-hand Telescopes, perfect order. "Hints on Reflectors," 13 stamps.—G. CALVER, F.R.A.S., Chelmsford.

Printing.—1,000 good Billheads, Memos., or Cards, 5s., carriage paid. Write for samples.—HOWDEN, Whitechapel, Liverpool.

Mail Cart Wheels and Perambulator Furniture.— WALKER BROS., Primo Wheel Works, Sheepscar, Leeds.

Model Boiler, 13in tubular, nearly new, tested 50lb., brass mountings, 17s.—51, Winchester-road, Romsey.

Motor Tricycle Fittings, castings or finished. Illustrated List.—F. HARDING, Brixton Motor Works, 303, Brixton-road, London.

"**Small Accumulators,**" "The Slidevalve," "Electric Bells." Three splendid handbooks for amateurs or students, 7d. each.—Below.

Bichromate Batteries, with lifting zincs, 1s. 4d. and 1s. 10d. each, free.—Below.

Electric Lamps, 2 volt, 6d. Holders, 4d. Reflectors, 3d.—E. WHITING, 109, Fore-street, E.C.

Bargain.—Induction Coil, 6in. spark; perfect condition. Viril Contact Breaker, with case. Sacrifice £8.—Below.

Also 12-volt Lithanode **Accumulator,** reliable, £3 15s.—C. BAKER, 55, Northam-road, Southampton.

A Good Investment.—Economic Electric Co.'s new illustrated list, 1d.—118, High Cross-road, Tottenham, London.

Microscopical.—Diatoms Slides in highly refracting media, including realgar, styrax, &c. Prices reasonable. Approval.—GATRELL, Barnes.

"**Gem**" **Gas-Engines.**—Still simplest and best for small powers.—MOTOGEAR Co., below.

"**Gem**" **Gas-Engine Castings.** — Easiest to make up.—MOTOGEAR ENGINEERING Co., 78, Queen Victoria-street, London.

Model Engine Castings, fully-illustrated catalogue, 6d.—ELSDEN and Co., Gloster Works, Old Ford, London.

Complete **Bench Lathe,** 10s., carriage paid. Slide-rest, 9s. 6d. Illustrated list, 1½d. Lathes and Castings, list 3d.— ELSDEN.

Wheel-Cutting.—Spur, bevel, mitre, or spiral gear, in all metals, to any pitch.—MOTOGEAR, below.

Differential and Spur Gearing as illustrated in "E. M." for motor tricycles. Special prices.—MOTOGEAR, below.

The Motogear Engineering Co. have duplicated their machines and plant to cope with orders received.

They regret **Past Delays and Orders Declined.** unavoidable through limited capacity to deal with the quantity of work placed in their hands.

Orders can now be dealt with more promptly.— Address, 78, Queen Victoria-street, London, E.C.

Denning's "**Great Meteoric Shower** of NOVEMBER," illustrated, one shilling.—TAYLOR and FRANCIS, Red Lion-court, Fleet-street.

"**Spesco**" **Belting Syrup** prevents slipping, and keeps belts in good condition; 1lb. sample tin, post free, one shilling. —SPESCO Ltd., Suffolk-place, Bermondsey, London.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, NOVEMBER 3, 1899.

INLAYING.—IV.

UP to now our aim has been to point out to the reader the different methods adopted to fashion the material at hand, with appropriate designs accompanying. It remains now to shade them; in other words, to give the necessary relief, so as to present them in as nearly their natural form as possible. The process of browning, or shading, is gained by semi-burning. The pan or other receptacle is filled with about 1in. of silversand, and heated up to such a degree that it will brown, but not burn. Whatever work we desire to shade, it is obvious that to gain the best results the sand must be kept at a uniform heat. If gas is not at hand, a coke fire should prove an excellent substitute. Having regard to the fact that our work assumes varied forms, some simple method must be adopted to shade the work, not only properly, but where wanted. It is not a difficult matter to shade work that is straight, or nearly so; but where the scroll is of sharp contour the sand must be drawn up to the form of the work, ever remembering that the greatest heat is near to the source of heat. It will be seen, then, that to insert the scroll direct, the two ends may just possibly be burned, leaving the upper portion white, or nearly so; but by canting the work a trifle a better result may follow. It is next to impossible to give hard and fast rules for each and every piece; much must be left to the reader. We can only say a gradual heat will give better tone than over-heating. The one is soft, while the latter is sure to be harsh. From long practice, we find the inner portion of a scroll is the most difficult to shade. To get over the difficulty, cut it up, where permissible, into one or more parts. In other words, divide the scroll at a vein, or a leaf can be divided into two portions. But only do that as a last extremity. If it is not possible to separate the scroll, a mound must be formed as near to the curve as can be got. If properly formed, a decent job should result.

FIG. 86.

FIG. 87.

For cross-shading, or the shading that predominates in the centre of an ornament, another means can be employed—and that is a flat-wick spirit lamp, that gives a flat and thin tongue of flame. It may happen such a lamp is not easily procurable, unless made. If so, let the slit be as thin as possible, and the wick correspond. A great body of flame is not wanted. By holding the work at a given distance, a darkening will be gained without burning.

The following points to be observed may help to lessen failures. The work should not be shaded in bulk, until proficiency is gained. Where more than one piece is being operated on, endeavour to keep them as close as possible, so as to have the same heat and depth of tone. Wor k out hollows in the sand for rounds, and little hillocks or mounds for hollow work. In shading coloured woods, watch closely that the heat is such as not to bleach the position between the browned and the dyed parts. Overheating will have a tendency to that end, and too slow or low a heat will also cause the same effect. Wood that has been hastily dried or flattened before partially drying will have a tendency to buckle in shading. If that occurs, reverse the position of the p iece, so that the heat does not play entirely on one face. Constant turning will ofttimes save a delicate piece of cutting. It must not be forgotten that the heat will render the work very crisp, and liable to snap very quickly—a little forethought and care will save hard words.

Again, where the shading is very pronounced in the centre of a leaf, or the segment of a flower, if the part is divided with the saw and equally shaded on both sides of the saw cut, the result will be satisfactory, providing the cut follows the path of the shading as it is intended to. The same holds good in ornamental cutting also.

In solid work that has inlay work chopped in, the rule is to cut the outline and engrave the details. The engraving is done with either very small hollow tools or V-shaped parting tools, handled and held in the same manner as engraving tools. With finer work special tools are used for shading, and are called "sine-gravers." They can be coarse or fine, having a given number of minute flutes or hollows in a given space, and vary from six lines to ¼in. width of face to 24 or even 30 lines to the same width.

All woodwork is engraved when the first stages of polishing are done, and in a hard condition. If the surface of the work is inclining to greasiness, the polish is liable to break up under the graver; or, where the thrust of the tool is too deep, it will have a tendency to lift the polish. Especially is that the case in using the line-gravers, on account of the acute angle of the tool, the lines being below, and the sharpening angle above or outwards. Where the shading is in a direct line, or nearly straight, the tool is canted so as to cut with one or two lines, inclining the tool downwards until the full number of lines are in use. In confined spaces, where the termination of the shading is an abrupt angle, the tool is canted inwards, finishing the cut with the tool canted outwards. It may be that some portion of the work cannot be done with the tools at command: then the etching needle is requisitioned; the final process being the filling in of the engraving with printers' ink.

The following designs have been compiled with the view to enable the cutter to shade with the sand or graver. If the flowers are cut in satinwood and the leaves are of a light green tint, the work will show up well. The petals may be of yellow dyed wood with a darker yellow terminal, which will add to the beauty of the whole when finely engraved; but if it is intended to shade them with sand, the dividing system can be adopted, where the shading is heaviest. The above remarks apply to Figs. 86, 87, 88, 89, and 90.

With respect to Figs. 91 and 92, which are

FIG. 88.

FIG. 89.

Fig. 90.

Fig. 91.

Fig. 92.

Fig. 93.

Fig. 94.

two frieze pieces, and are given as examples of display, they can be shaded either way, as above described. The two corners, which are intended for doors, are also examples of display, the one occupying a hollowed corner, as at Fig. 93, the other for a rounded ditto, as at Fig. 94.

There is yet another darkening agent that may often be required in imitating old work. We are dealing principally with mahogany. Where an inlay has been inserted, it may happen that the groundwork turns up light; in that case it is far better to darken with some soda water, or, if preferred, bichromate of potash in solution can be rubbed over the work. We merely mention it here because it may be that a darkening process is necessary; but the full process will be better treated in the part devoted to "Polishing."

SOME METEOROLOGICAL INSTRUMENTS AND THEIR USES.—VII.

It is generally considered impossible to see the wind; but some investigations which were made a short time ago bid fair to bring this operation within the bounds of the actual. As already intimated, nephoscopes and photography have been the chief auxiliaries which meteorologists have employed to explore the movements of the clouds and the upper currents of air by which they are borne along. An American observer has added the telescope to these useful aids, and although only a very little has been done in the matter, some very useful suggestions have been made for using certain kinds of telescopes for observing the currents of air at high levels. Similarly to so many other suggestions, the notion of thus employing the telescope was discovered, as it were, accidentally, and it was during the course of ordinary astronomical observation that the new line of meteorological reseach was revealed. These observations were being made at the Arequipa Observatory in Peru, some 8,050ft. above the level of the sea, one of the geographical circumstances of the situation being a neighbouring valley, which at night time, as the forces of radiation got to work, served as a sort of conduit for a cold current of air, which, as it flowed downwards, presently enveloped the observatory. Now, it appears that whenever this cold current thus manifested itself and reached the objective of the telescope, the seeing was at once ruined, and the observer states that when once this cold current was established no more good seeing was anticipated for the rest of the night. On one such occasion the planet Mars was under observation, and on removing the eyepiece and placing the eye in the focus it is reported that fine parallel lines could be seen to move rapidly across the illuminated lens in the direction of the wind. Subsequent experiments were made on this basis, and by thus looking, as so speak, at these upper winds, figures were obtained which showed their velocity and distance above the surface of the earth.

It would, at first thoughts, appear that there was a danger of taking the effects of the air currents in the observatory for those of currents far removed, but it is stated that in the foregoing observations it was clear that the lines produced on the lens were not due to currents in the tube of the telescope, or in the dome above it. The lines observed in the lens are of three different kinds. There are, first, straight equal parallel lines, equally separated, and moving longitudinally; and, secondly, fine but twisted lines, which move more slowly; and, thirdly, there are lines which are a mixture of the first two types, the peculiarity about this third kind being that they appear on the lens as bands or ribbons, and move very rapidly. These different lines or waves have been systematically observed, and their direction, steadiness, fineness, velocity, and conspicuousness on certain dates recorded. It has, moreover, been stated that these lines come into focus at certain given positions of the eyepiece of the telescope, and a formula has been used which gives the different heights of these currents based on the extension of the focus, the distance through which it is necessary to move the eyepiece to bring the lines to good focus

being the principal factor in the calculation. Further, it appears that the coarse lines represent the lower currents or winds, while the fine lines are representative of currents moving at higher levels. Thus one such observation resulted in calculations which indicated that the upper current was 12,000ft. above the level of the sea, and moving at the rate of 17 miles an hour. To meteorologists, however, the most interesting statement in connection with these observations is that the lines vary in quality according to the humidity of the air, and that the greater the dampness the finer the lines. If, therefore, these observations could be made to tell not only the height, direction, and velocity of the upper winds, but indicate also whether the upper currents are increasing or decreasing in moisture, they would prove of no mean assistance to the weather prophets. Such researches, from the necessities of the case, can, however, only be carried on by a few observers, and it is for those well acquainted with the uses of the telescope to tell meteorologists whether they may hope for further developments in this direction.

The observations thus made concerning the upper currents in the atmosphere may be checked by comparing them with the alterations taking place in the cloud forms at the time of observation. Considerable progress has been made as regards the discovery of the causes which produce these changes in the shape of the clouds, and it is now possible to make a very good guess as to the velocity of the wind associated with any given kind of cloud. Thus it has been shown that when a current of air blows over another one of different temperature, waves are produced which may be likened to the ripples which appear on the surface of a pond when a gust of wind steals across it. The result of this action on cloud formation is to cause the clouds to appear as long rolls which are grouped in parallel rows. The intervals between the crests of these aërial billows are, however, far greater than is the case with water waves, and the distances, instead of being a matter of 50ft. or so, may be expressed in hundreds of yards. Further, supposing a wind to spring up from another direction and blow athwart these furrowed or billowy clouds, they will be split up into divisions, and will then present that familiar appearance which has been popularly likened to a flock of sheep lying down. Such clouds as these occur at various levels, and when they form at a medium height they are called alto-cumulus, the name cirro-cumulus being reserved for those at the highest levels. The presence of these clouds informs an observer that they are the boundary-line between two winds of different temperatures and different velocities; and the direction in which the long rolls are lying indicates the direction of the upper wind, while similar information is to be gathered from the cross lines or cleavages by which these billows are so often broken up. For providing corroborating evidence as to the trustworthiness of other methods of observation, there are no better witnesses than these rolled clouds. They are very closely allied to the cirrus clouds, and, although they are not so intimately associated with stormy weather as the true cirrus, they, nevertheless, carry important messages concerning the weather, which may be developing in the recesses of the atmosphere.

There are also clouds which degenerate, as it were, and change from a higher to a lower type, and gradually disappear altogether. These changes may readily be observed, and among the clouds which thus alter their character are the cirro-cumulus and the cirro-stratus, and it is worthy of notice that when a cirro-cumulus changes to a cirro-stratus, rainy and stormy weather commonly follows. Thus, when a mackerel sky, which is composed of cirro-cumulus clouds, changes to cirro-stratus, the altered character is often shown by the haloes which are then produced, and these phenomena have always been a popular prognostic for bad weather. On the other hand, supposing the haloes are seen, and the clouds subsequently degenerate to cirro-cumulus, it will be reasonable to anticipate that finer days will ensue with less violent winds.

These researches into the character of the upper winds have made necessary a slight amendment in a well-known rule for ascertaining the position of a storm's centre. As commonly stated, this rule says that when standing with one's back to the wind, the lowest barometer readings will be to the left hand, and it is accordingly in this direction that sailors and others have been instructed to conclude that the worst area of the storm is located. These rules are to be found in the official meteorological publications, and they are, indeed, applicable to all those cases where a solitary observer on sea or land has to depend upon his own observations and the indications of a single barometer for his information concerning the weather. As shown by a weather-chart on which are drawn the isobars, or lines joining all places having a similar atmospheric pressure, the foregoing rule depends for its success upon the fact that the direction of the wind follows the trend of the isobars. The old rule for finding the centre of the storm, moreover, not only says that it is to the left hand when standing back to the wind, but further says that it is eight points to the direction of the wind. Thus, in the Northern Hemisphere, with a wind from the N.E., the bearings of the storm centre would be to the S.E. In the Southern Hemisphere, the circulation of the winds is opposed to that which obtains in the Northern Hemisphere, so that standing back to a wind blowing, for instance, from the N.W., the centre of the storm, according to the old rule, would be on the right hand and towards the S.W.

Seeing also that the winds are circulating in gigantic circles, it follows that in certain quadrants of the storm a ship would be in danger of running across the path or track of the cyclone, so that in the Northern Hemisphere a ship in the south-east quadrant would run a risk of being blown northwards and directly across the front of the advancing storm. The rules and hints which meteorologists have been able to compile for the use of seamen are accordingly among the most useful results obtained by the study of the winds. But as the use of weather charts increased it was noticed that the surface winds did not exactly follow the trend of the isobars, but blew slightly across them, so that if arrows were drawn to represent the observed winds it was found that their flight was directed a little towards the left hand, as if responding to an indraft of air flowing towards the centre of the cyclone. The angle of this indraft varies in different latitudes, but, roughly speaking, it may be said to depart about 20° from the direction of the isobars. Many of the old rules for calculating the direction of a storm's centre need therefore to be considered in the light of this fact.

When the direction of the upper currents in the atmosphere are observed during the oncoming of a storm, it is seen that in nearly all cases they are blowing at an angle to the lower currents, which is never less than 90°, and in many instances are directly opposed to them. These diversities are revealed by the movements of the clouds which form the elevated bank of cirro-stratus in the forefront of an approaching depression. Moreover, just in the same way that the surface winds back and veer, so do these more lofty winds, and there are excellent reasons for concluding that the more rapid are the changes taking place in these upper currents, the more turbulent will be the movements of the surface winds by which these changes will be followed. As regards the middle strata of winds, observations indicate that they blow almost exactly in the direction of the isobars, so that in calculating the bearings of the storm-centre, an imaginary line drawn eight points to the left or right hand, according as the observer is north or south of the Equator, will lead more directly to the desired spot than by applying the rule mentioned above merely to the surface winds. Thus, then, in considering the air currents in a cyclone there are first the surface winds blowing a little to the left of the isobars, then the middle winds blowing directly along them, and, thirdly, the upper winds, whose direction is opposed to those at the surface of the earth. The fact that there are variations introduced into this system by local geographical peculiarities, to say nothing of those changes introduced by the progress of the seasons, only serves to stimulate interest in the pursuit of new solutions to the problems which then arise. By slow degrees, however, the gyrations of the winds are being revealed, and, although many of the methods of research are perhaps only tentative, they are gradually clearing away many of the difficulties which beset the path of the oftentimes-bewildered weather prophet.

THE most important work on the Ghaziabad-Moradabad Railway line is the bridge over the river Ganges, consisting of eleven spans of 200ft. The line is on the standard gauge.

ORNAMENTAL TURNING.—XXX.

By J. H. EVANS.

AS intimated in my last, we now proceed to the circular movement of this instrument, from which, I may say, it derives its name of the spherical slide-rest. When the two slides, as

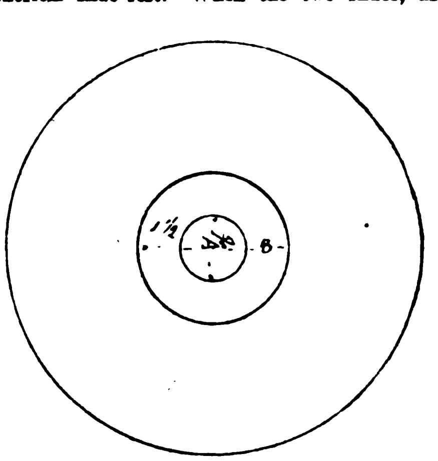


FIG. 1.

already described, are completed, it will be readily seen that the base or lower slide standing as it does at a right angle to the mandrel, the slide is moved parallel with the surface, and by this means the circular movement may have its axis placed immediately under that of the mandrel, or be moved as required to or from the same. The second slide, upon which the rotary action is fitted, moves it in a direction parallel to the mandrel, and the principal purpose of these two slides is to place the axis of the spherical movement at any required position below the work, after which they remain unaltered.

Let us now take in hand that which forms the succeeding part. This consists of a worm-wheel having 120 teeth cut in its periphery. This must

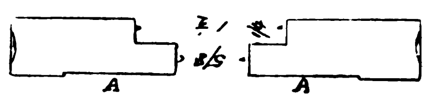

FIG. 2.

be made from a sound gunmetal casting—about $\frac{5}{8}$in. will be the depth; but I may say this must be governed to some extent by the exact thickness of those slides already finished. Sometimes, for reasons innumerable, I may say, the plates will stand up rather thicker than may have been allowed for. If this is so, and the difference is a mere trifle, also the plates are perfectly clean, what little difference there is may be cribbed—perhaps is a good term—from some other part. Reference to Figs. 1 and 2 will clearly show the manner in which the wheel is first prepared. Four inches full will be the required diameter for 120, supposing it is cut 10 to the inch. Some prefer rather a coarser pitch of screw. If this

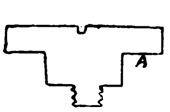

FIG. 3.

happens to be the case, the increase in diameter is a matter of no difficulty to calculate.

The casting should, in the first place, be well burred over, and then hammered to close the grain, and harden to some extent. It should then be chucked in a self-centring chuck, and the centre hole A be turned out to, say, $\frac{5}{8}$in. diameter; and for the convenience of fitting the screw, it is better to turn the fitting slightly taper. Following this, the enlarged recess B must be carefully turned out, taking great care that the face inside is quite true; this is also better if turned slightly taper, but being $\frac{1}{4}$ only in depth, it will be, of course, in a very small degree.

I should have advised that the face be first turned all over to certify the quality of the casting, which, if in any way faulty, must be discarded for another. The wheel must now be

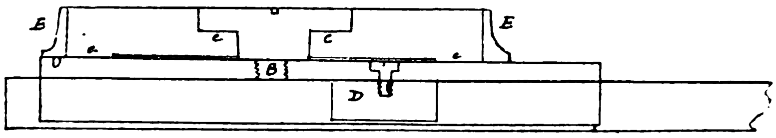

FIG. 4.

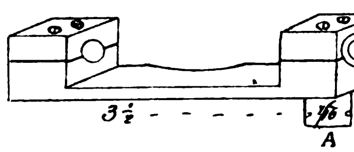
removed from the chuck, and a very carefully-made chuck, either of iron or gunmetal, made to fit the recesses perfectly. When thus fitted, the two should be soldered together, as it will be clear we have a lot to do before it will be removed.

When thus chucked, its truth will be certified by the accuracy of face already turned; this must be looked to before proceeding. The diameter decided, also the width, it must be turned to the proportions. In order to relieve undue friction, it is advisable to turn a shallow recess, *vide* A A, Fig. 2, leaving a rim of actual bearing width $\frac{5}{8}$in. wide.

And now we come to the cutting of the thread. Well, this class of work has been referred to many times, albeit there are times when it will bear further reference, and this is one of them. There are many ways and means to adopt, but I must not lose sight of the fact than many of my readers will not be provided with all the necessary tools, as recommended in some instances. In the first place, having turned the periphery to the necessary diameter, a plain horizontal cutter—

FIG. 5.



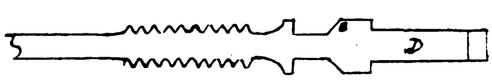


FIG. 6.

preferably one with a swivel movement—will be the tool to employ. In this is fitted to revolve between the centres a single cutter, which is a facsimile of one thread of the screw.

Now the object of my recommending a cutter-frame with a swivel movement is that it is necessary to incline this cutter to an angle suitable to the rise or pitch of the screw. However, assuming the swivel frame is not at hand, the frame must be carefully set over by pieces of angular packing. This will appear to some extent a makeshift; so it is, but if it effects our purpose, what matters? This series of articles is not written with any view whatever to showing forth expensive tools as made either by myself or others, but to help our amateur friends to enter into the interesting pursuit of making many, in fact, all, of the apparatus connected with the art that we are discussing, if they feel so disposed, so that any little dodge—workshop secrets some call them (I have none)—that I may explain will, I hope, be accepted in the spirit in which it is given.

The cutter, then, by the means explained, having been set to the desired angle, it is placed in position by the slide-rest. A slight curve (shown in Fig. 2) should be turned as a guide, also to relieve the friction after the single tooth has been cut. The index point is now fixed in the zero of the division, which will give the 120 consecutive incisions. The cutter is then inserted to an equal depth all round, the latter being signified by the division on the micrometer, which must, of course, be turned to the same number for each consecutive cut.

We will take it as a matter of course that the single tooth cutter has done its work satisfactorily, and the next thing will be to substitute a cutter made after the form of a master tap, but to revolve between the centres of the cutter-bar in the same way as the one it replaces. The diameter of the worm being half, the cutter must be accurately made to this size, and about four cuts will be sufficient. By cuts I mean flutes, throughout the length of the thread, and I think I may say that these, as a matter of fact, are more serviceable when put in with a triangular file than when cut with a round-edge circular utter. The cutting edge is too rank for our urpose with the latter. I have had in use now when required a cutter that I made myself 25 years ago, which I would not exchange for any number of the best that could be offered me. I cannot tell how many wheels it has cut, but a great many, as may be supposed. We have grown up together in the service.

This cutter finished, it is placed in the cutter frame, and our little dodging, in the shape of packing pieces, may be put away. Don't discard them. They will be sure to come in again. The cutter-bar is now placed simply on the bed of the slide-rest, which will, or should, present it quite truly in the perpendicular plane. The cutter must be gently and carefully presented to the wheel while revolving, and it will, of course, soon be obvious that the cutter carries the wheel round all the time it is cutting the teeth gradually deeper, the pressure being kept up by the screw of the slide-rest until the desired depth is obtained, which will be when it is cut full and sharp.

We have now completed a very important item in the construction of this instrument, and may, provided all has gone well, feel very satisfied, and our next proceeding will be to get it fitted to its place on the plate of the second slide.

The first thing to do will be to make a cast-steel screw as shown in Fig. 3, and this must be very accurately fitted to insure a successful result. The screw is obviously made with a large head, for the purpose of forming as much bearing as possible at the under surface A, and it will also be seen that when in its place the rotary movement takes place between the under surface of the wheel and the lower surface of the recess. The screw must fit well, and be screwed home thoroughly to its place, and then the circular bearing may be carefully ground up to a finish; so far, then, we have the wheel and screw ready to fix.

The correct position for this I have shown in section in Fig. 4; it must be in the centre of the plate as to its width, but about $\frac{5}{16}$ only from one end, the left, as seen, the object of which will become apparent as we proceed. By this section it will perhaps be more clear to some where the actual bearing of the circular movement really takes place; it is *c c c c*. Fig. 4 defines this in every respect. The screw B can have its hole tapped through the plate.

The present is perhaps a good opportunity for showing the proper place to fix the nut of the main-slide; it must be under the wheel, as shown by D, and is fixed by two screws, as previously explained, countersunk into the plate. One of the most important matters in the action of the tangent screw and worm-wheel is, they must be kept free and clean from dust, dirt, or shavings, which we all know do accumulate during the progress of the work. To avoid this, the periphery of the worm-wheel works within a circular fitting, as illustrated by E E, Fig. 4. This is simply a ring of gunmetal turned to fit the wheel, and is attached to the plate on which the wheel revolves by three small pins on its base. The tangent screw is ultimately covered with equal care by a plate over the frame which carries it.

Having the wheel thus correctly fixed to its place, the screw that actuates it will be our next consideration, or, rather, I should say, the frame in which it works, both, however, forming part of the same job. Now, of tangent frames there are many kinds, good, bad, and indifferent; in connection with the character of the work we have in hand, I do not propose to refer to any other than that which is the best in my opinion of the present time. I am very indisposed to take up the valuable space accorded me by our ever-courteous Editor with references to that which concerns us not. At times it may be desirable to show extreme differences; now it is not so.

It must be our great object to have the rotary action entirely free from any semblance of loss of time in its movement, and experience has proved to me that the frame which holds the screw, if made as seen in Fig. 5, renders this not only within our powers, but is simply a matter of good and careful fitting.

The first thing to do is to procure a steel forging the shape given, and as nearly as possible the dimensions. This should then be held in a jaw-chuck by the square; the base turned over perfectly true to the stem A, which is tapped to receive a screw. With the base thus prepared we have the groundwork to proceed from, and from this the whole frame must be filed up square and true. This is not by any means a difficult matter, care alone being required.

It will be seen that at each end the frame is cut through in order that the bearings become adjustable. The top bearing, as shown, is held to the lower by two steel screws. All this work should be done before the holes in which the screws work are bored. When the parts are severed, the centre should be filed perfectly flat, and from the base it must be made to exactly correspond in height with the centre of the worm cut in the wheel, so that when the hole is bored and the screw fitted, it will allow the latter to fit well into the worm of the wheel.

This surface thus obtained, the two top bearings must be accurately fitted to their places. We have now the centre line for the height, and only have to set out the frame in other respects. The top bearings must be screwed down tightly to the lower parts. Having correctly set out the work, it is advisable to drill a small hole through each end in the first place, this being a guide for the larger drills to follow, and helps considerably, preventing the drills running out of the proper course.

The finished size of the plain hole will be as nearly as possible the diameter of the bottom of the thread of the tangent-screw. This I have shown approximately in Fig. 6, and reference to this will show that the frame is countersunk at each end to suit the angle shown in screw at B. Of course, the particular angle of the cone is of no importance, but the idea will be fully gathered from the illustration. We have in this fitting a considerable scope for the display of skill, and the object of the cone will be fully appreciated when we see that it forms a means of adjusting the revolution of the screw within its bearing, so that not the least semblance of loss of time will occur. It may seem at first sight to be a rather long and tedious job; but, as I have already explained, it is the best, and it cannot be too good for our present purpose. Although not shown, both ends of the screw must, of course, be alike; that part which extends beyond the cone of the same diameter is utilised for the micrometer, and may be divided into ten equal parts. The extension beyond this mark D is slightly taper, to facilitate the filling of the pipe handle, the stem of which will be required of considerable length. This I will treat in my next, as we approach the third slide, which is fixed to the top of the worm-wheel. The present will afford plenty of practice and thought for those engaged upon the work.

MILLWRIGHT'S WORK.—XV.

ELECTRIC power has not yet displaced the belting from our factories. A few progressive firms have adopted it, so that the system is well on its trial. But the time is not yet ripe to express a pronounced opinion about its economical aspects. Much may be expected of the new method of transmission. The confession must be made that none of the present methods in use are entirely satisfactory, even when they exist under the most favourable conditions. When the opposite set of conditions predominates, then results are eminently disappointing.

There are five methods of transmission of power adopted: (1) belting, (2) ropes, (3) chains, (4) toothed wheels, and (5) frictional arrangements. The last two, of course, work under special con-

ditions, and do not come under exactly the same category as the three agents named first in order. Toothed wheels are used to connect adjacent shafts, friction arrangements are employed similarly, the other agents connect shafts which are usually separated by relatively long distances.

(1) *Belting.*— Few, if any details of millwright's work have caused more persistent trouble than belting. Rules, apart from experience, are of little aid in practice. The whole subject bristles with difficulties. Differences in length of drive, in proportion between thickness and width of belt, speed of driving, size of pulleys, and of belt tension complicate matters, and increase or lessen power cost very materially. Hence it follows that while some firms have incessant trouble with their belting, others experience immunity therefrom. Yet there is no chance work at all about this, but effect follows surely after cause, and common sense carries one farther than formulæ.

Any old engineer knows that belting is often a source of great trouble, that it is very expensive, and deserves much more attention than it receives in many shops. The spectacle of weak belts, patched belts, wavy, uneven belts, slipping and screeching belts, belts too short, belts too long, belts too tight, belts too loose, belts badly laced, and much more is witnessed in many shops. It is proposed, therefore, to devote a rather large section to this wide and somewhat involved subject.

The breakdown of belting, when that unfortunately happens, is often nearly as serious as that of the prime mover. It is bad enough when it stops for half an hour a machine, but immensely worse when it stops a whole line of machines, or an entire shop. Yet this is what frequently happens when belting is in the charge of an ignorant manager or attendant. The case is worse in some factories than in engineer's shops, in cotton-mills and flour-mills especially, where there is a sequence of dependent operations. We, therefore, as a rule, find better driving arrangements in the mills than in the engineer's shops.

Belting is made of leather of various grades, of canvas, of camel hair, llama hair, cotton, indiarubber, and guttapercha.

It is as well to say at once that no class of belting whatever is equally applicable and suitable to all the conditions which arise. So that before the most suitable agency for driving can be determined in any case, the conditions must be known. A matter which has to be considered in some situations is the ability to stand great heat, steam, frequent changes of temperature, moisture, and so on. A belt of good quality for some purposes will often be unsuitable for use because of the conditions of situation imposed.

But for the general purposes of transmission indoors, at ordinary temperatures, for the driving of machines in general, my own belief is that there is "nothing like leather" after all, provided it be good, honest leather. A good belt will live three or four times as long as an inferior one. It is not meant to imply by any means that the woven beltings are not good. But there is a durability, a rigidity about the best leather which renders it better qualified for hard, severe duty, than anything beside.

The reputation of belts has suffered in consequence of the employment of inferior leather and of ignorance of conditions which conduce to long life. If people will have cheap belts, they get the inferior parts of the hide, the flanks and offal, instead of the butt; such belting is dear at the best. It has a short life; is always stretching and giving trouble, and does not last a fourth as long as the best. A good leather belt, well cared for, will last the average man's working lifetime in the shops, and cannot be beaten by any other material.

Uniformity in the texture of a belt is an important characteristic as affecting the wear. This is not insured in the cheaper classes of leather belting, which are composed of various qualities sewn together. The result of non-homogeneity becomes apparent in unequal wear, which entails patching, and ultimate wavy motion. This evil is more likely to be developed in leather belts than in the woven ones.

The most favourable conditions for belt-driving are when the pulleys are of large size and situated at a reasonable distance apart, and the belt leading on the top of the driving pulley.

The least favourable conditions are those in which there is a wide disparity between the diameters of the pulleys, reducing the arc of contact on the smaller one, an evil which will be greater the closer the centres are brought together. The distances of pulleys apart cannot, however, always be regulated to fulfil the best conditions. Pulleys set too close together are very badly situated for belt-driving, requiring binder pulleys to tighten the belts, which increases their wear and tear. On the other hand, belts between pulleys far apart sag a good deal, especially at high speeds. Vertical belts are a bad arrangement, because there is no assistance derived from the sag of the belt.

The reason why vertical driving is not economical is that the tension is insufficient, unless the belt is very tight, and maintained thus. If such a drive is necessary, the best results are obtained by using a wide thin belt, rather than a narrow stout one. Diagonal drives as a rule are objectionable when they approach too nearly to the vertical. In such cases binder pulleys are often employed to intensify the grip.

The larger the pulleys the better for the belts. But here, again, the diameters are imposed by conditions in the shops, and small pulleys must often be used to transmit high powers. Broad thin belts are then preferable to narrow thick ones, because the latter are greatly strained in their outer layers in passing round the pulleys.

Within economical limits, it is best to reduce the weight of belting as much as possible. The weight has to be carried round by the engine, and excess means wasted power. The centrifugal force, too, of the belt becomes increased by increased weight, again absorbing power. Belts too tight on their pulleys tax the bearings and shafting, and require more power to drive than those which fit easily—another reason for using light belts, and those possessing a maximum of strength with a minimum of weight. It may be laid down as an axiom that belts should be as slack as they will run without slip. When a belt is in the habit of slipping off its pulleys, there is evidently something which should be looked into. Either the belt is too narrow, or the pulleys are not hung truly, or the bearings and shaft journals are too tight. In short, something is wrong with the fitting, or else the belt has too much work to do. A slack belt which is strained a long way within its maximum capacity will not run off, provided other conditions are carefully safe-guarded; and the life of such a belt will far exceed that of a highly-strained and tightly-fitting belt, and it will not cost so much power to run.

A belt that is constantly overstrained may slip off or break several times in a year, causing delay to work every time. Multiply that by the number of delays, and the result is a serious item of loss. Fracture is prevented by keeping the working strains low, and this is the secret of a good belt design. It is best to keep a long way within the limits given in textbooks, which are based on the ultimate strength of leather and laced joints, but which do not take sufficient account of the severity of working conditions. In this respect, belt users may take a hint from the designers of rope drives, who long ago found out that the stresses on ropes must be kept very low if trouble is to be avoided. With low stresses, the life of a belt may be prolonged to an almost indefinite period.

If a belt, true in itself, runs in a wavy manner, the pulleys should be looked to. If these are not set truly on their shafts, they will produce a wavy motion.

Friction is the principal element in belt-driving. It is compounded of two elements. That due to contact between the belt and its pulley, which is governed by the natural action of the surfaces in contact, and the dimensions of the arc of contact. The other is dependent on the amount of tension given to the belt, which diminishes rapidly, due to stretching. The amount of natural friction is termed the "coefficient." This, taken alone, would be of little value. In practice, the flexibility and tension of the belt are of greater importance. From this point of view, a thin flexible belt is better than one which is comparatively stout and inelastic, and a belt which stretches but little is better than one which lengthens rapidly under tension.

Thick belts sag less than thin ones; but they bend with difficulty, and do not lie so closely round the pulleys as thinner ones.

Belts continue to stretch when not running, which is the reason why they are often thrown off the machines at night. As they stretch, they slip, and cause increased creeping, and in time they require relacing.

The flesh side of a belt should run next the pulley. The grain side grips better when new; but it is not the proper way to run, because the belt is more flexible when running against the flesh side. The latter will soon grip as well as the former if the surface is dressed with boiled linseed oil. The oil oxidises and gives a smooth driving face, slightly gummy, which is better than a hard face. A belt dressed thus does not slip, and does not polish the surface of the pulleys. Messrs. Tullis recommend three coats of linseed oil once a year. Resin is often used on belts, but it does harm, and its gripping effect is only transient. Dubbin is also recommended for application.

Belts are cleaned by washing them in warm soda-water, leaving the belt wet for a couple of hours, after which the grease can be scraped off, a clean surface resulting. If a belt becomes foul with oil from bearings, chalk, finely powdered, will absorb it.

Rounding or crowning the faces of pulleys keeps the belts well about the centre. Pulleys running on vertical shafts should have more rounding than those on horizontal ones. From $\frac{1}{16}$in. to $\frac{3}{16}$in. is enough for high-speed pulleys of about 6in. in width—about $\frac{1}{32}$in. per foot of width. Those on vertical shafts may have double this. There is no advantage, but rather the reverse, in increasing this amount. Fast-and-loose pulleys should not be rounded, but left quite flat.

An excessive amount of convexity has often been given to pulleys, with the idea of keeping the belt from slipping off. This is now known to be a mistake. Really, it too often was a consequence of the bad fitting of shafting, bearings, and pulleys. If these are set out of line, the belts will run off, in spite of crowning. Actually the slightest amount of convexity is better than a deal. Much rounding means that the belt, if only moderately thick, does not bear nearly across its entire width; and, if a double belt, it will probably not bear so much as one half, and its frictional grip, on which so much depends, is thereby diminished.

The evil is increased with increase in speed, because the effect of centrifugal force comes into force, throwing the belt off the pulley, to which it ought to adhere closely.

The edges of belts become frayed when they run against flanges or against the forks of striking gear. This cannot be avoided—the only thing is to take the capability of a given quality of belt to resist the action as a point in its favour. Belt forks must be polished, and large belts must be shifted by rollers instead of by plain forks.

J. H.

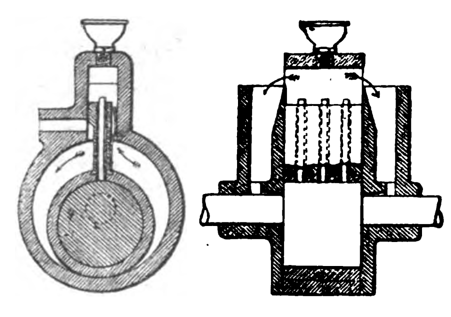
FRENCH SUBMARINE BOATS.

THE flotilla of submarine boats in France promises to present as great a variety of types as the battleships. After the enthusiasm following upon the performances of the *Gustave Zédé* had simmered down, and people began to look at it from a more practical standpoint, it was recognised that its small range of action was calculated to lessen considerably its utility as a war engine. The new vessel, it was said, had, at any rate, proved the practicability of the submarine boat, and in the hope of getting something better the naval authorities gave fresh attention to the somewhat despised Goubet boat. This vessel, however, showed a tendency to dive to the bottom and stay there, and the naval experts begin to pin their faith in boats of the Morse type. Recent trials with the Morse submarine showed that as regards the range of action it had scarcely any advantage over the *Gustave Zédé*, and it had to be admitted that the boat could not be used for any other purpose than harbour defence. After all these experiments, however, it did not seem as if much headway had been made, but the naval department, with praiseworthy optimism, conveyed its favours to the *Narval*, simply because absolutely nothing was known as to the behaviour of this type of vessel, and plenty of scope was consequently allowed for the exercise of a vivid imagination. The *Narval* has been constructed upon the plans of M. Labeuf, a naval engineer, who secured the gold medal in the competition for submarine boat projects organised by M. Lockroy. She was put upon the stocks at Cherbourg in July, 1898. Constructed of steel, she has a length of 34m., a width of 3·75m., and draws 1·60m. of water when navigating at the surface. Her displacement is 160 tons. The motive power is supplied by a Forest oil-engine, which not only drives the propeller when the boat is either navigating at the surface, or with only her look-out and chimney exposed, but also operates a dynamo for charging batteries of accumulators, these being used to propel the boat when she is entirely submerged, and the chimney unshipped. Sailing at the surface at 12 knots, the *Narval* promises a range of action of 252 miles, and at eight knots the range is

to be 624 miles. When submerged the accumulators will propel the boat 25 miles at eight knots, and 70 miles at five knots. The *Narval* is equipped with four torpedo tubes, and carries two officers and nine men. The boat was launched at Cherbourg, and the greatest interest is being taken on the other side of the Channel in her forthcoming trials, and it is this type of vessel which carries the hopes of France. —*The Engineer.*

ROTARY PUMPS.

THERE is a difficulty in using rotary pumps for exhausting air on account of the airtight sliding contact, which, if airtight at first, does not long remain so in working. A patent has been obtained in this country by Siemens Brothers, Limited, on behalf of Siemens and Halske, of Berlin, in which the difficulty is said to be obviated. The pump consists of a cylindrical casing through which the driving-shaft passes centrally, having fixed upon it an eccentric cylinder that revolves within a cylindrical piston or slide, and which is so arranged that by its rotation the piston (which does not revolve) is always in sliding contact at one point with the inner cylindrical surface of the casing. The cylindrical piston or slide has projecting from it a flat plate, which, as the piston performs the motion, slides with a combined vertical and slight lateral motion in a corresponding vertical rectangularly-shaped extension of the cylindrical



casing, of sufficient width to leave the piston extension free play. In one side of this extension, near to its lower end, is the inlet branch by which the pump is connected to the chamber to be exhausted of air, and the upper end of the piston extension has on the same side a lateral rounded projection which, in bearing against the side of the casing extension above the air inlet, causes a space to be left between the piston extension and the casing through which the air passes from the inlet into the cylindrical part of the casing on one side of the piston, which, by its before-described eccentric motion, first causes the air to be drawn in on that side, and then expels it on the other side of the piston and extension, the air being made to escape through lateral holes in the upper end of the casing extension. The lateral projection of the piston extension is kept in close contact with the surface of the casing by a spring or springs placed between the back surface of the extension and the opposite wall of the casing. A more or less viscous lubricant is introduced into the upper end of the casing extension, and flows down first between the projection of the piston extension and the casing, so as to insure an airtight contact between the two, and secondly down vertical channels formed on the piston extension (in which may be contained loose rods for facilitating the flow), and between the eccentric cylinder and the annular piston or slide, from the ends of which it passes into the casing, forming airtight joints at all sliding contact surfaces between piston and casing. The excess of lubricant is then expelled from the casing, together with the air on the expelling side of the piston, passing up between the back surface of the piston extension and the casing extension, and eventually escaping through the before-mentioned holes in the latter. From these the lubricant flows down in external vertical channels, the lower ends of which communicate with the bearings of the driving-shaft, the said lubricant being made to pass through channels in such bearings into the pump-casing again, where it is made to circulate as before. A continuous circulation of one and the same body of lubricant through the pump is thus effected, insuring the airtight working thereof, while any loss of oil is made good from a cup at the top of the casing extension.

HELICAL SLOTTING ON THE MILLING MACHINE.

IF the milling-machine is not well adapted for turning the rims of hand-wheels and other kinds of lathe work, I send herewith sketches of a planing, or, rather, a slotting, job, to which it seems, and has so proven, admirably suited. We had the job of putting five grooves in a piece of

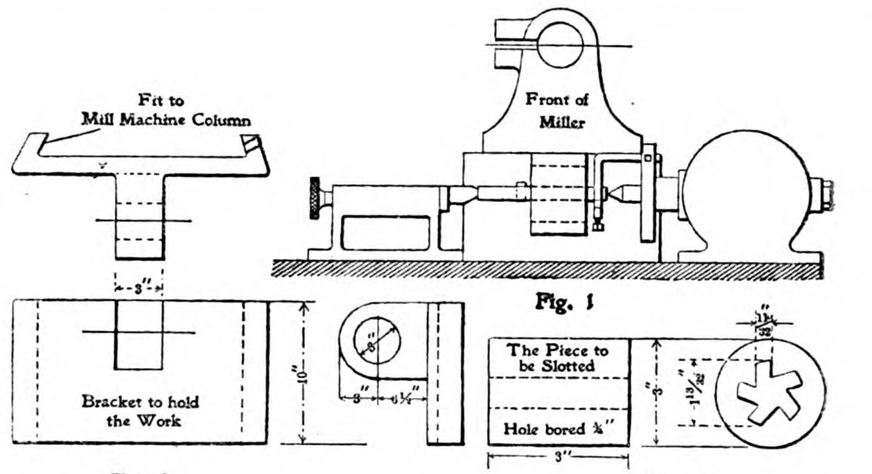


Fig. 2 Fig. 3

tool-steel (see Fig. 1). These grooves are helical, making one turn in 60in. A casting was made to hold the work (see Fig. 2), this casting being planed to clamp to the front face of the milling-machine frame, where the table-bracket slides. A bar was slotted, and tools of different sizes inserted, one after another, and put in position on the index centres. The spiral head was geared up to give the proper amount of rotation, and the feed was speeded to give a fairly good cutting speed. The cutting was done by the feed motion, and not by the right or machine movement. The machine being started up and the feed thrown in, consecutive cuts were made until most of the stock was removed for the reception of the finishing-bar. This bar was made with five ribs to fit loosely in the grooves already made, and was very stiff. Several tools were made, each tool being about ·002in. wider than its predecessor. When running the table back to take a new cut, the tail centre was slackened to save the edge of the tool. The time made on this job was good, and the results first class.—E. BURY, in *American Machinist.*

THE TOOL-SMITH.*

IN the reports of our proceedings tool-steel has been very prominent, the various articles leaving little to be added. But nothing is said about the tool-smith, who, if not the most important workman in a large establishment, is next to him. He is as a rule not easy to replace, and is conspicuous by his absence if that is even temporary.

Whence do we derive a substitute to fill this important, or, rather, responsible, position. Some advance an old smith, others a carriage or country smith, others again take a handy helper and put him to the roughest part, such as dressing track-tools, until he is advanced enough to fill the vacancy at the tool fire. I do not deny that many of these men have turned out the best kind of work, but at the same time many have proved failures. This branch above all others in the trade makes the strongest call upon the intelligence and reasoning powers of the workman. This trade is not learned from books, but is the outcome of reason and experience; therefore it calls for men above the average to comprehend its intricacies, such as the points suitable for the various metals, angle and twist in cutting-tools, heating and tempering, making special forgings of tool-steel and the many odds and ends which are used in any large establishment. The tool-smith knows by intuition what kind of steel he is working on, and his memory is taxed often to accord a certain mode of treatment to a certain brand of steel. He attends to this without any apparent effort, although the material he works in costs from six to thirty cents per pound. This is dearer than copper; but you can sell copper scrap to better advantage than steel scrap.

In these days competition follows in every line. The best articles at the lowest figure. But it is not economy to take cheap steel and expect it do the work of the best in the market by bringing the resources of the trade to bear upon it, and do about once or twice what it should do always. A visit or two to the shop equalises the cost in two various grades of steel. But I digress. I will ask you: Is this material cheap enough to place in the hands of a novice? Or, worse still, a man who is careless, and ignorant of the properties of steel?

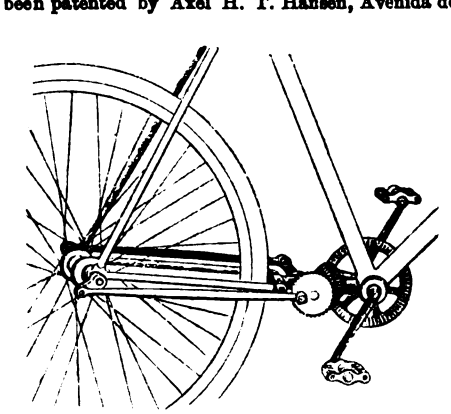
The mechanical Press of late years gives recipes for apparatus and hardening solutions, generally emanating from the tool-room of a manufacturing establishment, the presiding genius being a machinist. He, by the bye, does his own forging and tempering. Does not this strike you as something strange, that a man of another trade offers to do the most artistic and scientific part of yours? Suppose you were to advise this: do my own forging and fitting, understand gearing the micrometer, vernier, &c.? This is easier to learn than to work steel to perfection, and there must be something wrong.

The wrong lies, as far as I am able to judge, in the selection of men who are placed at the principal fire doing the steel work, and instead of the experience of one being handed down to the next, it becomes, like an unwritten language, lost in the absence of the speaker. I need not point out to you what all of us would be without the art of writing or printing, which gives us the crystallised thought of bygone generations. But, to return, we wish to educate the tool-smith, so that he will be above believing in liquids or solutions to restore burnt steel. All of these stand in line with charms and incantations. Our progenitors passed through all of this and learned. Well? Wisdom and distrust. Development is the order of the day, and this is surely a case of the survival of the fittest. In short, the tool-smith should be taught his business, and that well, and if he cannot be brought beyond the bridge, must be relegated to whence he came, and the sooner the better.

* By T. C. LACK, a paper read before the Annual Convention of the National Railroad Master Blacksmiths' Association, Milwaukee, 1899.

HANSEN'S CHAINLESS BICYCLE.

THE chainless bicycle shown in the illustration, in which one-sided strains are avoided, has been patented by Axel H. T. Hansen, Avenida de



Mayo 748, Buenos Aires, Argentina. It is noteworthy for its strong construction and for the novelty of its driving mechanism, which consists of a bevel-gear in place of the usual sprocket-wheel on the pedal-shaft, meshing with a wheel bevelled on both front and rear faces, and mounted in ball-bearings on the rear stay, which is made single instead of double as usual. The rear face of the doubly-bevelled wheel on the side opposite the first-mentioned bevel-gear engages a bevel-pinion secured upon a transverse shaft journalled in the rear stay. The pinion is provided with a crank-pin, and at the opposite side of the pinion the shaft carries a crank.

THE new Royal yacht *Victoria and Albert* will be undocked at Pembroke Dockyard on Nov. 18, instead of Dec. 6, as was previously intended. The engines will then be subjected to a series of trials, which will probably occupy about a fortnight. If the result is satisfactory, the ship will immediately thereafter proceed to Portsmouth to be completed.

MAKING A SPRING SHAFT.

THE following method of making a spring shaft is given in the *Blacksmith and Wheelwright*, by Mr. Clyde C. Henderson, of Lyons, Kansas:—I inclose some sketches showing the steps in the making of a spring shaft such as is used in a salt plant—not a very familiar job, but which is interesting, and at some time or other any smith might be called upon to do. In Fig. 1 is shown the piece of Norway iron, 4in. square, 7in. long, A, and the same is forged into its first shape, B. The corners are then dressed, as shown in Fig. 2, C, and it is drawn out and cut open with a tool as shown at D in Fig. 4. Fig. 3 shows the other portion of the shaft as it is made to fit into D, Fig. 4. Scarf the ends, as shown in Fig. 4, after which it is welded to the shaft spring and the ends threaded and nuts put on. The completed job is shown in Fig. 5.

THE COMING METEORS.

ONE thousand years ago almost, on the night of 12th October, 902, King Ibrahim-Ben-Ahmed passed out of this world, and as he lay a-dying a strange thing happened, for throughout that night "a multitude of falling stars scattered themselves across the sky like rain."

This record from the pen of Conde resembles a genuine Arabian tale in all respects, save only that it is altogether credible. And now the significant period of 1,000 years is nearly completed and we are once again, though without misgiving, expecting the return of the self-same portent. Thirty times save one since the night that the old Moorish King died the full torrent of the same shower has rained down on the earth. Of his fact calculation makes us sure, and we are able to foretell within narrow limits the day and the hour, shortly approaching, when the stars will again fall from heaven.

Much general interest is manifested in the coming event; but to avoid disappointment as far as possible it will be well to consider briefly the main facts of which we are in possession. Records through many hundred years go to show that showers of the same meteors—called Leonids from the fact that they always issue from the constellation Leo—must have occurred at three distinct periods in each past century, and as a rule in the same years in each century. Or, in other words, at intervals of approximately 33 1-3 years.

Prior to the last display in 1866 the researches of Prof. Newton, of Yale College, America, made it appear that the meteors must travel in one of five possible paths; but it was left to the unrivalled genius of Prof. Adams to determine which of these was the true orbit. The immortal discoverer of the planet Neptune succeeded in showing, from considerations of the calculated disturbing effect of the planets, that the path of the Leonid meteors (which are known to follow in the wake of Tempel's comet) must extend beyond the orbit of Uranus, and, avoiding technicalities, it will not be difficult to form a mental picture of the physical circumstances of the case thus:

Conceive a circuit line of railway of an elliptic form extending some 21 miles in its greatest length, and along it to be circling ceaselessly once in 33¼ years a train of mineral trucks of the usual breadth but of the inordinate entire length of some four or five miles. Further, near one extremity of the elliptic line, and lying athwart it in a slanting direction, suppose there to be a level crossing formed by a track nearly circular and of some two miles diameter, along which a 6in. globe is creeping once round in each year. Now in imagination transfer this system to space, augmenting linear dimensions a hundred million-fold. Let the mineral train become a flight of meteoric bodies sweeping out to the confines of the Solar System, and the globe our own earth confined within its true orbit. We shall then have sufficiently grasped our true relation to the meteors which we are about to encounter.

It will at once be seen that at each period when the meteor train is passing the level crossing, it is certain, owing to its extreme length, to be met by the earth once, or possibly twice—i.e., two years running—and the width of the train is such that the earth may occupy, say, some five or six hours in traversing its more central and denser stream. It then becomes a question on what part of the earth will the more concentrated portion of the shower fall, and this admits of no certain answer. It chanced that in 1866 the earth encountered the advanced portion of the main train during hours when the Eastern Hemisphere was exposed to its attack, while the year following the earth came in contact with the after portion of the storm, which on this occasion fell over the hemisphere of the new world.

The cause of this uncertainty is to be found, as already hinted, in the interference caused by our brother and sister planets which come sufficiently near the field of the meteors to disturb their motions, and in some degree to divert their path. Indeed, a careful calculation of the past disturbing effect of the planets led Le Verrier to suppose that the meteors must, as a cluster, have been actually captured from outer space and introduced into our system in the year A.D. 126, since which time, during more than 50 returns, they have been drawn out into the extended train in which they are now found.

A very little reflection will show that when the meteors manifest themselves they are seen proceeding from a definite region of the starry vault which will hold its true position with regard to the constellations as they rise and set in the heavens, and it will be necessary to bear in mind that this region, "the eye of the storm," will not be well risen above the horizon in England till near midnight, at which time it will be found slightly north of east somewhere within the curve of the well-known and well-defined "sickle" in the constellation Leo.

Every individual of the meteor train which the earth entraps will rush into our atmosphere at this point, and, being rapidly raised to incandescence, the spectacle presented to the observer will be that of a multitude of brilliant trails apparently radiating outwards, in obedience to the laws of perspective, as they approach. Past observations combine in showing that the flying bodies—supposed to be individually small—commonly descend in bursts of 10 or 20 per minute amid perfect silence, and become consumed utterly in the higher portions of the atmosphere, most of them flashing out as brilliantly as the brightest stars; many of them leaving phosphorescent tracks of light lingering on for several minutes.

The most probable hour of the *maximum* display, according to latest calculations, is in the morning of November 16, and unfortunately at that time the neighbourhood of a moon not many hours from the full will tell greatly against the effect observed. At the same time, a full moon notwithstanding, we have record of a "grand display" in 1864, and even if, as has been explained, the main shower should not fall on our side of the globe, it is scarcely to be doubted that at least some of the many outlying streams which are known to accompany the central swarm will fall to our share and exhibit a rare and sublime spectacle through the early morning hours possibly of both the 15th and 16th.—*The Times.*

WHITE SPOTS IN BROMIDE PRINTS.

SPEAKING some time ago before the New York section of the Society of Chemical Industry, Dr. Leo Baekelandt dwelt on the sources of trouble in the coating of emulsion papers, and instanced a case, the particulars of which may be noted by those engaged in a similar occupation. A certain raw paper was coated with bromide emulsion; on development, the paper, which bore a baryta coating, was covered with millions of small white spots, some round, others elongated. Dust, defective emulsion, defective mechanical appliances are among the causes capable of producing these spots; but as the defect only appeared on this particular brand of paper, another reason for it had to be sought.

However, with a view to settling the question, the author cut out of the prints small portions where the white spots were most apparent, and, imbedding these strips in paraffin whilst holding them in an upright position, cut cross strips of paper by means of a microtome. These sections, which were only $\frac{1}{1000}$in. in thickness, were examined successively until the microtome reached the centre of the spot. The fact that the film presented everywhere a uniform thickness, without any depression of the film where the spot was located, was evidence that air bubbles or mechanical imperfections were not responsible for the defect. Examination by reflected light under the microscope did not show any dust or foreign matters where the spots existed, but in some of the white spots a central black nucleus was faintly visible, which, in some cases, could be rendered plainer by gently scratching the film away with a small dissecting scape. Treated under the microscope, with a drop of dilute hydrochloric acid, these black nuclei at once showed a yellow bronzed appearance, as copper would do; and on neutralisation, and addition of potassium ferrocyanide, the characteristic brown colouration for copper was obtained. Moreover, the ashes of the prints yielded an appreciable amount of copper.

Now metallic particles yield, in the case of a printing-out paper, the well-known "metallic spots" which appear soon after the paper is made. They are due to the reducing action of the metal on the soluble silver salts in the paper, an action which is assisted by the presence of the organic acid. The case is different with bromide prints, which are neutral in reaction and contain the silver as insoluble bromide. Then again, the spots under examination were white (pointing to zones of insensitive emulsion). The way in which the metallic particle can give rise to an insensitive patch was thus explained and illustrated by Herr Baekelandt: the metallic particle, imbedded in silver emulsion, sets up an electro-chemical action, becoming itself electro-negative whilst the surrounding zone is "electro-positive." As a result, the metallic particle is gradually dissolved and replaced by silver,

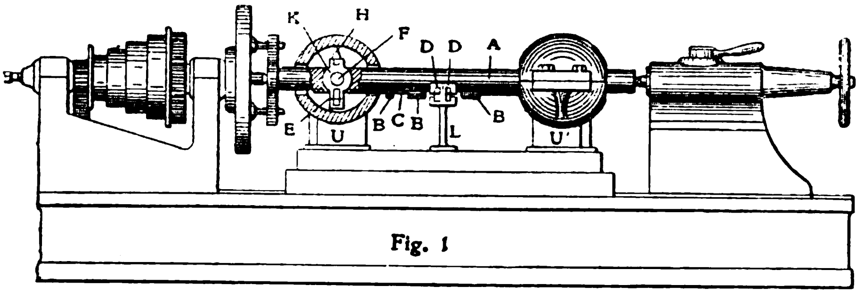

Fig. 1

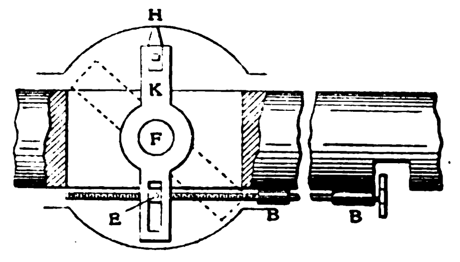

Fig. 2

whilst in the surrounding emulsion a very small amount of bromide or other electro-negative element is liberated, destroying the sensitiveness of this portion. That this was the probable explanation of the trouble was made clear by the following experiment. A sheet of bromide paper was placed (in a dark-room) in a dish of water, containing a little potassium bromide to increase its conductivity, and two platinum electrodes placed about a quarter of an inch apart on the paper, connected to the terminals of a Leclanché cell and left for about twenty minutes. After removal and washing of the paper, short exposure to light, and development, it was found that the spot covered by the positive electrode was white.—*The Photogram.*

BORING SPHERICAL BEARINGS.*

AMONG the early designs of electric generators was one with spherical bearings, as shown in my sketch. The bearings were extra heavy, to stand the pull of the belts. As we had a number of them to make, it seemed expensive to bore by hand-feed in a lathe, and it was very difficult to do them in a boring-mill with ordinary cutters. The method here shown suggested itself, and was adopted. A strong lathe was selected, and a cast-iron plate was fitted to the bed and bolted fast. On this we clamped the bed and bearings of the generators for boring. The bar designed for the job was of cast iron, and fitted with two swivel-heads, K, or tool-holders, the right distance apart for the bearings. Into one end of each head K was clamped a cutter, H. The other end was slotted, and a swivel-nut was fitted for the feed-screw C. There were two bearings B B fitted to the bar, for each feed-screw to run in. On one end of the screw was fitted a star, operated by the bracket L bolted by the generator-bed. There were collars fitted on the screws to receive the thrust when in service. D D are the stars for feeding, and are let into a recess in the bar A. This was necessary on account of the feed-screw being located so near the bar in order to clear the open end of the bearing U.

The arm K rotated on a pin, F, in the centre of the bar, and was made a good fit, so as to bore a smooth surface, free from chatter, for the bearing. Fig. 2 is an enlarged view of the bar, showing the circular boring device. With this arrangement we were able to bore both bearings at the same time, and, with two cuts, to make a true spherical surface in each. By using different lengths of arm K we could bore any diameter required.

Sometimes we look at a job of this kind and say, "The designer might have worked out a bearing very much cheaper than that, and would have saved a good deal in special tools." But the shop does not always understand why these designs are made so apparently expensive, and takes the work as it comes to it and suits the tools accordingly.

MAKING WROUGHT-IRON AXLES.

THE following report on the "Best Method of Making Wrought-Iron Axles" was presented by the committee (Mr. T. Wren and Mr. H. Jeffrey) to the Annual Convention of the National Railroad Master Blacksmiths' Association, at Milwaukee, this year:—

As car and locomotive axles in almost all roadroad shops are produced from scrap iron, the first operation is the selection of the old material for the purpose; this is an important matter, and should be in charge of a competent man, as the best quality of scrap only should be permitted to be placed in the piles preparatory to making into slabs for axle purposes. All scrap material from old boilers that have been badly coated with scale from impure water or other foreign substances adhering to the old material should be thoroughly cleaned by passing it through the rattler before placing it in the pile. Low carbon steel should be avoided in all cases. Slightly oxidised or rusty iron is not injurious, as the rust is pure oxide of iron; this same oxide will become a flux similar to slag, which is absolutely required to more perfectly cement together the atoms of iron which have been reworked many times over and become what the smith terms "dry iron" when brought to a high heat.

The next operation after the iron has been carefully selected is to put it up in piles of 160lb. or 200lb. on boards about 10in. by 14in. The long pieces of scrap should be placed lengthwise on the board on the bottom and sides; the centre should be filled in with short pieces; care should be taken to have the short pieces lap each other for the purpose of producing fibrous iron. Sufficient binders should be placed across the ends of the pile, so that they will not fall apart in handling. The careful selecting, cleaning, and piling of scrap your committee considers important factors in the production of good axles. Often the initial point in the manufacture of axles is not properly looked after; the consequence is that much material gets into the piles that has no affinity to iron. Defects from this cause will be very pronounced in the finished axle.

The next operation is placing the piles in the reverberatory furnace to be brought to the proper heat for working into slabs; this is one of the most important operations in the manipulation of scrap material for axle purposes. Quality of fuel has its influence for good or bad; fuel impregnated with sulphur or other elements that are injurious to iron will be absorbed by the semi-molten porous scrap piles, causing what is known as red short and cold short iron; its injurious effects can never be eradicated. Undoubtedly gas is superior for heating purposes, as the elements referred to have been partially removed before the heat comes in contact with the iron.

The man in charge of the furnace should see that silicon from the furnace bottom or any of the furnace lining does not adhere to the surface of the heated piles while manipulating the same in the furnace. Each pile should be turned over for the purpose of heating it through thoroughly; should any foreign substance adhere to the piles it should be swept off while passing from the furnace to the hammer.

The heated pile is placed under the hammer; the forger should square up the pile by light blows of the hammer, then draw the slab to the required dimensions. It is often the case that the forger plates the pile thin with the first two or three blows, then turning the plated slab edgeways, doubling the same over. This is a bad practice, and should not be permitted, as the scaria or impurities that may have adhered to the surface of the pile while being manipulated in the furnace, will be worked into the centre of the doubled-over slab and prevent a perfect union. Defects of this character will not be visible from the outside; such imperfections cannot be eradicated in the after process of completing the axle.

The slab should be drawn to about 1¼in. or 1½in. thick and about 6½in. wide for the standard M.C.B. axle. The quality of the axle depends in a great measure on the proper working of the slabs.

The next operation after the slabs are cut to the proper length is to lay a sufficient number together to produce the axle required; as many of these piles are placed in the furnace as the capacity of the same will permit. The same conditions exist as in heating piles for slabs, as regards fuel, foreign substances adhering to the surfaces, &c., and should be guarded against the same as when producing the slabs from the scrap pile.

The axle pile being brought to the proper heat is in charge of the forger. The first operation is to shape the pile roughly in round dies the entire length; this requires considerable dexterity, and should be done quickly. The method practised in the Southern Pacific shops is to grasp one end of the heated pile with a pair of tongs at the furnace door, and swing the heated pile under the hammer, roughing the opposite end down as quickly as possible. A pair of tongs is ready on the opposite side of the hammer to receive the end so treated. The tongs that took the pile from the furnace is quickly released, and the same operation performed as on the other end of the axle pile. A rough, uniform billet is produced. About two-thirds of the billet is placed in the reheating furnace, the same operation gone through with all the piles in the initial furnace, and the rough ingots placed in the reheating furnace. The first furnace is again charged with cold piles, and the heat progressing while the axles are being finished from the reheating furnace.

The reheating of the rough shape to a proper welding heat about two-thirds of its length is the most important part of the whole operation. If care is not taken, or the bridge wall of the furnace is not in proper shape, the end of the ingot will become overheated before the centre of the axle is sufficiently hot to form a perfect union in the centre of axle. The end, if finished after being brought to too high heat, will produce a bad crystalline journal, and will also be defective at the wheel fit. In our opinion this defect is the cause of many axles breaking at the wheel fit. If the centre of the billet is not sufficiently hot a perfect union of the different layers is not produced, although the outside can be worked over, so that the defects in the centre of the cross section are not visible.

Three axles broken at the centre came to the writers' notice inside of four weeks; on examination the broken section showed good fibrous iron, but the different layers had not been welded in the centre, which was the cause of the axles breaking. The forger is responsible for the perfection of the axle, and if he is a reliable man, will destroy a defective axle at once by cutting in two for re-slabbing.

The portion of the axle to be finished being brought to the proper heat, the full length of the portion to be worked, the forger should place the centre of the pile in the roughing recess of the die, manipulating the same until the end is reached as quickly as possible. Should the pile have a slightly higher heat at the centre than at the end, the operation should be reversed, commencing at the end and working back to the centre. The axle being worked down sufficiently in the first large swedges, is placed in the next smaller die or swedge for finishing the half of the axle to the proper dimensions; this swedge should be a little high in centre, as shown in diagram, for the purpose of giving the axle the proper taper to its centre. The third swedge or recess is provided with a projection at the bottom of the swedge, tapering to nothing at the upper sides of the die, for the purpose of cutting in the journal. The end of the axle should be placed in this die at as high a heat as practical for the purpose of producing good journals. The forger has become so expert in making axles that the portion operated on is almost down to its proper dimensions at a white heat. The metal does not attain its strength or ductility, however, until it is worked at a low red heat, and for the purpose of expediting the work a trough of water should be placed convenient to the hammer and crane, and the heated portion of the axle partially cooled. After cooling, the iron should be again placed in the finishing dies and lightly hammered over until the axle attains a blood-red heat, or until it will cease oxidising in cooling.

We often see axles finished at too high heat, causing scales in cooling. Such axles, on being broken, will show a crystalline structure. The proper weight of hammer is an important factor in the production of good axles. A light hammer will affect the iron on the outside only, even though the same dynamical force is attained. A hammer of the proper weight will affect the iron to the centre of the ingot. J. W. Nystrom advises that the weight of the hammer "at least should be in pounds the diameter of the shaft squared, multiplied by 80 in inches"; consequently a 2,880lb. hammer would be the weight necessary by the rule. The writer of this article gets much better results with a heavier hammer, and would advise that it be not less than 4,000lb.

Large locomotive axles are produced by similar methods as car axles, but being much larger are not so easily and quickly manipulated; consequently the scaria is more apt to settle between the layers, and when finished in the lathe dark streaks will sometimes appear in the journal and the scaria can be picked out with a sharp instrument or in service will work out, giving the appearance of a defective journal. To avoid this, in the Southern Pacific shops our master mechanic suggested placing plates of iron over the seams formed by the different layers or slabs, the full length of the journal, the fibre of the plates running in the same direction as the axle. This method properly carried out will produce perfect journals. We have had but little cause to

* By H. S. Brown, in *American Machinist.*

reject axles on account of imperfect journals since this method has been adopted.

Another method of producing axles is to hammer the slabs, then roll them into smaller dimensions for piling. In the opinion of your committee either method will produce a good fibrous axle if attention given to all details as above described.

THE MAGICIAN'S OMELETTE.*

THE magician has never proved himself an adept at the art of cooking, from an epicure's standpoint, yet the ease with which he can bake cakes in borrowed hats and cook omelettes in empty pans has long been a source of wonder to the economical housewife as well as to the professional cook. To see the magician hold a small, shallow, empty pan over the blaze of a spirit-lamp for a few moments, when an omelette, done to a turn, appears in the pan, and is cut up and distributed to the audience, one is almost convinced that at least one person has solved that most perplexing of all problems, how to live without work.

But has he solved it? No! my friend; no more than you or I. He has merely deceived you, but most cleverly, you must admit. The pan is without any preparation whatever; but so much cannot be said of the wand, which he is continually stirring round in the pan. This wand is hollow, with an opening at one end only, and in the wand, previous to the trick, of course, is placed the properly-seasoned ingredients of an omelette, after which the end is closed with a metal plug, that is turned and enamelled to correspond with the opposite end of the wand.

2

When the pan is being examined, the performer is holding the wand in his hand, and such an innocent-appearing black stick is never suspected of being in any way connected with the trick.

Just before holding the pan over the lamp the performer finds it a most easy matter to remove the plug from the end of the wand, when by holding the wand by the closed end he can empty the contents into the pan in the mere act of passing the open end of the wand round the inside of the pan.

The metal of which the pan is made being thin, and there not being a great quantity of the omelette, assisted by a large flame from the lamp, it only requires a few moments to cook the omelette, when it is turned out on a plate and carried down to the audience.

It is hardly necessary to say that when the cooked omelette is carried down the wand is left on the stand, which prevents any inquisitive person asking to see it.

THE power-plant at Niagara Falls is to be extended, doubling its capacity. Estimates have been asked for the excavation of a new wheel-pit on the opposite side of the canal from the present station. This pit is to be 400ft. long, 20ft. wide, and 180ft. deep, cut out of the solid limestone, accommodating ten of the 5,000H.P. units adopted.

ACCORDING to tests recently made by Mr. A. S. Cooper, and described by him in the current issue of the *Journal* of the Franklin Institute, the use of salt or sea water in gauging cement is bad practice. The tests were made with both natural and Portland cement mortars, and comprised tensile and compressive tests. The ages of the briquettes when tested were one week, four weeks, three months, six months, and one year. In the short-time tests the briquettes gauged with salt water stood ahead of those gauged with fresh water, but the long-time tests nearly always showed the superior strength of the briquettes mixed with fresh water, and this was just as pronounced in the compression as in the tension tests. The deteriorating effect of the salt water seemed to be the greatest with the richer mortars.

SCIENTIFIC SOCIETIES.

BRITISH ASTRONOMICAL ASSOCIATION.

THE ninth annual meeting of the members of the B.A.A. was held on Wednesday, October 25, at Sion College, Thames Embankment, Mr. W. H. Maw (the president) in the chair.

The names of 13 candidates for admission were read and passed for suspension, and the election by the council of one new member was confirmed.

Mr. Petrie (hon. sec.) read the report of the scrutineers of the ballot, who declared the following persons to have been duly elected as officers and council for the ensuing session:—President, Mr. W. H. Maw; vice-presidents, Messrs. N. E. Green, G. M. Seabroke, G. Johnstone-Stoney, and W. H. Wesley; treasurer, Mr. W. H. Maw; secretaries, Messrs. J. G. Petrie and W. Schooling; librarian, Mr. F. W. Levander; other members of the council, Rev. J. M. Bacon, Dr. Downing, Mr. A. Kennedy, Mr. G. J. Newbegin, Capt. Noble, Miss M. A. Orr, Dr. Rambaut, Mr. S. A. Saunder, Dr. Smart, and Mr. C. Thwaites.

Mr. Petrie also reported that the following had been appointed editor and directors of sections, subject to confirmation at the present meeting:—Editor, Mr. E. W. Maunder; Sun, Rev. A. L. Cortie; Moon, Mr. W. Goodacre; Mercury and Venus, Mr. Henry MacEwen; Mars, Mr. E. M. Antoniadi; Jupiter, Mr. Arthur Cottam; Saturn, Mr. G. M. Seabroke; Comets, Mr. A. C. D. Crommelin; Meteors, Mr. W. F. Denning; Star Colours, Mr. G. F. Chambers; Variable Stars, Mr. J. E. Gore; Double Stars, Mr. G. M. Seabroke; Spectroscopy, Mr. J. Evershed; Photography, Mr. R. Wilding; and Zodiacal Light, Capt. P. B. Molesworth. These appointments were unanimously confirmed.

The President said all the members had received a copy of the statement of accounts for the past session, and he, as treasurer, would be pleased to give any explanations with regard to them that might be desired. On the whole, it was by far the most favourable statement he had had the pleasure of submitting. They had written a very substantial sum, over £28, off the value of their stock of journals; they had added £60 to the reserve fund; and they had a surplus of income over expenditure of over £63. The number of members in arrear was much less than a year ago, and a very substantial proportion of those in arrear last year had paid up—45 out of 80. Unfortunately, a large proportion of the arrears in respect of the past session was due to the Australian sections. There were 71 members in arrear for the last session, and 19 of those were Australian members. The arrears, including the Australian deficiencies, represented under 5 per cent of the main body of members—by far the best result they had had for some years.

The accounts were then unanimously adopted, as was also the report of the council for the past session.

Col. Burton-Brown proposed a cordial vote of thanks to the retiring members of the council, Mr. Cottam, Sir Wm. Huggins, Mrs. Maunder, and Dr. Isaac Roberts. The Association, he said, had made its way, owing, to a large extent, to the untiring energy, zeal, and ability of the members of the council. Not only had they on the council men of note and distinction, but men who were hard workers, and it was their cordial co-operation which had led to the prosperity achieved. Then they had been favoured by the fact of two or three eclipses of the sun having taken place in the period during which the Association had existed, and, if all were well, they were going to have another in May next. He hoped to go to Algiers to witness it, and if, as he proposed, he went out in advance of the main body of the Association's expedition, he would be glad to render them any personal service in his power.

Mr. Crawford seconded the motion, [illegible] approved.

On the proposition of Mr. J. D. Hardy, seconded by Mr. Cottam, the thanks of the Association were tendered to Messrs. Miller and Ellis, the auditors: and a similar vote of thanks was accorded to Messrs. Crawford, Adams, and Holmes, the scrutineers of the ballot, at the instance of Mr. Ellis, and Dr. Smith.

The Presidential Address.

The President, upon rising to deliver his address, was enthusiastically received. In opening, he reminded the members that with the present meeting the Association commenced its tenth session, and remarked that inasmuch as it had been his duty as treasurer during the past nine years to look after the finances, it might perhaps naturally be expected that now, when he addressed them as President, he should say something concerning the progress which the Association had made, and the position in which it at present stood. Mr. Maw then pointed to a diagram which he had prepared, showing at a glance the progress which had been made with regard to the number of members, and also how the Association's finances had stood from year to year, from several points of view. Having mentioned that the present membership totalled 1152, he proceeded: I do not, however, regard these figures as indicating that we have even now closely approached the probable limit of our membership, but rather as showing that we should take steps for developing fresh districts in which, as yet, little has been done. The establishment of our provincial branches has always been attended by an increase of membership, and there are several districts, notably in the south and south-west of England, and in Ireland, where such branches ought to meet with substantial support. Our membership, large as it is, for a society of this kind, really represents but a very moderate fraction of those strongly interested in astronomy in this country—a class which I am glad to say is, with the spread of scientific knowledge, steadily extending every year. After dealing with several financial matters he went on: Having thus dealt briefly with the past history and present position of our Association, I have next to say something of its future prospects as they appear to present themselves to me. Our Society has now reached such a stage of development that the composition of its membership may be regarded as fairly representative of what it is likely to be for many years to come; and it is thus possible to form a just idea of the work which the Association can profitably undertake, and of the value which such work is likely to possess. Roughly, our members may be divided into three classes—viz., first, the professional astronomers, connected with established observatories, and having at their disposal more or less ample instrumental equipment; second, amateurs having instruments fitted for serious work, and possessing, moreover, a fair amount of experience in the use of such instruments; and third, members who are students of astronomy, but who are either not possessors of instruments at all, or who have not facilities for observational work of an original kind. This third class may possibly be advantageously subdivided, as I shall indicate later on. As regards the first class, the professional astronomers, it is, I am sure, a great satisfaction to us all that we have been able to enrol so many of them in our ranks. A reference to our list of members will show that it includes professional astronomers in nearly every civilised country—men whose names are household words, and the history of whose work constitutes to a great extent the history of the recent progress of our science. It is impossible to overrate the value to our Association of the collaboration of these professional astronomers. Their contributions to our publications may be comparatively few, for, as a rule, the accounts of their researches are, almost of necessity, issued through other channels; but we are indebted to them for some very valuable papers, while we have constantly benefited by their presence at our meetings and by their aid in various ways. Without them the status of our Association would certainly not be what it now is. Next, as to the second class, that consisting of amateurs possessing more or less excellent instrumental equipments. It is this class which has formed the backbone of our observing sections, and to it is due the bulk of the original work which has been recorded in the publications of the Association. . . . It is satisfactory to know that this second class of our members, upon whom we depend so much for original work, is an ever-growing one, while year by year it is becoming possessed of more powerful and more perfect instruments. And this brings me to a point on which I wish to say a few words—namely, the influence of the large telescopes, with which some of our more important observatories are now provided, on the usefulness of the work of amateur observers. In considering this point it must be borne in mind that the great telescopes of the present day are of a very different class to the giant instruments of the past. The great reflectors of Herschel, of Lassell, and of Rosse were all instruments made and used by

amateur astronomers, and although they possessed great light-grasp and did some admirable work, they were, owing largely to the nature of their mountings, utterly unfitted for the class of observations on which the large telescopes of the present day are chiefly employed. The 36in. and 60in. reflectors of Dr. Common may, perhaps, be regarded as the latest of this older class of large telescopes, although it would probably be more just to consider Dr. Common's instruments as forming a connecting link between the giants of the past and present. In the case of such large refractors as those at Pulkowa, at Washington, at Vienna, at Mount Hamilton, at Nice, at the Yerkes Observatory, and at Greenwich, the cost of the telescope itself is but a small portion of the total outlay incurred. Not only must such an instrument be thoroughly well mounted to fit it for modern research work, but it must be protected by a well-constructed dome, and, in order that every moment of good seeing may be utilised, provision should be made for effecting all movements of both telescope and dome with the least possible amount of labour to the observer using the instrument. How perfectly this can be done is well shown by the great Yerkes refractor, which, notwithstanding its enormous size and weight, can, with its dome, be so readily handled by the electric motors with which it is provided, that it can be—and is—efficiently used by a single observer through a whole night, without any assistance whatever. It is satisfactory to know that two of our own members, Messrs. Warner and Swasey, were responsible for both the design and construction of this admirably perfect mounting, while the rising floor, which forms such an important feature in the equipment of both the Yerkes and Lick Observatories, and contributes so much to the convenient use of these large telescopes, was the invention of another of our members, Sir Howard Grubb. But by the time a refractor of this kind had been erected and equipped the outlay upon it will have become so large, that it would be utter folly to use the instrument for work other than that for which its great power renders it specially fitted. The result of this is that our modern giant telescopes are, with few exceptions, employed not in doing work which was formerly done by smaller instruments, but in doing work which formerly could not be done at all. Such, for instance, is the bulk of stellar spectroscopic work, including determinations of velocity in the line of sight, the measurement of close double stars, the spectroscopic examination of nebulæ, the discovery of new planetary satellites, and similar matters. We see, therefore, that the establishment of these powerful telescopes has been accompanied by the development of new fields of research, and that the work which was formerly done—and can still be well done—by instruments of moderate size, has not been reduced. On the other hand, many professional astronomers have withdrawn from the work which they formerly did with the instruments then available, and they have thus left to amateur observers the continuance of their former labours. We thus see that there is ample work for the members forming our observing sections, and that such work, if faithfully carried out and recorded with judgment and discrimination, is calculated to be of great and permanent value.

The President next dealt at some length with the character of the reports of the observing sections, and with the mode of recording the work of those sections, in which connection he suggested some improvements which might be made. He continued: I have now to deal with the third class of our members, namely, those who are either non-observers, or who, if they observe at all, are provided with a very limited instrumental equipment. This is a very large and important class, and it may, as I have already hinted, be conveniently subdivided into at least two sections, one comprising those who already possess a considerable knowledge of astronomy, and the other consisting of those who are more or less beginners in the study of our science. To both these sections our Association should be of considerable service, while both, on the other hand, can materially aid the objects which the Association has in view. To our members forming the first sub-division much really useful work is open. In the first place, they may render valuable aid to our observing sections. . . . Then, again, there are other directions in which the class of members with whom I am now dealing can do useful work. Some may strike out original lines of mathematical or geometrical investigation, as has been done by Mr. Whitmell, whose papers contributed to our *Journal* aid us so much in realising aspects of the Solar System regarded from other planets than our own; others may take up optical matters and assist in the perfecting of our telescopes and spectroscopes, while still others may afford to our hard-working editor much-needed assistance in his preparation of those abstracts of foreign astronomical publications which form so valuable a feature in our *Journal*. I have, however, I think, said enough to show that the fact of not possessing an observatory or instrumental equipment is no bar to the accomplishment by competent members of work of real value to our Association, and to astronomical science generally. I have now finally to deal with the second section of the third of the three classes into which I have ventured to divide our members. This section, it may be remembered, consists of those who are commencing the study of astronomy. I will not call these members "learners," because that is really not a distinctive term. An astronomer devoted to his science never ceases to be a "learner" however eminent he may become, and, in fact, with the growth of knowledge comes inevitably the growth of the conviction that great as has been the progress of astronomical discovery we have as yet only touched the fringe of that great science whose possibilities are as limitless as space itself. Using then, for the want of a better, the term "beginners" to denote the class of members of which I am now speaking, I wish before concluding this address to offer a few remarks on the manner in which I consider that the study of astronomy can be most advantageously commenced. . . . . I trust that the remarks which I am about to make on the commencement of the study of astronomy will not lead anyone to suppose that I in the least underrate the value of the numerous popular works on our science, or the admirably illustrated magazine articles dealing with astronomical subjects, of which so many have appeared during recent years. On the contrary, I believe such books and articles have done great good, and have, by the interest they arouse, caused many additions to be made to the ranks of amateur astronomers. But the beginner who, wishing to study astronomy, confines his attentions solely to such writings as I have just referred to is much in the position of a man who thinks he can become a soldier by reading glowing accounts of hard-won victories. Such a beginner, who has had his imagination stirred by the examination of beautifully reproduced photographs of comets, or nebulæ, or lunar views, is apt to experience more or less severe disappointment when he is shown these objects through a telescope of moderate size. Not having had experience in observing, he misses much detail which even such an instrument can show, and realising how far what he sees falls short of what he had been led to expect, he is apt to jump to the conclusion that observational astronomy, at all events, offers few attractions to those who have not at command an expensive instrumental equipment. Now, this conclusion is an utter mistake—a fact which the beginner who approaches the study of astronomy in the proper spirit will soon recognise. It has to be borne in mind that, great as are the attractions of modern astro-physical research, the real basis of our science is that which is sometimes called, by way of distinction, "gravitational astronomy." It has, further, to be borne in mind that the earlier astronomers working with instruments of a very elementary kind obtained a considerable knowledge—which was in many respects really remarkable for its approximate accuracy—as to the motions of the heavenly bodies, and as to the phenomena presented by the chief members of our Solar System. Now, what was done in the olden times can be done in the present day; and I wish to prominently direct the attention of beginners to the fact that by the employment of quite simple apparatus they may make observations which will bring home to them, in a way which mere reading can never do, a knowledge of many astronomical phenomena which they will find to be, not only of immediate interest, but of great value to them in their further studies. What I wish to urge, therefore, is, that those commencing the study of astronomy should not be content with reading only, but should work in the open air, faithfully and systematically recording their observations, however elementary these may be. I lay great stress on this latter point, because unrecorded observations have, as a rule, little educational value. The mere fact of describing in writing any observation, however simple, which has been made, is of immense assistance in securing completeness and accuracy. . . To the beginner who has thus taken up the study of celestial motions an endless number of problems will suggest themselves for examination, and it will be found that the solution of these problems will afford work which is not only of great immediate interest, but will lead to the acquirement of knowledge of considerable future value. It has been often said that "learners should not be ashamed to ask questions." This is quite true in a certain sense, and no beginner should be ashamed to acknowledge that he has much to learn. But the practice of asking questions is not one to be advocated, except within certain strict limits. The beginner who immediately he gets into a difficulty asks for aid to get out of it, is not likely to make any great progress. It is the battling with difficulties, the habit of regarding a problem from various points of view, and the practice of "getting at the bottom of things," which impresses truths and principles on the mind, and a few facts so learned are worth ten times the number acquired by the question and answer method. The statement I have just made appears to me to apply with special force to the use of instruments. Many present have no doubt been struck, as I have, by the character of numerous queries respecting the use and adjustment of instruments which, from time to time, appear in print. These questions suggest the idea that those proposing them are of opinion that scientific instruments should be made on the "You-touch-the-button-and-we-do-the-rest" principle, and that their employment should require no special knowledge on the part of the user. Now, this is a frame of mind which is much to be deprecated. Nothing is more essential to secure the best results with any instrument than a clear comprehension of the principles on which such instrument is constructed. It is only by the possession of such knowledge that the user of a telescope, a spectroscope, or other astronomical appliance can determine whether or not any defect in performance is due to a radical fault in such instrument or to a comparatively trivial fault in adjustment. For this reason I would thoroughly urge beginners, when they take up actual observing, to study carefully the theory of any instrument they may employ, and make themselves familiar with its principles and construction. Were this more generally done, much disappointment and loss of time would be saved, and instrument makers would be spared many unjust complaints and much worry. I am afraid that my remarks on the section of our members which I have classed as "beginners," have run to an undesirable length; but it must be remembered that the "beginners" of to-day are those from which we shall at an early date expect work which will promote the interests and strengthen the position of our Association, and any suggestions which may aid in their training may thus possibly be regarded as excusable. In conclusion, I may quote a passage from the works of Bacon, which was written to have a wide significance, but which appears to me to apply with peculiar force to the science to which we are all devoted. Says the great philosopher: "Knowledge is not a couch whereon to rest a searching and restless spirit; nor a terrace for a wandering and variable mind to walk up and down with a fair prospect; nor a tower of state for a proud mind to raise itself upon; nor a fort for commanding ground for strife and contention; nor a shop for profit or sale; but a rich storehouse for the glory of the Creator and the relief of man's estate."

Mr. Maunder was sure there was only one feeling amongst all the members present, and that was one of very great gratitude to their President for the address he had just given them. They had been greatly indebted to Mr. Maw from the very foundation of this Association, for he had undertaken the charge of its finances from the first, and although, of course, the money side of an undertaking of this sort was not the highest, yet one thing was perfectly certain—that if such an association were not financially sound, its usefulness would very soon come to an end. Consequently, they were deeply indebted to Mr. Maw for having kept them from the beginning upon a sound financial basis. Mr. Maw had not only carried out the ordinary duties of a treasurer with extreme diligence and faithfulness, but had added a variety of other duties to it far more numerous than he (Mr. Maunder) could describe. Only those who had been behind the scenes could tell how much of the actual work of the Association had been done by Mr. Maw himself. It had been a rule amongst them from the beginning, when in any difficulty whatever, to go to Mr. Maw and have it cleared away. And now they had had from Mr. Maw, as their president that evening, a most helpful address upon the position and prospects of the association, and he (Mr. Maunder) hoped that address, when it reached the hands of the members, would be carefully read, and the advice contained in it taken heed of and adopted. They had had in the past nine years a most gratifying amount of success, but there was no reason why they should not have a great deal more in the future. Nor was there any reason why what many of them felt to be somewhat weak places should not be strengthened, why their various sections should not be doing a great deal more work even than they were doing, and why the membership should not develop much more even than it had in the past. If they paid good heed to the address which Mr. Maw had delivered, he thought very much of that would be seen in actual practice. Mr. Maunder concluded by moving that a very hearty vote of thanks be accorded to the President for his address.

The vote was heartily accorded.

The President, in acknowledging the compliment, said he had only done what all the other members of the council, the secretaries, and the directors of sections had done. He thought that without any self-glorification he might say they had all worked very hard for the association. Good work had been done by the council right away from the beginning, and they had always worked together very harmoniously, which was a great point. They had all done their best for the Association, and he had certainly done no more than anyone else.

Mr. Maunder read a paper by Mr. Cecil J. Dalmage on "The Apparent Enlargement of Heavenly Bodies when in the Neighbourhood of the Horizon." The writer referred to the fact that

many attempted explanations of the phenomenon had been offered from time to time, and desired to add yet another. He pointed out that if an observer looked up towards the zenith and considered the expanse of sky presented to his gaze, he would notice that it contained practically no trace of curvature. This was evidently because his field of view was not extensive enough to include any appreciable portion of the dip of sky towards the horizon. If he lowered his eyes gradually towards the horizon he would notice that on account of the dip of the sky in front and, particularly, on either side of him coming more and more into the field of view, the plane heaven which he had just been looking at would little by little assume an appearance of concavity, this appearance of concavity rapidly increasing and finally reaching its maximum when the gaze was directed to a point on the horizon. Pointing out the effect this change would have upon a definite portion of the sky as seen by an observer, Mr. Dolmage said it must be clear to anyone who for a moment considered the matter that the distance between markings upon a plane elastic surface would be increased in proportion as the plane was bodily hollowed out so as to assume a concave shape, the boundaries of the plane being always preserved at the same initial distance from each other. This gave the clue to what took place when an observer viewed the heaven. The eye, looking zenith-wards, perforce considered the expanse as a plane; then, as the gaze was lowered, and the dip around the sky towards the horizon came increasingly into view, the eye unconsciously considered this plane as gradually becoming more and more concave towards it. Therefore the total area of the field of view of sky (regarded chiefly in its lateral extent), and, in consequence, the area of any definite portion of it, was considered as having enlarged.

Mr. Maunder said that some years ago a Belgian astronomer, M. Stroobant, made a number of experiments with pairs of electric lights in a large dome. He had a pair of electric lights put overhead, and another pair at the same distance from him against the wall, and then he had the two altered in distance until to him they seemed as if they were the same distance apart; then, measuring, he found that this same apparent expansion of objects looked at straight forward on the horizontal plane took place with regard to the electric lights as held with regard to the stars: the distance apart of the pair of lights before him seemed exaggerated, that of the pair above him seemed diminished. He regarded it, therefore, as purely and entirely a physiological effect, due to something connected with our ordinary upright stature, so that when looking straight ahead an object looked very much larger, at the same distance, than it did when overhead.

Mr. McCarthy remarked that the effect alluded to by Mr. Dolmage was one upon which an explanation was reasonably asked. The only answer which it was possible to give at present was that they did not know. In order to obtain information on the subject, the librarian of the R.A.S. had looked through a large number of articles which had appeared in the ENGLISH MECHANIC. He found a series of suggestions to account for the apparent enlargement of these celestial objects on the horizon, and their corresponding diminution at the zenith. The suggestions made in some cases were that this was caused by the atmosphere, one writer endeavouring to show that the effect observed would be apparent, supposing the atmosphere surrounding the earth could be regarded as a huge crystal; in looking along the horizon they looked through more of it, and in looking to the zenith they looked through less. Of course care had been taken not to confuse this effect with that due to refraction. Another group of writers pointed out that it had been suggested that the effect arose from a comparison with objects on the earth, and seen against the sky. The complete refutation of that suggestion was arrived at by making the observation on the ocean, where the constellations appeared wider apart and the moon and sun appeared larger when near the horizon and gradually diminished in size as they approached the zenith. It was also said that when they took a hollow tube and looked through it at the sun (or the moon) just after it had risen, its apparent magnitude sank to the ordinary magnitude of the sun when seen at the zenith. He tried this, and found that when he shut one eye and looked through the tube the moon always looked smaller; but if he viewed the object with one eye when it was at the zenith it looked smaller than if he used both. Consequently he took two tubes and looked at the moon carefully night after night with both eyes and found the tubes made no difference whatever. The suggestion was that these tubes cut off the view of the surrounding objects, and confined the vision to the moon when rising, and then, of course, the moon was sure to appear as it did at the zenith. He found that would not stand the test of so simple an experiment. He would suggest to all interested in the science of astronomy—that a certain amount of attention should be given to this question to see whether a satisfactory conclusion could not be arrived at with regard to it. If, however, the explanation suggested by Mr. Dolmage could be taken as reliable, then the alteration in the position of the person observing, from standing up to lying down, would entirely overcome the difficulty. But that had been tried many times, and every attempt to alter the position had failed to remove the apparent difference. If the effect arose from the construction of the eye, then the atmosphere might be entirely removed without altering the effect, which, to say the least, was doubtful. He quite understood the suggestion that there was a wider vision taken in by the eye when looking towards an object on the horizon; but he had explained previously that a person altering his position found the object just as much enlarged or diminished in appearance whatever the position of the observer.

Mr. W. H. Wesley said Mr. Dolmage's explanation was somewhat similar to the well-known suggestion that the celestial vault does not appear to us as half a hollow sphere, but as an ellipsoid in form; so that it is apparently much nearer to us in the zenith than at the horizon. The question still remains: if it is due to an illusion of this kind, is the illusion optical or mental? He had tried the experiment of turning his head downwards, and looking at various objects in this position. They all appeared the same way upwards as they are in reality; but if he looked at a page of a book in the same way, that appeared to be upside down. This seemed to show that what at first sight seemed an optical effect was really a mental one. He was inclined to think that the cause of the apparent difference referred to was mental rather than optical.

Mr. E. M. Nelson suggested that it would be a good plan to photograph the moon at the zenith and on the horizon. There was no possibility of refraction cheating the photographic eye. Most of them were photographers, and everyone would have noticed in photographing a cliff with a lens 10in. focus how very much dwarfed the cliff appeared in the negative when developed. He thought the phenomena were identical.

Mr. T. Clapton, referring to the suggestion as to photographing the moon or sun, said the result would be more accurately arrived at by measuring the disc with a sextant. That had been done over and over again, and the diameter was just the same whether the object was at the horizon or the zenith. It seemed to him that the whole thing was a matter of mental perspective. Let them measure 40ft. on the ground and see how little it looked; yet that was a respectable height for a house.

The President remarked that the apparent enlargement was vertical as well as horizontal. Anyone watching the rising of Castor and Pollux could see this. That, he thought, was the most striking instance that existed in the sky.

Mr. Clapton said the fact remained that, measuring the angle with the sextant, it would be the same in every position, except that the upright angle would be affected by refraction.

Mr. L. B. Tappenden mentioned what he considered a cognate illustration. If a person went out of doors on a starry night, and fixed on a star which he assumed to be at an elevation of 45°, and afterwards took the measurement of the angle, he would find, as a rule, that the elevation was considerably less. If he took two stars which he thought to be at an elevation of 30° and 60°, he would find the 30° was considerably less, and that the 60° was also less, though not quite so much. He thought these mental illusions were very cognate.

The President said 60° was a most deceptive angle. Anything at 60° looked very much higher than it really was.

Mr. Maunder said the sun and moon had, of course, often been photographed at almost every conceivable altitude above the horizon, and the only difference in the diameter of the photographs was that due to refraction, the effect of which, of course, compared with the apparent difference now under discussion, was quite negligible. For instance, on the solar photographs taken at Greenwich, after correcting for the distance of the earth from the sun and for refraction, they got just the same diameter in midwinter as in midsummer. The photographic plate, therefore, knew nothing whatever of this enlargement near the horizon. It struck him that M. Stroobant's explanation might be tested by the simple experiment of looking at the rising or setting moon, when lying on one's back with the head towards the moon. If the suggestion of that gentleman were correct, it would seem that the rising moon, when so viewed, should appear to be of the same diameter as it ordinarily appeared to be at or near the zenith. M. Stroobant's experiment seemed to show that the effect had nothing to do with the atmosphere, because he conducted the experiment in a building and had his electric lights, those on the level and those which were overhead, both at the same distance from him.

The President remarked that the discussion was an interesting one; but he did not think they had got much nearer the explanation than they were before. With regard to refraction, he might point out that the effect of refraction would be to tend to decrease the distance between any objects situated one above the other, as was the case with Castor and Pollux, and the lower star would be raised more than the other.

Mr. Petrie read a paper by Mr. Edwin Holmes, being a sketch of the life and work of John Bird, who in the early part of this century visited nearly every town in the kingdom as a lecturer on astronomy. Concluding his paper, the writer said, "Mr. Bird, apparently, may never have possessed an astronomical telescope, or entered an observatory. His observations were upon wooden orbits and tin stars and planets, which troubled him not with vagaries of definition. He never found any canals on Mars or Venus, or elongated the satellites of Jupiter. He never divided double stars one-tenth of a second apart with 6½in. Gregorians, or other telescopes of that aperture, as three anonymous observers have done of late. He may not have framed any theory of the colour of Martian vegetation, or of the varying intellectual capacities of the inhabitants of that and other planets, but he did such work as was within his scope—such as lay next his hands—and enlarged the ideas of many thousands about the phenomena of the heavens, who, but for him, would have had no conception that the twinkling lights of the midnight sky were of any more importance than the moving discs upon his calico screen produced by Mr. Bird for their instruction."

The President said they were much indebted to Mr. Holmes for this interesting piece of history. Mr. Holmes had rescued it from pages which doubtless they would never have seen.

ROYAL MICROSCOPICAL SOCIETY.

AT the last meeting (Mr. E. M. Nelson, President, in the chair), the President called attention to an old microscope made by Cary, presented to the Society by Mr. Gleadow, which was a very interesting addition to the Society's collection. An instrument of the same design was figured in the *Journal* for 1898, p. 474. Messrs. Watson and Sons exhibited their new School microscope, which was provided with a diagonal rack-and-pinion coarse adjustment, but no fine adjustment; their idea being to produce a strong well-made instrument at a low price. Dr. Dallinger had seen this instrument, and thought it would admirably answer the purpose for which it was intended; the coarse adjustment was so well made that he had no difficulty in focussing a ⅙in. objective with it. The President thought the microscope was strongly made and well fitted, and would be found to be a very useful instrument. Messrs. Watson also exhibited a new form of eyepiece named the "Holoscopic" which was fitted with an adjustment to render it either over- or under-corrected, and suitable for use with either achromatic or apochromatic objectives. Dr. Measures exhibited a microscope for photo-micrography made by Zeiss, having a new form of fine adjustment which admitted of the arm being made of any length without throwing extra weight upon the fine-adjustment screw. Dr. Dallinger considered the way in which the speed of the fine adjustment had been reduced was most ingenious; the motion was extremely slow, being only $\frac{1}{315}$in. for every revolution of the screw. A protest had always been made in the Society against the fine adjustment having to carry much weight, and it was therefore satisfactory to to find that this one had only one-fifth of the weight usually put upon the fine adjustment. The President said the application of an endless screw was a novel way of slowing down the fine adjustment. The reduction of weight upon the thread was an important improvement, and the increased length of arm was another good feature. The President then described a new form of fine adjustmunt by Reichert, which was shown applied to his "Austrian" model, exhibited by Mr. C. Baker. The indicator to this fine adjustment was movable so that it could be set to zero when required, thus greatly facilitating the reading of the divisions on the head of the screw. The instrument was fitted with the English standard substage, and the axis of the trunnions was placed above the stage to insure a better balance. Two other microscopes by Reichert were also exhibited, one being a student's, without fine adjustment, but fitted with a dissecting loup as a substage condenser. The President next showed a microscope fitted with his new stepped rackwork coarse adjustment by Messrs. Watson and Sons. There was no loss of time, though the pinion was pressed but lightly into the rack. The President also exhibited a dissecting stand by Andrew Ross, which was about 40 or 50 years old, and was still a thoroughly good working instrument, and though the lenses were not achromatic they gave very good images. Mr. C. Lees Curties exhibited some stereoscopic photo-micrographs taken on the Ives principle by Mr. E. R. Turner, who briefly described the method of taking them. Dr. Hebb said they had received Part VI. of Mr. Millett's report on the Foraminifera of the Malay Archipelago, which would be taken as read and published in the *Journal*. Mr. F. Enock gave an extremely interesting account of his observations on the life-history and habits of the British trapdoor spiders, illustrating the subject by most excellent optical lantern views.

SCIENTIFIC NEWS.

THE new planet Eros, the nearest to the earth, although numerous observations are now available, seems to puzzle the skilled calculators of orbits; but in *Ast. Nach.*, No. 3597, Herr H. Osten, of Bremen, gives provisional sets of elements, which, however, vary considerably.

Someone, advising Reuter from Santiago, Chile, states that Biela's comet has been observed, and is visible to the naked eye. It is not probable that the object seen was Biela's comet, which has not been identified since 1852.

The Rev. Edward Lyon Berthon, M.A., F.R.A.S., late vicar of Romsey, died on Friday last in his 87th year. He was the inventor of the Berthon collapsible boats. Mr. Berthon was educated at Magdalen College, Cambridge, and was ordained deacon in 1845 and priest in 1846 in the diocese of Winchester. He was perpetual curate of Holy Trinity, Fareham, from 1847 to 1857, and vicar and rural dean of Romsey from 1860 to 1891. He did much to restore the ancient Abbey Church of Romsey. The deceased was well known by his works throughout the civilised world, for, besides his collapsible boats, pontoons, &c., he made several useful inventions in connection with astronomical instruments, and constructed some notable telescopes, amongst others an 18in. reflector for the late Rev. Cooper Key, and a smaller one for the late Rev. T. Webb. The Berthon observatory is well known to all our readers, as is also the Berthon dynamometer. At the beginning of this year, Mr. Berthon published "A Retrospect of Eight Decades," a notice of which will be found on p. 146, March 31 last.

Prof. Edward Orton, president of the American Association for the Advancement of Science, died suddenly of heart disease at Columbus, Ohio, Oct. 16. He had been state geologist of Ohio for the last fourteen years, and for a number of years was president of the Ohio State University. He resigned the latter position in 1881, but remained professor of geology, a science in which he attained an eminent reputation.

Dr. John Thomas Arlidge, the author of numerous well-known medical works, died at Newcastle-under-Lyme last week. Dr. Arlidge, while medical inspector of factories in the pottery districts, first drew serious attention to the evils in the lead processes, and the public agitation which followed ended in the framing of special rules. He held among other medical degrees that of M.D. of London (1867), and was physician of the North Staffordshire Infirmary. His best known work is "The Hygiene, Diseases, and Mortality of Occupations," delivered at the Royal College of Physicians as Milroy Lecturer.

The death is announced by cable of Mr. Otthmar Mergenthaler, at Baltimore, Maryland, the inventor of the Linotype machine, the first patent for which was, we believe, taken out in 1884.

The late Lord De Tabley, besides being a numismatist of no mean order and a collector of book-plates, was a botanist and collector of dried plants. His "Flora of Cheshire," published recently, proves beyond a doubt his skill as a botanist and his intimate acquaintance with the flora of the district. It is not generally known, however, that he had an entire collection of the whole British flora, comprising some 20,000 sheets of specimens. This herbarium, which completely filled three of the rooms in his London house, 62, Elm Park-road, has been generously given by his sister, Lady Leighton, of Tabley House, Knutsford, to the Science and Art Museum, Dublin, and the Keeper of the Herbarium, Prof. Johnson, D.Sc., considers that it will form a very valuable acquisition to the Museum. Lady Leighton has also met the cost of remounting and labelling, and each specimen bears the name of the genus, species, and locality, besides the name of the collection.

In a presidential address delivered at the Birmingham and Midland Institute last week, Sir J. Evans, F.R.S., said that forty years ago the almost universal belief of those who had but superficially approached the question was that a literal interpretation was to be placed on the opening chapters of the Book of Genesis, and that the chronology of Archbishop Usher and others in fixing the creation of man at the year 4004 B.C. was beyond all reasonable question. It was not until 1859, when the subject was investigated by the late Sir Joseph Prestwich himself, and others, that the presence of objects of human workmanship in association with the remains of extinct mammals in beds of gravel, sand, and loam was almost universally regarded as an established fact. The long-continued studies of Mr. Joseph Landon, of Saltley College, Birmingham, had resulted in his discovery in the gravels of the valley of the Rea of an implement of the same general type as those from many other valley gravels in England and France, but formed from a brown quartzite pebble, and not, as usual, chipped out of flint. If further discoveries of this kind were made, our present views as to the northern limits of the existence of such implements would have to be materially modified, and the area over which discoveries of this character were made might be considerably extended. Assuming that the occupation of the earth by man had been continuous, there must at some time or other have been a transition from the palæolithic stage of culture to the neolithic, but of such transition little trustworthy indications had as yet been found, and over a great part of Europe, at all events, there appeared to be "a great gulf fixed," which at present it was impossible to bridge over in a satisfactory manner.

A memoir has been presented to the Paris Academy of Sciences by M. Henri Moissan on the production of ozone by the decomposition of water with fluorine. A current of fluorine was passed rapidly into water which was at the freezing point, and the oxygen set free was analysed and found to yield a percentage of ozone, on some occasions reaching 14 per cent. The ozone was said to be practically pure, and may possibly be useful in some manufacturing processes, as it can be produced (most probably) at a low price.

The report of the Committee of Council on Education for England and Wales has been "presented to Parliament," and is not without historical interest. In April next the new Board of Education will come into existence, and will absorb the functions of the Education Department and of the Department of Science and Art.

The whaler *Esquimaux*, which was purchased last year by Mr. Andrew Barclay Walker, of Liverpool, has returned to Dundee from a successful trip to the Arctic regions. Mr. Walker and his party joined the vessel at St. John's, and she sailed thence for Davis Strait in April. The party have brought home a quantity of gold quartz, the value of which remains to be determined, but it is believed to be "rich."

According to M. A. Debierne, in a communication to the Paris Academy of Sciences, a new radio-active substance has been discovered in pitch-blende, differing from polonium and radium, and not spontaneously luminous. The rays emitted are stated to be about 100,000 times stronger than those given off by uranium.

A conversazione of the Geologists' Association is to be held in the library of University College, Gower-street, W.C., this evening.

The discussion about the poisonous properties of yew-leaves and shoots, so far as horses and cattle are concerned, continues; but so far the conclusions are not definite. It is stated in most of the textbooks of botany and vegetable physiology that yew-leaves contain a toxic principle injurious to some animals, and Gilbert White stated positively that they were certain death to cattle. Taxine, which is probably the toxic alkaloid, was obtained by Marmé in 1876.

Payta, in Peru, is said to be the driest spot on the face of the earth, as the "average interval between two showers is seven years." "The flora of Payta consists of about nine species; of these seven are annuals, the seeds of which must remain dormant in the ground for eight years. Notwithstanding the scarcity of rain, the natives subsist by the growth of the long rooted Peruvian cotton, which is able to maintain itself without rain for seven years in the dried-up river bed, and yields profitable crops of the coloured short staple cotton, which is used as an adulterant for wool." Travellers' tales must be taken with "caution." Possibly some of our correspondents can give information about this district, which is in about 5° south of the Equator, it is explained—which seems somewhat superfluous.

The exploration of Mount Kenia, in British East Africa, seems to have been thoroughly accomplished by the expedition which left England for the purpose last June, and the leader (Mr. Halford Mackinder, reader in geography at Oxford) is now on his way home, and may be expected to reach London shortly. The work was one of danger as well as difficulty, for the natives were decidedly hostile.

At the opening meeting of the Institution of Electrical Engineers on the evening of Thursday, Nov. 16, the premiums awarded for papers read or published during the session 1898-99 will be presented, and the President, Prof. Silvanus P. Thompson, will deliver his inaugural address.

MM. Jean and Louis Lecarme, in a memoir presented to the Paris Academy of Sciences on some experiments in wireless telegraphy carried on between Mont Blanc and Chamounix, state that the signals were not interfered with by the ice nor by the absence of water in the soil. Atmospheric electricity was without effect, but whilst the electric light was in action at Chamounix it was impossible to signal.

Lieut.-Col. G. F. R. Henderson, in the November *Blackwood*, makes some interesting comparisons between the battles of to-day and those of years ago. The former, he says, differ as much from the latter as did those of Alma and Inkerman from Flodden Field. The quick-firing field-gun, sweeping the ground with a hail of 1,500 shrapnel bullets at the rate of five aimed rounds a minute, is as far superior to the smooth-bore cannon as the smooth-bore cannon to the catapult. A few machine-guns would have destroyed the massed batteries of Napoleon before even the limbers were unhooked. High-explosive shells have turned walled cities into veritable death-traps. The new powder has entirely altered the aspect of the battlefield. The assailant is shrouded by no friendly veil of smoke, and all open ground is covered by the fire of unseen defenders to a distance outside the limits of accurate vision. Nor have auxiliary appliances failed to make corresponding improvement. Balloons, become a component part of every army, have but little in common with the clumsy machines used a century since at Fleurus. Signalling, by flag and heliograph, supplies a means of communication which renders tactical combinations far simpler than in the days of Wellington. The telegraph, annihilating distance, has so altered the relations between time and space, that principles of strategy which have held good since the campaigns of Alexander are no longer applicable; while railways, pontoons, steamers, and compressed food-stuffs have greatly lightened the difficulties of supply.

It would appear, says the *Athenæum*, that the authorities at the Patent Office Library do not keep their copies of the *Proceedings* of the Royal Society up to date. The last number available was issued as far back as January 23rd, 1899, thus leaving a blank of thirteen numbers, almost a whole year's scientific record. The Science Library located at South Kensington Museum is scarcely more helpful as a centre of reference. Here bound volumes are purchased, and as these only appear at intervals, it follows that the library is always a good deal behind the numbers published in separate form.

Some curious patents are granted in the United States; but one recently issued to Gustaf M. Westman, of Broadway, New York City, will attract some attention, for it is stated to be the "application of a new physical principle to engineering." The "title" is a "Method of and Apparatus for Generating Power," and is briefly described as follows:—"The operation of the motor involves the free expansion of the motive fluid. Free expansion is the condition of the fluid in which it can expand to the surrounding pressure without doing any work or putting other bodies in motion. In such condition the velocity of the fluid is increased; but when putting other bodies in motion, the fluid necessarily loses velocity proportionate to that acquired by the body set in motion; consequently the fluid loses power or ability to expand, and its temperature cannot sink as low as it would have done if no body had been put in motion. This may be regarded as the application of a physical principle to engineering."

IT is stated that the deepest oil-well in America is situated in the Monongahela River Valley, about 25 miles from Pittsburgh. The hole has been drilled to a depth of 5,532ft., but work has been suspended owing to a break in the 2¼in. rope used. As a result 1,000ft. of rope and a string of tools are at the bottom. Experts are at work, and hope to be able to resume drilling soon. It is proposed to sink the well 6,000.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

THE MOON AND THE WEATHER—A POPULAR OBSERVATORY—SEA-SICKNESS—STEREOSCOPIC VISION—RAINBOWS: OR HALOES—REFRACTION — MOUNTAINS QUAKING—BLAIR'S FLUID OBJECT-GLASS—SUN VIEWS BY DIAGONAL PROJECTION — DRAWING AN ECCENTRIC ELLIPSE — TIDES — TWELVE-HOUR DIURNAL ARC—NUMBER OF COMETS IN THE SOLAR SYSTEM — STARS ABOUT ε LYRÆ AND VEGA—PARALLAX OF 61 CYGNI—THE "VESTIGES OF CREATION" — EVENING AND MORNING IN A NEBULA — MEAN TIME DIAL—LIGHTING THE FIELD OF A TRANSIT INSTRUMENT.

[42973]—THERE are few, if any, greater authorities on meteorology than Prof. Hazen, and hence his paper on "The Moon and the Weather," which you reproduce on p. 227, is deserving of the most serious attention, exploding, as it does, one of the most widely-extended superstitions in connection with atmospheric changes. Over and over again in these columns have I insisted that the moon has *nothing* to do with the weather, and now I have one of the first meteorologists in the world not merely repeating my allegation, but giving irrefragable scientific facts and statistics in support of it. Not, by the way, that this will influence your genuine lunatic. A most valued friend, who was almost a second mother to me, would listen patiently to my exposure of the nonsense about the (so-called) "changes" of the moon and the weather, and would answer: "Yes, my dear, all you say is absolutely true—but I shall go on believing it all the same." An intellectual attitude I am afraid assumed by a good many others besides dear old Lady S.

All honour to the Lincolnshire men, who (as you state in your "Scientific News" on p. 229) have consented to the erection of a public observatory in Lincoln Castle; but, merely as a matter of course, that observatory will have to be endowed, and the amount of capital to be sunk to provide adequate remuneration in perpetuity for a competent astronomer must of necessity be very considerable. I seriously doubt if such a sum can be raised—for such a purpose—by public subscription, and I don't know what the rank and file of the ratepayers will say if any future demand is made upon the rates. Perhaps, though, this has been provided for in some fashion not at present apparent.

Your announcement of the death of Admiral Colomb, on the same page, reminded me that on the final trial of the Bolton and Colomb system of flashing signals prior to their adoption by the Admiralty and the War Office, he and I were together on board H.M.S. *Pigmy* which went out from Portsmouth nearly to Cherbourg, exchanging signals with a station on the top of St. Catherine's Down in the Isle of Wight; and that on going up on deck after mess, Admiral (then Captain) Colomb was, to use a vulgar phrase, "as sick as a dog." Considerably astonished, I said to him, "Why, bless my soul! this is your bread and cheese; are you sick when barely out of sight of land?" To which the answer was, "If I am at sea for six months, I am ill every day." Nothing, I venture to think, could show more forcibly than this how purely constitutional, and, if I may so say, idiosyncratic, sea-sickness is, and how fallacious any universal remedy for it must be. By the bye, an uncle of my own in the Navy was always ill every time his ship was fresh commissioned; but, then, that was only for the first day at sea.

My experience in connection with any single picture is identical with that of "Carlos" (letter 42947, p. 234). I think that anyone will find the stereoscopic effect of an oil-painting (say at such an exhibition as that of the Royal Academy) materially enhanced by viewing it with one eye only.

In reply to Mr. Harman (query 96879, p. 237), I did not observe the rainbows to which he refers on October 11. having been occupied as a member of a County Licensing Committee in confirming (or refusing to confirm) licenses, at the hour he specifies. Moreover, I doubt if the particular phenomena he describes were visible at any distance from Tunbridge Wells. Such bows as he describes have their origin in reflection from, and refraction through, the spicules of ice in the cirro-stratus clouds between 20,000 and 30,000ft. above the surface of the earth. I assume that he understands how an ordinary rainbow is formed, and how purely local it is.

If I were to work out the pretty little calculation set me by "Miner" (in query 96880) on p. 237 in detail with rigid accuracy, I should have a very nice morning's work indeed before me. I trust, however, that the following formula will furnish him with what he requires:—

Call the star's zenith distance z, and 57″ × tan. star's zenith distance r; h, the height of the thermometer (Fahrenheit); b, the height of the barometer in inches. Then the refraction, which we will call—

$$R = 57'' \times \frac{b}{29\cdot6} \times \frac{400}{350 + h} \times \tan.\ (z - 3r) \text{ nearly}$$

In the example given for solution this becomes—

$$R = 57'' \times \frac{24\cdot3}{29\cdot6} \times \frac{400}{385} \times \tan.$$
$$[75^\circ\,20' - (3 \times 3'\,37\cdot79'')]\text{—i.e., } \tan 75^\circ\,9'\,6\,64''.$$

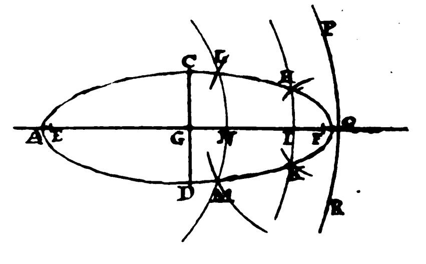
If "Miner" will calculate this out, he will find that with the data he gives the refraction will be 3′ 3·38″ very approximately indeed. As he says nothing about dip, I assume that he obtains the altitude of his star (or other celestial body) by measuring the angular distance between it and its image, as seen reflected in an artificial horizon, and halving the quantity thus obtained, to determine its apparent altitude above his true celestial horizon.

Yes, "E. L. G." (query 96888, p. 237), we do read in Exodus xix. 18 (there is no 27th verse at all) that "the whole mount quaked greatly"; but any one who will read the Bible as he would another book, and will note what is previously said in vv. 12, 13, 16, and 17, will see that this "quaking" was confined to the mountain itself, a novel phenomenon in earthquakes! and that the whole occurrence is related as miraculous. Moreover, when (not "shortly," but) twenty years afterwards, "the earth swallowed up Korah and his company," it is again idle to speak of such an occurrence as an earthquake in any legitimate sense of the word at all. It must have been a curiously *eclectic* specimen of seismic disturbance.

"Curious" (query 96889, p. 237) has evidently come across a specimen which has been preserved of the long disused "fluid object-glass" invented by Dr. Blair during the last decade of the 18th century. He inclosed solutions of chloride of antimony and corrosive sublimate (diluting them with pure hydrochloric acid) between a plano-convex crown glass, and a meniscus of the same material so placed that their convexities faced each other and the solution formed a double concave lens. As for the value of such a thing nowadays, it has none, save that incident on its archæological interest and as a curiosity. I mean, of course, pecuniary value.

I do not possess Proctor's "Half Hours," and am hence unable to check or verify the quotation from that work professedly given by "E. G. R." (query 96891, p. 238); but surely there must be some extraordinary mistake about employing a reticle of lines ruled only $\frac{1}{200}$in. apart on glass. Such an arrangement might exhibit coarse diffraction phenomena; but would be utterly useless as a micrometer. I should think that Slade's micrometer, which is not a costly affair, might suit your correspondent. Any reticle arrangement placed between the lenses of a Huyghenian eyepiece in the focus of the eye-lens is accurate enough in the middle of the field, but not equally so at its edges. The Ramsden form gives a flatter field, Of course, in the latter case the ruled glass is outside of the field-lens. The question with which "E. G. R." concludes can only be answered categorically when the position of the diagonal reflector is known. Suppose, however, for the purpose of illustration, that it is used with an ordinary Huyghenian eyepiece, and that it is so placed as to cast the sun's image vertically downwards on to a sheet of paper, then (in north latitude) will the sun's north limb be at the top of the field, the south limb at the bottom, his east limb at the right-hand side, and his west one at the left. Hence it will be seen that the ultimate reversal will be in the direction of his diurnal motion only, and he will seemingly travel from right to left, or west to east, instead of from left to right, as he does when viewed with the naked eye.

As "B. B. M." (query 96896, p. 238) does not apparently possess an ellipsograph or "trammel," and seems to fail in describing a symmetrical ellipse with the old-fashioned pins and thread, I think that the method of description explained in Chambers's "Practical Mathematics" is as likely to insure what he wants as any one, and so copy it verbatim, with a very slight modification of its illustrative figure. The problem is "to describe an ellipse, having given its major and minor axes." Let A B be the major axis. Draw a line, C D, bisecting it perpendicularly, and make G C, G D each equal to half the minor axis; then C D is this axis. From C as a centre, with half the major axis A G as a radius, cut A B in E and F, and these points are the foci. Produce



A B to Q till E Q = A B; then from E as a centre describe an arc, P Q, and this arc is a species of directrix to the ellipse. With any radius E I, from E as a centre, describe an arc, H K, and, with the distance I Q as a radius from F as a centre, cut H K in H and K, and these are points in the curve. Describe from E as a centre any other arc, L M, and find as before the points L M. Proceed in the same manner until a sufficient number of points are found, and the curve passing through them—namely, A D C B—is an ellipse. I should unhesitatingly recommend "B. B. M." to obtain Moy's most ingenious patent ellipsograph, but for the fact that it can describe no ellipse whose major axis exceeds 1½in. in length.

It seems to me that "Fleur-de-Lys" (query 96899, p. 238) is to a certain extent creating his own difficulty. The times of high water given in the tables "at Full and Change of the Moon" are reckoned from *apparent* noon, and give the actual times of high water when the moon and the sun are on the meridian together; or the intervals between the times of the moon's transit and those of high water on full and change days.

Query 96914 (p. 238) is a curious one. A star which rises due east must be *on* the Equator, or have no declination, and will obviously remain 12 sidereal hours (= 11h. 5m. 2·04s. of mean time) above the horizon. I have excluded all notice of refraction, which is so curiously irregular on or near the horizon as to make a notable difference in the times of rising and setting of the stars and planets under varying conditions of pressure and temperature.

"D. B." (query 96915, p. 238) may rest assured that no one worthy for one instant of the name of an *astronomer* ever pledged himself to the monstrous assertion that there are at least 17,000,000 comets of all sizes in the Solar System. This is the veriest penny-a-lining, and destitute of the slightest atom of proof.

Has Mr. Ashby (query 96917, p. 238) no friend who could obtain a sight for him of any of the plates of the regions to which he refers, taken for the International Astrographic Chart and Catalogue? A comparison of these with Mr. Bassnett's chart and with the map (if such exists) of α Lyræ and its neighbourhood would show at once how far the alleged statements as to the number of stars in the vicinity of the respective objects are trustworthy or not. I have said above that I do not possess Proctor's "Half Hours," so in that matter must walk by faith.

I cannot answer the query put by Mr. Monck (in letter 42951) on p. 251 without a very great amount of research; research, moreover, for which I do not possess the materials in my own library. My data were derived from No. 3590 of the *Astronomische Nachrichten*, whence I roughly computed the position of the star, to whose use as one of reference for the determination of the parallax of 61 Cygni your correspondent so legitimately demurs. But it is pretty evident that Dr. Schur himself is not satisfied with his own results, as he proposes to reinvestigate the parallax of this particular object, the star *a* of my paragraph, *ab initio*.

Surely your "Subscriber," who wrote letter 42952, on p. 251, does not imagine that Hugh Miller wrote "Vestiges of the Natural History of Creation"? Why, I thought that by this time every human being who has ever read the book was aware that its author was the late Dr. Robert Chambers.

I had to complain (in letter 42896) on p. 184 of the disingenuous character of Mr. Garbett's polemics, and here I find him furnishing a fresh illustration of the truth of my charge in letter 42967, p. 254. "The 'F.R.A.S.'" he there says "is quite mistaken about the Nebula in Andromeda, which he tells us in p. 184, appeared in 1884." Now passing over, as a possible *lapsus calami*, the allegation that I ever made this idiotic statement with reference to the *nebula* itself, who was it who supplied me with the date of the apparition of the temporary sun which blazed forth in its midst in the '80's? Let us turn back to letter 42878, p. 159, where we shall find the infallible and

ominiscient Mr. Garbett himself saying "the new world that appeared in the Andromeda nebula in 1884"—and so on. In commenting on this (letter 42896, p. 184), I never for an instant dreamed of attempting to verify the *date* of the apparition as given by Mr. Garbett himself, because it was utterly irrelevant to the question at issue. I myself repeatedly observed the star as well as Mr. Maw did, and, although it was not situated absolutely centrally in the nucleus of the nebula, it was, to my eye, evidently immersed in it, and, this being so, it is idle to talk of even a dark body experiencing the phenomena of day and night, or evening and morning, when *surrounded by light*. However, as it was vividly self-luminous, and itself a sun, this really matters, for the purpose of legitimate argument, nothing whatever.

In reply to query 96941, p. 258, I quite fail to see how the dial suggested by "A. S. L." could be geometrically constructed—or, for the matter of that, mechanically either—owing to the inequality of the motion of the sun in the plane of the Equator. In using the shadow of a gnomon to determine time we must use the actual sun and apparent day, and your correspondent must know, e.g., that its length on, say, March 16, 1904, will certainly not be identical with that of March 16, 1899.

I think that if "R. A." (query 96947, p. 259) will get a plano-convex lens of 1in. or less in focal length, and insert it in the pivot of his transit instrument, with the convex face outwards, he will find the field fairly well lighted with the ordinary little bull's-eye lantern supplied with such instruments. Again, though, I must say that this is on the assumption that the diagonal reflector in the telescope between the pivots is in order, and has not become dull or scraped.

A Fellow of the Royal Astronomical Society.

COLOURS OF STARS.

[42974.]—A trained eye can no doubt see distinctions in colours which are not visible to ordinary persons; but the great difference of opinion between apparently competent observers as to the colours of particular stars leads me to think that imagination is not wholly inactive in the case. As to the five stars mentioned by Mr. Ellison in his letter 42948, on p. 251, last week, four of them seem to me to be white stars without the bluish tint which he mentions, save that a white star seems to me always to assume this tint when viewed with a high magnifying power. The fifth star, Rigel, however, seems to me always to exhibit this flash of blue, which is noticed by Mr. Webb. Mr. Ellison will find distinctions between the spectra of these five stars noticed by Miss Maury. Rigel belongs rather to the Orion type (the B of the "Draper Catalogue") than to the ordinary Sirian (A).

Of the four brightest stars (after Sirius) visible in this country, Arcturus, Vega, Capella, and Rigel, it is worth noticing that the "Harvard Photometry" places Arcturus first and Rigel last, while the "Oxford Photometry" exactly reverses this. Have the colours of stars any effect on these methods?

W. H. S. Monck.

OMICRON CYGNI—A PRETTY PAIR—NEW COMITES TO Σ 2707, AND 15 CEPHEI — THE RING NEBULA IN LYRA—THANKS.

[42975.]—Omicron Cygni is a fine wide object for a small telescope. o^2 is of mag. 3·7, and pale orange. The most distant of the two stars is o^1, and is of the 5th magnitude, and the nearer is 6·5 mag. Both these stars appear blue by contrast. Burnham has added several distant *comites*, which are lettered *b*, *c*, *d*, *e* in the diagram inclosed. On Sept. 20, 22, and 23, in bright moonlight, I re-examined this object, and noted one or two things which may be of interest.

The most distant star of the group, o^1 (which is too far away to be shown in the diagram) has a faint *comes* for which I got roughly the following:—

A B. P. = 251·8° D. 36·1″ Mags. 5, 13.

Burnham's *comes* *d* is itself double, which I estimated as—

$d\,d^1$. P. = 268°± D. 5″± Mags. 12·7, 14·0.

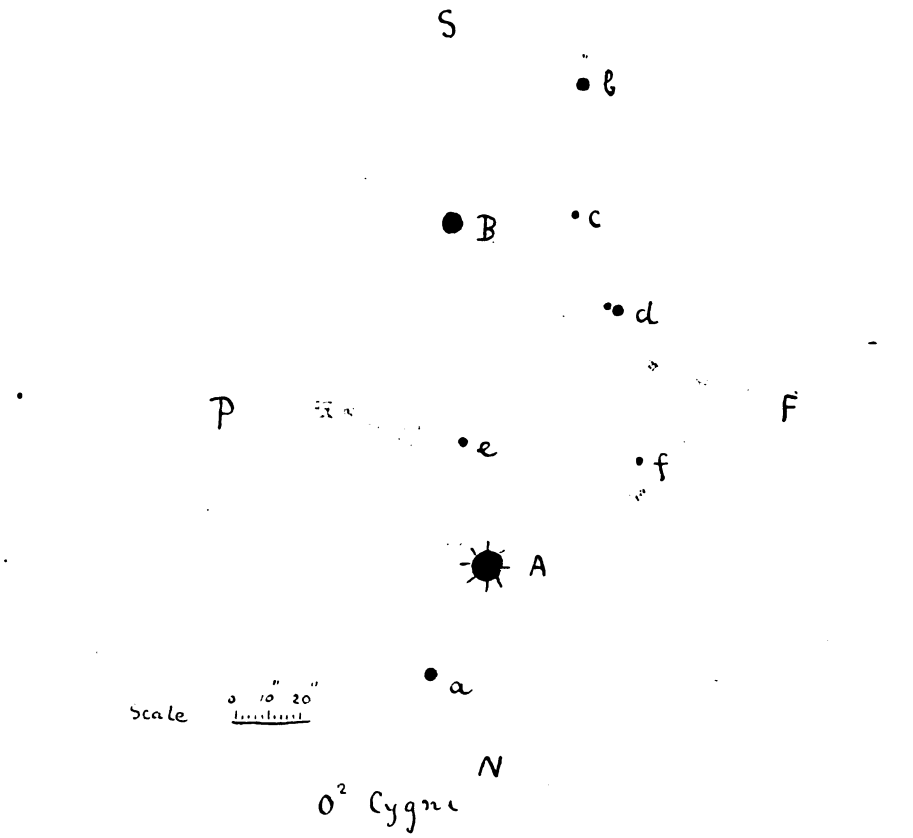
The following are the means of my estimates of the magnitudes of the small stars:—

a (Sm.'s companion)	11·8
b (β's companion)	12 0
c " "	13·8
d " "	12·7
e " "	13·6
f " "	14 3

There are several more distinct *comites*. Following A (0^2) by 39sec., and 3·8′ N. of it, is a pretty pair hitherto unrecorded, which I roughly measured as follows:—

P. 252·3° D. 3·6″ Mags. 10·0 10 3.

This star is B.D. + 46·2886°. The star Σ 2707, "Celestial Objects," p. 99, lies 0h. 24·1m. following, and 1° 9′ N. of 0^2 Cygni, and is a wide triple. Σ's mags.



7·1, 7·9, 8·6. I looked it up on Sept. 20, and found a minute star nearer than the Σ companion. I re-observed it on Oct. 19, when it was seen with difficulty, on account of the bright moonlight. I got the following results from the settings:—

A B (new).	P. 188·7°	D. 18″	7·1, 14
A C (Σ 2707).	31·0	22·5	— 8·0
A D. "	196·7	55·6	— 8·5

The star 15 Cephei ("Celestial Objects," p. 78) has a faint companion which was found by O Σ, and is O Σ 461, and rated by him as 10·6. While examining it on Sept. 22, I found a second and more distant companion. This was seen again on Oct. 19, but was so difficult in the moonlight that the attempt to measure it was a failure. I give the results, however—

A B.	P. 200·6°	D. 11·0″	6·0, 11
A C (new).	336·9	17·6	13·5

Some time ago a question was asked as to the magnitude of the little star *f*. the Ring Nebula in Lyra. I looked it up on Oct. 19, and saw it the same as I have always seen it. I should estimate the magnitude as 13·5. I have to thank various correspondents for their information concerning ε Lyræ. I have had several interesting letters privately as well. Had the object been examined on a dark night instead of in bright moonlight, perhaps the other stars mentioned by your correspondents would have been seen. **T. E. Espin.**

Tow Law, R.S.O., Co. Durham, Oct. 24.

METEOR.

[42976.]—A beautiful meteor was observed here on Oct. 25 at 10h. 8m. G.M.T., particulars of which follow:—

Path: 127° + 77° to 180° + 86°, length ± 11°.
Duration: 1·2sec.
Magnitude: Brighter than Venus.
Colour: Bluish-white.
Appearance: Brightness increased during flight; had a dense streak visible for fully three minutes, fading gradually to an irregular oval shape.
Probable radiant: Camelopardalis (47), No. XCII. in General Catalogue (Denning, 1899). Certainly not very far from its radiant.

Farnborough, Hants. **J. H. Bridger.**

PERPETUAL MOTION — TELECTROSCOPE—CALCULATING MACHINE.

[42977.]—I think "perpetual absurdity" would more correctly describe F. W. Baker's attempt, as well as the thousand and one previous attempts, to attain the impossible. As, however, he asks to be shown its defects, I will try to oblige him. So far as I can understand the machine, the ultimate object of all the links and levers is to induce the weight c^1 in descending from its position in Fig. 1 to its position in Fig. 2 to lift up the pendulum weight c^2 to the position in Fig. 2, whence in falling it drives back c^1 to its original starting point. On applying a scale I find that the descent of c^1 (measured vertically) is about the same as the ascent of c^2, and as these two weights are said to "counterbalance" each other, there can be no surplus force to overcome the inertia and friction of the moving parts. If the experiments referred to lead to any such conclusion as that mentioned, it may be taken for granted that some mistake has been made in carrying them out.

As to the telectroscope, I have a vague idea that I once answered a query about it; but I will give H. Mather a few particulars of the arrangement, as described in Szczepanik's specification, though I doubt whether the scheme has ever got beyond the stage of taking out a patent for it.

A ray of light from a small lamp in passing through a glass prism is decomposed into the primary colours, one only at a time being allowed to pass through an opening in an opaque screen. If, however, the prism be rotated on its axis, any colour at will can be sent through the hole in the screen. As H. Mather apparently knows, the conductivity of selenium is varied by letting light fall upon it, and thus the strength of an electric current actuating the mechanism that moves the prism is varied. It is here, however, that the fallacy appears to me to come in. Though the selenium is sensitive to variations in the *intensity*, there is no reason to conclude that it is sensitive to variations in the *colour* of the light, and, therefore, the assumed power to correspondingly alter the angle of the prism has no foundation in fact. There are other difficulties, such as the enormous rapidity of motion needed to build up a series of coloured dots into a continuous image, that help to render the idea impossible of attainment on the lines indicated.

I wish to strongly support the request for further particulars of Babbage's calculating machine. Though I have myself (in a manner) worked it, I could never follow out its action, more especially the way in which the connection was made from one line (or "cell") to those above and below it. Of course, it is possible to obtain a series of square numbers by adding a series of differences. Thus, taking the squares 1, 4, 9, 16, &c., their differences are 3, 5, 7, &c., of which latter series the difference is the constant number 2, and it is not difficult to imagine a mechanical method of dealing with such a case. It is also quite possible to design two curves which shall, in working together, produce the same result; but when it comes to higher powers than the square, or to intermediate values as in tables of logarithms, the problem necessarily becomes very complex. A clear description of how it is managed in Babbage's machine would therefore be very interesting. I think there is a mistake about the printing mechanism not having been attached to the calculating part, as I remember seeing pages of figures printed off from such an attachment, which may, however, have been merely a temporary arrangement. If I recollect right, some

of the printing showed white figures on a black ground.

As the result of a lawsuit, it was decided that the machinery and tools belonged neither to the Government that paid for them, nor to Mr. Babbage who designed them, but to Clements, the workman who made and used them. It would be curious to know what ultimately became of them. Is it not rather a fallacy to assume that a machine must necessarily make calculations more accurately than an ordinary computer? In working the machine, one movement of the handle too little or too much (a quite possible error) would entirely vitiate the result, without it being possible to discover that any such mistake had been made. Even a warning-bell may be wrongly fixed or fail to act. A. S. L.

MORE PERPETUAL MOTION.

[42978.]—In his letter 42965, Mr. F. W. Baker describes a perpetual motion machine, and asks the opinion of other readers with regard thereto. Having considered the letter with his accompanying sketch, it is, in my opinion, impossible to balance the weights C^1 with C^4 *in every position*, because whereas the former moves in a straight line, the latter moves in a circle, and this is fatal to his principle. Any arrangement I could think of to obviate this would result in the same objection turning up in some other form. Please go on, nevertheless, ventilating this fascinating subject. It is a grand and enjoyable hobby, and this striving will, I verily believe, sooner or later, be crowned with success.

The critics who talk about ignorance on the part of those endeavouring to produce a machine of this kind should reflect that a man working in this direction, and with such bent of mind, has, in all probability long passed the "elementary stage of applied mechanics," which is, after all said and done, merely the knowledge that by doubling the length of the lever you double the power half the distance, and vice versâ. J. H. Schucht.

THE WIMSHURST FOR X RAY "FACILE PRINCEPS."

[42979.]—Referring to p. 251 of your issue dated Oct. 27, as a subscriber of your paper since its commencement, I ask your permission to assure Mr. Bottone that he is not quite correct in stating that the Wimshurst is *facile princeps* as compared with the coil for X-ray purposes. He is probably aware that one important objection to the influence machine for X-ray work is the length of the exposure required owing to the very small ampèrage of the current. The thicker parts of the human trunk when an influence machine is used require an exposure of three-quarters of an hour, whilst a good coil takes only ten seconds. Mr. Bottone may have sent out from his works several hundreds of special X-ray influence machines; but I venture to object to his statement in regard to these being *facile princeps*.

The large number of E.P.S. Small Storage Batteries supplied by my company for X-ray work with coil during the past two and a half years is, I submit, a proof that influence machines are a considerable way from being *facile princeps* as compared with the coil and storage battery.

J. W. Barnard,
Sole Agent for Electrical Power Storage Co., Ltd.'s, Small Storage Batteries.

[42980.]—In addition to Mr. Bottone's letter respecting his use of the Wimshurst for X rays ever since 1897, it is worth drawing attention to the fact that in America many of the chief workers with X rays have been using influence machines since 1896, and they claim to produce rays of quite as much power, at least, as with a coil. This is possible, because they have designed tubes specially suited to the static current, which do not overheat, and which last without danger of perforating, and with the correct convexity. The heart can be seen beating plainly with the screen from 10ft. to 20ft. away. M.

[42981.]—A letter (42955) appears in this week's issue bearing on this subject. It may be well for your readers to know that the Major called unexpectedly upon Mr. Wimshurst, and was at once shown all the apparatus in working order. After certain tests he inquired as to the best form of the machine for field work. Mr. W. told him that at the request of Messrs. Newton, of Temple Bar, he had made a drawing of the best arrangement, having all vulcanite in substitution for glass, and that Messrs. Newton would show him the drawing, &c. About six weeks after this I learned that he had gone elsewhere and obtained a machine with glass plates, the plates being covered with paraffin. Well, we know how unsuited glass is for a portable machine, and that when loaded with paraffin they must be more liable to injury. Then, looking a long way back for experience with plates coated with paraffin, we have the work of Mr. Spottiswoode, who found the keeping in order and the cleansing a serious labour.

Next we may take the work of Mr. Wimshurst. He first tried the coating of the glasses and the sectors with shellac, and following this he cemented two glasses together, the sectors being between the glasses; but with neither of these did the results justify the added cost and complication.

With these works before us, we may easily conjecture the individually known lessons which the Major will acquire. The influence machine is unquestionably and by far simpler and better for X-ray work than is any coil yet made, and it is a great pity that the present opportunity for trial in the field has been so unfortunately and so certainly wasted. J. W.

REDUCING LIGHT IN TELESCOPES.

[42982.]—I tried perforated zinc, as Mr. Ellison did, on a 6in. o.g., and got exactly the same results. When I advised the use of a 16° angle prism, I meant that it would be the best also for reducing light of stars and planets when the aperture is large enough to need it; it would be available for all objects. G. Calver.

THE DIALYTE—TELESCOPICAL MECHANICS.

[42983.]—I am glad to find our Transatlantic friend Mr. Clark has been so successful in the cleaning and adjusting of his old Gregorian, of the ultimate performance of which I hope those of your readers interested like myself in that form of telescope may soon receive an account. Of course, there are Gregorians and Gregorians, but Mr. Clark's may well happen to be of similar excellence to the one of which Mr. Stielow has just given us so admirable a record.

Concerning the "corrector" lenses of his dialyte, the proper placing of which, Mr. Clark tells us, turns out to be different from that indicated by me (42842), he is good enough to mention—and that courteously—that I there admitted the question of correct position in his case, and in the absence of certain data, to be a somewhat uncertain one. May I here add that the position I gave (the convex crown-glass lens in front with its least curved side outwards) is that shown in the inventor's (Roger's) original paper, as well as in Herschel's account of it, in his work "The Telescope"?

But, clearly, much depends upon the curves of the simple object-glass, and the way these are placed; besides, it must also be noted that just as the flint-glass concave in some forms of the double achromatic object-glass is placed in front of, instead of behind, the convex lens (the latter being the usual position), so may the lenses of Mr. Clark's *particular corrector* require to be placed in a position differing much from the customary one. For example, at present I am finishing the lenses of a 10in. aperture achromatic, in which, contrary to the usual practice, I have placed the concave lens in front, the reasons for which procedure I shall explain when I come to give an account of that lens on its completion. It would give me much pleasure to respond to Mr. Clark's request for helpful advice in the matter of his projected dialyte, had I not already referred him to a superior source of information,—Mr. Ingall. That gentleman's address I now give in full, as it stands in the latest list of Fellows of the Royal Astronomical Society:—Herbert Ingall, 1, Champion-grove, Champion Hill, London, S.E. I shall be much surprised if your correspondent does not from the above source meet with a courteous and intelligent response.

It pleases me much indeed to find your polite and energetic correspondent bringing to the practical construction of an amateur-made telescope the skill of an experienced mechanic; for, in remembrance of the exhibition of the "fearfully and wonderfully made" pieces of celestial artillery that has now and again been made in "Ours," one is almost constrained to think that while a certain modicum of knowledge of theoretical mechanics, and of the use of tools, not to speak of the proper choice of material, seems to be a necessity with amateur makers of model engines, fancy turning machinery, or even of children's toys, the average amateur maker of telescopes would appear to have made heroic attempts to get along without such cumbrous qualifications. Indeed, there seems even reason to believe that in order to preserve the proper family likeness, certain caterers for amateur observers adhere to the same rickety styles of mounting so much affected by the designers and makers of home-made telescopes—styles and qualities of workmanship which, while good enough, perhaps, to sustain the trunk of a Newtonian reflector for casual star-gazing, need scarcely be said to be totally unfitted for proper observing telescopes, where either accuracy of vision or of place is a requisite condition. H.

MOTOR CYCLES, ETC.

[42984.]—Replying to Mr. E. H. Micklewood (42940), I cannot say, without experimenting, whether the vibrating contact-breaker on the induction coil can be dispensed with. Without it there would only be one spark; with it there are several at each contact of the cam on the springs. However, it would be worth trying, and if found satisfactory, the trembler could easily be screwed up and rendered inoperative.

I beg to thank him for his suggestion *re* motor car. I had already intended to commence with a general arrangement, as I agree in what Mr. Micklewood says. The motor will not be the same as for the tricycle. I propose using a single-cylinder engine with water-jacket. The castings and forgings will be obtainable from the Inflexible Works Co., Wolverhampton.

I will endeavour to follow Messrs. Miller's and "R. M. G.'s" suggestion (letters 42958 and 42959) *re* getting the castings made simultaneously with or shortly after the publication of the drawings in "Ours."

My thanks are due to the readers of "Ours" for the hearty reception my articles on Motor Cycles were accorded. I will endeavour to deserve their approval in the forthcoming series.

The Writer of the Articles.

THE LIGHTNING-FLASH AND WITCH'S KITCHEN.

[42985.]—It is a remarkable coincidence that the magic believed in during the 15th century has become the actual science of the 19th century. The exemplification of this is to be found in the development of many sciences. For instance, Paracelsus, in the infancy of chemistry, was searching for the elixir of immortal youth when he discovered alcohol and died drunk on the floor of his laboratory. It was the magic believed in during that age, the same as the "Philosopher's Stone," which was to turn everything it touched into gold, that gave birth to our glorious knowledge of chemistry. One of the most startling illustrations of the above is to be found in the scene of the "Witch's Kitchen" in "Faust," where that celebrity is looking into a magic mirror and sees "Margaret at her spinning wheel" in a distant town, and in the recent issue of *Pearson's Magazine*. In the latter is given a descriptive article of the electrical machinery by means of which it is alleged the magic of Faust of the 14th and 15th century can be instantaneously accomplished. Your readers are aware (and here is the difficulty which makes me incredulous) that the magazine also gave diagrams of the camera, revolving discs, slits, vibrating selenite plates, and electric light. In that article the author stated that the Polish inventor was under a fine of 2,000,000f. if he exhibited his discovery before the Paris Exhibition of 1900. Is it at all likely that he would have forfeited the money by giving the information in *Pearson's Weekly*? Or is it a case of an "exploited invention." By this I mean that it often happens that an inventor submits his invention, showing the "principle" to a firm, or, perhaps, a manager of the firm, and he never hears anything further thereof; but soon after another form of machine, embodying the same principle, is patented in America. It is this species of dishonesty which operates as a drag upon industries, and the direct cause of it is unquestionably our expensive and elaborate patent laws, which are no protection or encouragement at all to inventors who are not capitalists. Thus it happens that many of the most beautiful things never see the light of the day; and unless a man wants to be robbed, he does not submit his inventions to others, but patiently waits until he is able to put them on the market himself, or not at all. It was this feature of our national character to checkmate which the Patent Office was founded, but which it does not carry out, that drove Edison to America.

If the Polish schoolmaster really has accomplished the magic in "Faust," and has placed himself under a pledge of secrecy to the committee of the Paris Exhibition of 1900, how comes it that the article, with illustrations, appeared in *Pearson's*? Or is the whole thing a hoax, or has someone broke faith with the schoolmaster by letting the cat out of the bag? Consequently, I am incredulous of the whole thing, but I am not so of the fact you have stated that something similar, though not completed, has been already accomplished. Writing can be conveyed by electricity, wherefore, not pictures?

Having said this much, what I wish to call your special attention to is the lightning-flash, and its capability of conveying impressions. The invention of the Polish schoolmaster is acknowledged to be a practical application of this power of lightning flash, and I also wish to bring in review before your readers several important features respecting the *essential nature of lightning*. The object I am driving at is not to assert in any dogmatic or conceited manner any statement, but to start a most important inquiry in order to elicit, if possible, something *new*, and it may perchance prove *definite* knowledge.

It is astonishing how little we know, after all is said and done. Dalton wrote in 1801 that "This world is founded upon one that was; it is now

furnishing the means of a world that is to come. This process is from everlasting to everlasting, without limit of duration, and there can be discovered in the Solar System no vestige of a beginning or signs of an end." We have got not one jot further than this even yet. The ancients believed in fire being the cause of all things, and there existed once a wide-spread faith called, to the best of histrionic evidence, "Æther Fire." In the Pagan mythologies there was the "Black Fire," or the fire of hell, which burnt, but did not consume, and there was "The Sacred Fire of the Sun," whose altar was tended by the Vestal Virgins. It was an old-world notion, and it is a modern one, and, to use a form of words which are a modern "caddism"—an "up-to-date" notion that the ether pervades all space. Priestley was undoubtedly the first chemist who froze oxygen into liquid air, although he did not use the modern means of doing it; but that he did it will be at once apparent by looking into the chemical works of the scarcely less celebrated John Dalton, chemist, Manchester, published in 1801. It is an ascertained fact that all metal is full of what chemists term "fixed air," and it is also known that magnetism is not electricity. It does not become so until it passes through the atmosphere. The essential parts of a dynamo are the iron horseshoe and the vibrating cylinder consisting of layers of metal alternately insulated, generally with layers of mica. When this is set revolving it instantly lays hold of, and sets in motion, the fixed air in the metal, and when the circuit is completed, contact at any point of circuit cannot be broken without the liquid air instantly leaping from point to point, and the intensely cold liquid air coming into contact with the hot or warmer atmosphere, fires it, and this is the lightning-flash. After all is said, heat and cold are only relative conditions. The proof of this is that a stick of charcoal, which is very loth to absorb and retain heat, and which is of the same temperature as the surrounding atmosphere, instantly becomes red-hot if plunged into liquid air. How, then, is the lightning flash to be reasoned out and accounted for? Simply enough. Away in what is simply infinite space, above our heads to an illimitable infinitude of distance exists the ether—liquid air—it matters not how attenuated, though of this attenuation there is no proof. Beneath this imponderable—unelemental, as some would say—ether there are the waves of hot atmosphere, and the moment the circuit is completed, either between the liquid air in the earth or that of the realms of space, a stream of magnetism, or of liquid air, results, and there follows the lightning-flash until equilibrium is established, the thunder being simply the detonations or explosions of the dissolved atmospheric gases all along the line of the flash in the atmosphere. On this exposition it is easy to see the why and wherefore that thunderstorms so rapidly cool and clear the hot summer air. The lightning, although it comes round its immediate course in the shape of the hottest fire, is really diffusing every flash and explosion a certain necessary amount of liquid air, many hundreds of times colder than zero, or ice, and it is so instantaneous that a gentle, genial, pervading, cool, and refreshing breeze diffuses itself directly after the flash has done its work.

It now becomes apparent why sometimes, when people or animals are struck by lightning, they are not burnt. It is because the stream of more than icy-cold liquid air has destroyed their life while passing through them without contact being broken; but if from any movement at the time going on contact is broken, then shoes may be ripped off, portions of the body, or even the whole of the body, sometimes reduced to charcoal. There is a recorded instance of two persons sitting on a seat and on being struck by lightning, both were dead, but the body of one was not burnt, while that of the other was reduced to ashes. Now on examining nature a little further, it was an old-world notion that "electricity is life," and moderns have suspected it to be more than true. Galvani discovered its motive muscular power, and everyone now admits that our bodies never cease to be full of this mysterious element in its all-pervading magnetic form. The two conditions have been pointed out—viz., its cold form and its form of fire; the former must precede, it matters not how infinitesimal in point of time, which is only a relative condition, its explosive fire form or condition. It is not reasonable to suppose that magnetism can be the conscious thinking element of life, but it is more than probable that it is the force made use of by the life force as a motive power. Is there anything in nature which points to this conclusion? Yes, there are the two conditions of magnetism to be found in animal physiology—viz., the hot and cold blood. The heart of every living creature is a dynamo, generating and kept in motion by the magnetic vibrations of all-pervading æther; hence its continued unwearied action. It has long been known that the heart of a fish is a *two*-lobed heart, that of a reptile is a *three*-lobed heart. The heart of a bird is a three-lobed one; but the bird possesses organs which neither the fish nor reptile does possess. The heart of a mammal and of man is a *four*-lobed heart. The hearts of the fish and reptile generate magnetism in its first form—that of liquid air; hence the cold blood and cold skin of a frog, lizzard, or snake. The heart of a mammal or of man generates magnetism in such a way, that at every beat of the heart contact is broken sufficient to give the body warmth. This also bears out the fact of what are called "cold sweats" generally before people die, because the part which breaks contact ceases to do so until the obstruction is removed. First there is formed the dark, thick, purple blood of arteries; the next change is into the bright scarlet blood of veins [?], and I hold that the final change is made by the white corpuscles which the blood has extracted from the food, becoming the fluid which circulates in the nerves, which I hold are a continuation of the venal system; also, it is the absorbent system which builds up or pulls down the flesh or bones; the latter in health and the former in disease and old age. Can anyone gainsay this? The reason why fire pains is simply because it is acting on a body which it throws into a state of violent combustion. This seems so simple that any poor fool could understand it; but is it really so simple as it looks at first sight? If the substance of our bodies were not combustible—had no oxygen or hydrogen in them—light, no matter how brilliant, would neither hurt the eye, nor yet heat, no matter how fierce, burn the body. To the Almighty the sun is a dark simulacrum.

A Constant Subscriber.

ACETYLENE.

[42986.]—We send the inclosed letter in reply to the article you reprint from the *British Journal of Photography*, [p. 203] and as the statements contained in that article are really calculated to impede the development of the new industry, we trust that you will kindly give publicity to our remarks.

Thorn and Hoddle.

[COPY.]

The Editor *British Journal of Photography*,

"SIR,—Your article upon acetylene in last issue is, we are sure unintentionally, calculated to do harm to this new industry, and we crave your favour to supplement it by further information. The Fire Insurance Offices do not 'continue to throw in the way of would-be users difficulties of a harassing and obstructive character'; on the other hand, many of the offices have taken great pains to make themselves acquainted with the characteristics of and conditions surrounding carbide and acetylene, and, speaking generally, their regulations are only such as to protect themselves from careless or ignorant persons. One office has gone so far as to issue a notice that they do not charge an increased premium when acetylene is used.

"The remark that impurities are liable to produce explosive compounds when in contact with metal, or to initiate spontaneous combustion, is a relic of the early days, when the gas was not properly understood. Such ideas have long been swept away by practical experience.

"Mention is made of several foreigners who have experimented with methods of purification; but, as Englishmen, we cannot help remarking that in 1897 we patented a purifier, with a special mixture, which has been extensively used ever since, and has never failed to satisfactorily remove the unpleasant smoky fumes, which render the use of the gas in closed rooms unbearable without purification.

"The grave source of danger, said to result from the after-formation of gas in the generator when the carbide has been removed, is only present in machines of unscientific construction, or self-contained generators such as used for bicycles, &c."

SMOKE FROM LOCOMOTIVES.

[42987.]—IN these days of "fogs," some attention should be given to the locomotive engines on our railways. Why are they allowed to make the smoke they do? Is there any law upon the subject? For instance, the Railway Regulation Act of 1845 I believe refers to the matter.

On the 1st August last the London County Council decided to put the law in force, but nothing has been done. It would be interesting to know what is required in a locomotive so as to burn its own smoke.

Loco.

THE largest insect known is the elephant beetle of Venezuela. It sometimes attains a weight of half a pound.

GLASS plates cast with wire gauze inclosed in the substance, submitted to tests at the Chemnitz Technical Institute and the Vienna Technological Museum recently, were found to possess great consistency, as well as resistance to pressure, shock, and the effects of heat, the resistance being 3611b. per square inch, and the consistency 3,610lb. per square inch of the transverse sectional area. While plates of ordinary glass frequently broke under the sudden application of pressure, the strengthened glass was only cracked; and the cracks caused by rapid changes of temperature permitted neither damp nor flame to pass. Glass so made has already been used for water-gauges.

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[96487.]—**Torpedo-Boat Destroyer** (U.Q.)—Sections of American destroyers appeared on page 818, Vol. LXVI. *Engineering*. I do not think you can obtain the sections of boats by British builders.

GLATTON.

[96496.]—**Canary Complaints** (U.Q.)—I know nothing of the subject; but probably "General Management of Canaries," which describes diseases and their treatment, would be of use to you. It is published at 2s. 6d., by L. Upcott Gill, 170, Strand, W.C.

GLATTON.

[96555.]—**Equation.**—Mr. Burgess is quite right as to the possibility of x being a surd provided x and y contain *the same* surd; the three values of x y and z given by him may be put in the form $a\sqrt{6}$, $b\sqrt{6}$, $c\sqrt{6}$. This subject is interesting, as the method I have introduced enables us to dispense with a tiresome biquadratic, and even to solve an equation with three unknown quantities with only two equations, so that if Mr. Burgess (to say nothing about our Editor!) is not tired of the subject, I would like him to refer to the equation at foot of p. 163. Reducing two of the fractions under the radical to their lowest terms by dividing by 7, the radical term can be put in the form—

$$\frac{4x^2}{3 \times 36}\sqrt{3 \times 4 \times 13 - \frac{9 \times 5 \times 83}{2x^2} + \frac{9^3}{8x^4}}$$

To find what values of x^2 will make the terms under the radical sign a square number, put $x^2 = \frac{q^2}{p^2}$, the two last terms become—

$$\frac{-9 \times 5 \times 83 \times \frac{1}{q^2}}{\frac{2}{p^2}} + \frac{9^3 \times \frac{1}{q^4}}{\frac{8}{p^4}}$$

Then equating the denominators (see my last reply, p. 234), $p^2 = 4$, and the two terms become—

$$\frac{-2 \times 9 \times 5 \times 83}{q^2} \times \frac{2 \times 9^3}{q^4};$$

the value of q^2 which will divide them without remainder is 9; it may be objected that if we put $q^2 = 3$, giving q the surd value $\sqrt{3}$, q^2 will divide out; but this value is a mere logical consequence of the first value given to q, as it is evident that if any number is divisible by m^2 without remainder, then *à fortiori* it is divisible by m. Hence, $q^2 = 9$. This value of q^2 makes the terms under the radical sign $784 = 28^2$, and the whole expression becomes $\frac{7}{3}$ as before. Hence there is no ambiguity as to the value of x, unless we put $q = 1$; but this gives no square number.

Bath. M.I.C.E.

[96574.]—**Jets** (U.Q.)—Are these really facts? Where have you seen them stated? GLATTON.

[96651.]—**Transposition** (U.Q.)—I am afraid it would take too long to explain. The method will be found in every work on algebra. You must complete the expression by putting some symbol for the quotient—say x for instance; your sum then reads thus—

$$\frac{A \times B \div c}{d + e} = x,$$

which is the same thing as—

$$\frac{A \times B}{c\,(d + e)} = x.$$

Hence $A \times B = x \times c \times (d + e)$.

Now, to find the value of any of the terms on one side of the sign =, it is only necessary to place the other terms on the opposite side as divisors. Thus—

$$A = \frac{x \times c \times (d + e)}{B}$$

$$B = \frac{x \times c \times (d + e)}{A}$$

$$C = \frac{A \times B}{x \times (d + e)}$$

$$(d + e) = \frac{A \times B}{x \times c}$$

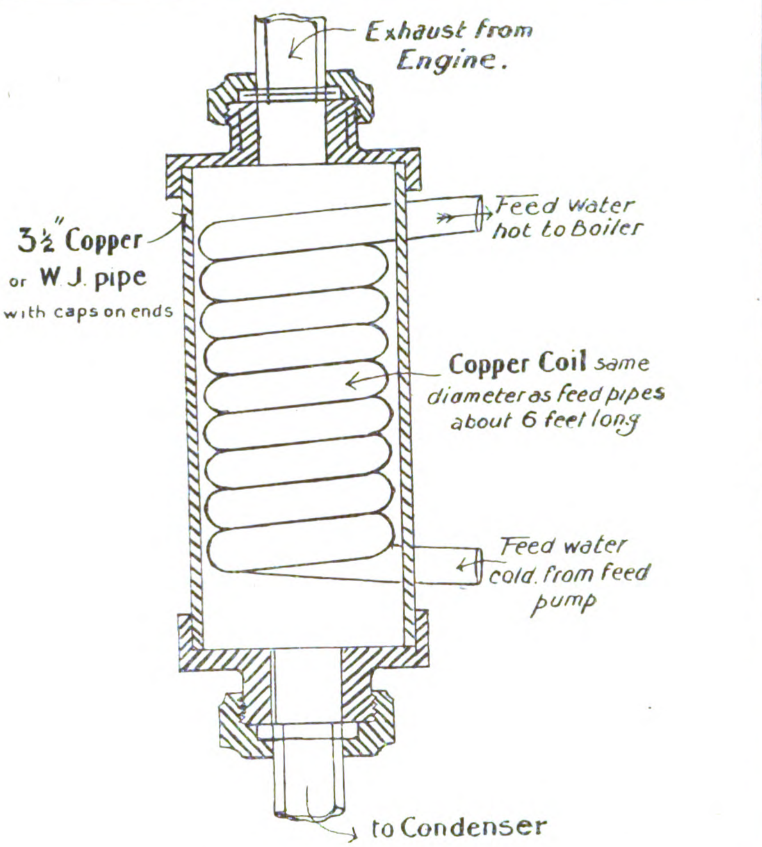
$(d + e)$ I have considered as one term. To find the value of either, place the other on the other side with a (−) sign before it. Thus—

$$d = \frac{A \times B}{x \times c} - e$$

$$e = \frac{A \times B}{x \times c} - d$$

GLATTON.

[96633.]—**Green Water.**—The little bubbles on the surface of the water confirm my opinion as to the cause of the greenness. These bubbles are oxygen, resulting from the breaking up of carbon



dioxide by Euglena. In regard to a remedy, I can think of no other plan than by killing off by chloride of lime or permanganate of potash (say about half a pound of the latter, for the quantity the tank contains), then rinse out and refill. They may not appear again. I had a glass-fronted aquarium tank containing 400 gallons quite green through Euglena. They died off at the end of the season, and none have appeared since. If "Quex" will send me, say, a one-drachm bottle of the green water, I shall be able to give him more information.

12, Royal Crescent, Jersey. J. SINEL.

[96659.]—**Joy's Valve-Gear** (U.Q.)—The objections you state appear well founded; but I have no personal experience of this gear. Marshall's valve-gear would probably suit you better. I have not a diagram by me, but it is shown in Seaton's "Manual of Marine Engineering." GLATTON.

[96681.]—**Boilers with Projecting Studs.**—I do not know in what respects these systems of fitting studs to boilers differ, but I think I know that neither is worth bothering about. Naturally the more surface that is exposed to the source of heat the more of that will be captured; but the idea of applying studs to kitchen ranges or the bottoms of ovens has not yet been introduced into the manufacturing world. The one place where it is necessary to capture all the available heat is the boiler of a cruiser or that of a locomotive, and I have not heard that any designer has used studs under these conditions. METOPS.

[96759.]—**Bikes and Prams.**—As s. 85 of the Local Government Act, 1888, expressly enacts that bicycles are to be deemed "carriages" within the Highway Acts, there is no necessity for a court of law to decide the question. Nothing is said therein about prams, nor is any distinction made between a ridden or led bicycle. The word carriage, according to Chambers's Etymological Dictionary, means "a vehicle for carrying"; according to "Rota's" contention, an empty carriage is no longer a "carriage." Will he say what it has become? Prams are, I agree, frequently a nuisance, especially when they are wheeled along three abreast while the peculiarities of "missus" are discussed, and their propellers are legally liable for obstructing the pavement, not on the ground that they are by law "carriages" (as they are not), but because any undue blocking of the footway is an obstruction. They have, however, been tolerated for so long that, as "F.R.A.S." pointed out, the police wink at the offence, and a magistrate would probably not inflict a fine as the practice has been in use for years. To compel prams to go in the roadway would endanger both nurses and infants, while the mere cyclist is supposed to be able to take care of himself; hence, probably, the license accorded prams. The above section repeals all previous powers exercised by local authorities to make rules for bicycles. B. H.

[96796.] — **Marine Condenser.** — A suitable condenser for the size of querist's boiler would consist of about 6ft. of 1¾in. diam. copper pipe, made D section, and fitted alongside the keel of the boat outside, being attached to the skin by suitable ends. The cost would be about 20s. It will also be necessary to lead a jet of live steam into the funnel, to liven up the fire, and assist the draught. Fitting fresh water-tanks connected to the hot well, and using the water to make up the auxiliary feed, will add considerably to the life of the boiler, whilst a feed-water heater, something like sketch below, between the feed-pump and boiler check-valve, will also be found to be worth the expense. If "Old Colonial" can get a chance to thoroughly examine one of Messrs. Simpson Strickland's launches, he will see the above fitted in the most complete way, and be able to understand it. D. C. G.

[96778.]—**Barometer.**—The barometer is simply a measurer of the weight of the atmosphere, and is no sort of guide to the probable weather unless the local conditions are well understood. If a mercurial barometer has been screwed up to keep the column intact, it will be only necessary to release by unscrewing. The vacuum should remain intact, even if the bag of mercury has been screwed up. But what is the difficulty? A barometer is simply so many inches of mercury in a tube supported by the weight of the atmosphere, and the mercurial column falls or rises accordingly. M. T.

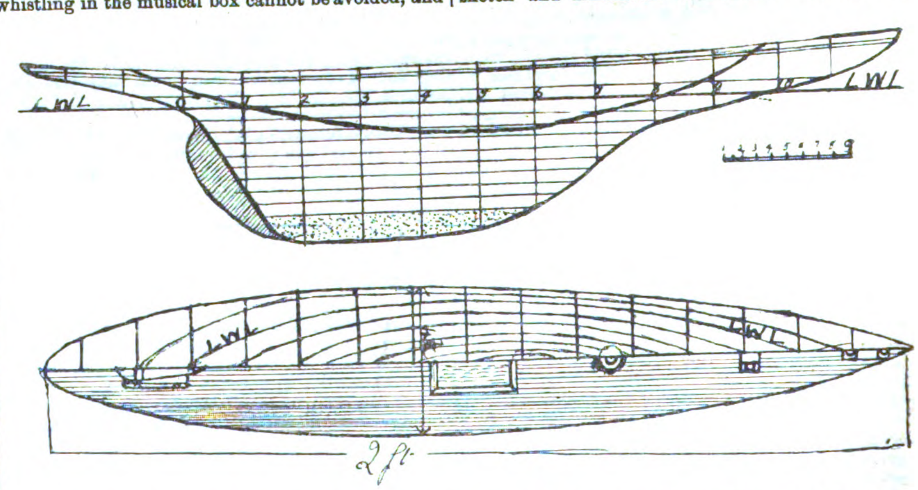
[96816.]—**Musical Box.**—The scratching and whistling in the musical box cannot be avoided, and is there when you buy it new, only then it is not so noticeable, on account of the cylinder moving faster than it does now. This scratching is caused by the reeds, which are set in vibration by pins and still continue to vibrate while other pins come up to chip them again, and in which they vibrate before the pins obtain a firm hold.

J. H. SCHUCHT.

[96840.]—**Microscope.**—For a microscope (compound) the lenses necessary are: (1) An objective of short focal length to form an enlarged image of object. (2) An eyepiece to receive and further amplify first image. If your convex lens ¼in. has a short focal length—e.g., anything below an inch, you could use it as an objective, which, however, ought to be plano-convex; you would not, of course, be able to have an achromatic combination. For eyepiece, you again want plano-convex glasses. If the 1in. or ½in. or $\frac{11}{20}$in. were such, they should be mounted as field-lenses with the ⅜in. as eye-lens. Read any book on elementary optics or on the microscope. OPTICIAN.

[96873.]—**Whole-Meal Bread.**—There is no such article as whole meal or whole-meal bread; the correct name is "entire wheat meal" or "entire wheat-meal bread." Thus wheat is a Triticum; wheat meal is no longer Triticum (wheat), but Triticum farina. As no doubt "D. W. G." requires his bread for domestic purposes, I need not here discuss the theory and practice of the various blends of wheat for the said purpose, as, from practical experience, I find that English wheat of this year's growth will produce a good loaf. The method of grinding is an important factor, as well as the sample of wheat. Doubtless you can obtain good wheat meal; if so, I give you two methods which I used nearly twenty years. Wheat meal being a variable absorbing product, proceed thus: Gradually heat four pints of milk (or water) to 80° Fahr.; then dissolve an ounce of distiller's yeast in same; then stir in 2oz. of moist (brown) sugar and 10oz. of your wheat meal. Do this in a medium-sized pail, or a similar-shaped vessel; cover over with a board and a cloth, and stand aside in a comfortable warm place until ready. This is the "ferment," and it will rise up the pail (sometimes more so than others), and then drop. When ferment has dropped—not before—dissolve not less than 1oz. nor more than 1¼oz. of salt in half a pint of hot water, 100° Fahr.; stir this into the ferment, and make a dough of a soft consistency. This can be done in the said pail to perfection by simply stirring in the wheat meal (with a strong wooden spatula) until you have a very stiff batter dough; it need not be touched by hand. Now scrape your "spat," and leave the dough in the pail in a fairly warm place until well risen—not more than double its volume. When risen, take your scales and a large spoon, or a smaller spatula, and weigh off 20oz. for each loaf, plus your tin. The last portion may be less than 20oz. That can be added in equal portion to the others with a palette knife. Your pail should be quite clean; no dry meal or scraps should be there. Stand tins in a comfortably warm place (not less than 65° Fahr.) until the dough has risen (in tins) to not more than twice its volume. You can, of course, go higher or lower. Bake in an oven of the temperature of not less than 400° Fahr.—no more than 450° Fahr.—for about forty minutes. Your loaves on top should be convex. Your fermentation is then correct. Second method: milk 4½ pints (or water); heat to 90° Fahr.; then dissolve in the same 1oz. of distiller's yeast; then add 2oz. of sugar and 1¼oz. of salt. Make the dough stiff; cover over pail, and stand all night on the kitchen table (this can stand from nine to twelve hours); in the morning give it a stir, and stand in a warm place an hour or so. Then proceed as above. RAGLUS.

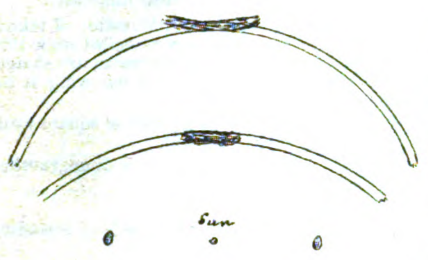
[96876.]—**Model Yacht.**—I trust the inclosed sketch and dimensions will enable "Harold" to make a good and efficient yacht. The design is very much after the lines of the *Shamrock*. The boat sits well on the water, and is about 17in. on the water-line. The boat should carry about 950sq.in.



of sail. If "Harold" would care to advertise his address in the Sale Column, I should be pleased to send him drawings of sails and mast, fittings, &c.

WOODHOUSE.

[96879.]—**Rainbow.**—The remarkable series of rainbows or solar haloes referred to by Mr. Harman as having been observed at Tunbridge Wells on the afternoon of Oct. 11, was also plainly visible in London on the same afternoon, although at an earlier hour, and possibly under somewhat modified conditions. Whilst passing through the City at about 2.30, my attention was attracted to a vivid streak of coloured light about 10° in length, resembling a portion of a rainbow, situated apparently about 45° above the place of the sun, and being curved slightly convex towards his position, as if forming the lower segment of a large circle reaching far beyond the zenith, of which, however, no other portion could be seen. Other features were then noticed, which I sketched on the spot, and now reproduce. The usual solar halo at 22½° distance



from the sun was not visible in its entirety; but two mock-suns appeared in their usual positions right and left, and a second rainbow streak at a similar distance over the sun, and, therefore, midway between it and the upper and more brilliant streak. The upper portions of two other haloes could also be plainly traced, the first being distant about 45° from the sun, and consequently touching the upper streak, the other being apparently of larger radius, the apex passing through the lower streak, consequently not having the sun in its centre, the curves on either side being prolonged to a distance nearly reaching the other halo, their tendency being apparently to intersect at points distant 45° on either side of the sun, thus giving it somewhat the appearance of a parabolic curve with the sun in its focus. This had all faded away by about three o'clock. In both streaks the lower colour was red.

W. T. N.

[96881.]—**Malting Wheat.**—If "Merchant" advertises his address, he can be put into communication with those who are ably acquainted with the above subject up to date.

ACROSPIRE.

[96882.]—**Vinegar Plant.**—The vinegar plant is a fungus which is used to convert alcoholic solutions into vinegar. The fungus is a bacterium called the Mycoderma aceti, and consists of short bacilli about 2 μ long, contracted in the middle, and resembling the figure 8. To develop the vinegar plant, plenty of oxygen and a fairly high temperature is required. It is firstly produced in the manufacture of vinegar as follows:—The malt or barley is mashed in hot water till all the soluble matter is extracted. The clear liquid is then run off into a vessel and yeast added. Fermentation then sets in. This liquid is pumped over piles of birch twigs, placed in high vats. The twigs become coated with the Mycoderma aceti, or vinegar plant. This plant, when placed in any warm alcoholic solution, sets up fermentation and converts it into vinegar. The vinegar plant can be kept for any length of time. To keep the plant, it is necessary to place it in a diluted solution of beer or any other solution containing alcohol. Care must be taken to change the liquor every ten days or so: otherwise the plant will die.

ERNEST N. W. HUME.

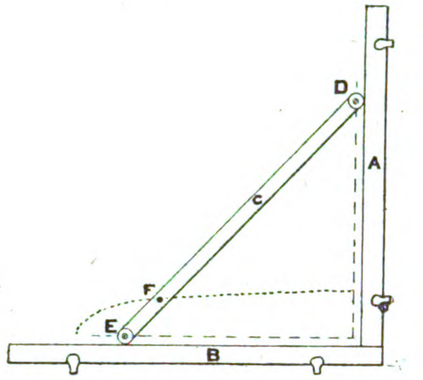
[96883.]—**Diamonds.**—Yes; 760° C.—i.e., 1,400° Fahr. Read Crookes' lecture on "Diamonds," delivered at Royal Institute, 1897.

M.

[96886.]—**French Verbs.**—The old spelling, hardly extinct in 1814, was with *ois, oit, oient*, where they now use *ais, ait, aient*. The sound became like *ai* more than a century ago.

E. L. G.

[96896.]—**Ellipse.**—Your correspondent "B. B. M." seems to have tried the common method by means of two pins and a cord, without getting the required exactness. The following is a modification of a very old method of drawing a quarter-ellipse:—Let A and B in the figure be two straightedges clamped at right angles to each other on a board. Prepare a flat ruler, C, exactly 11⅞in. long from the point D to E. At F, which must be 1⅞in. from E, let the pencil or steel scriber be fixed in a suitable hole. At D and E let circular pieces of metal (coins will do) be accurately fastened by screws through their centres to the ruler C. These discs need not revolve. The quarter-ellipse is drawn by sliding D along A while E slides along B. F will then describe a quarter-ellipse with an accuracy almost absolute if the apparatus has been carefully constructed and intelligently used. These quarter-ellipses may be cut with scissors from thin zinc or cardboard, and used as templates for drawing the whole ellipse by placing them in four different positions. The drawing pen must be dry

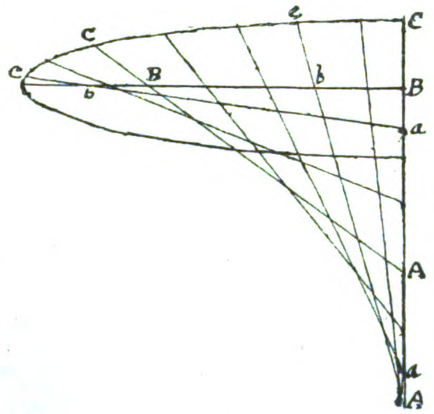


on the outside to avoid blotting. By varying the position of F, any elliptic curve can be drawn, the centre of C describing a circle, points near the end making very long ellipses, and those nearer the middle very round ones. D F must be half the long axis, and E F must be half the shorter one.

RICHARD INWARDS.

20, Bartholomew-villas, N.W.

[96896.]—**Drawing an Eccentric Ellipse.**—The use of foci and a string is a very bad way of drawing any ellipse. The principle of the trammel is always best. Having two lines accurately at



right angles, you have only to mark on a straight-edge the two semi-axes, A C the longest and B C the shortest; then keep the marks A and B on the two axes, and C is always on the ellipse.

E. L. G.

[96897.]—**Slade Micrometer.**—It is very easy to illuminate the Slade micrometer eyepiece of a small refractor. My telescope is a 2⅝in. refractor, and for some years I lit up the eyepiece in this way. A hole existed in the brass tube of telescope about the middle point, which was once used for attaching it to a brass pillar-and-claw stand—very soon done away with, by the way. I had this hole enlarged to about ½in. diameter. A small piece of white card, elliptical in shape, say ½in. or ⅜in. by ¼in. is attached to some fine brass wire—fine enough to be pliable and yet stiff enough to hold the cardboard in any desired position. This wire is made into a sort of letter Z shape, and the cardboard is then inserted in the tube, the wire being by trial bent or adjusted so that the cardboard is in about the centre of the tube, opposite to the circular hole, and inclined at angle of 45° or thereabouts to the axis of tube. This arrangement is secured in the tube by one or two turns of fine twine or cord lapped round outside of tube. A small wooden table may now be made to slide up and down one of the legs of the telescope tripod. The top of this should be secured by a screw in a washer, so that it revolves easily, and can be brought nearly up to the hole in the tube. A small candle lantern is then placed on the top, and with a very little adjustment the eyepiece can be graduated to the desired amount of light. Of course if it is too strong, the stars are obliterated, and if too weak the lines in reticule cannot be seen. Quite lately I have discarded lamp and table, which can only be used conveniently when an object is near the meridian, for a tiny electric lamp worked from a pocket dry battery. The lamp is just large enough to fit into the hole of tube, and is inclosed in a little brass cylinder open at one end only. A switch is provided which can be held in the hand, and the light turned on or off as desired. The light is secured into the hole by a turn or two of cord outside tube. In this way the light can be turned on when the telescope is in any position, even when the light is at the lower side of tube. I have found this useful in filling in sketch of stars surrounding a variable star. I may say that I prefer a Ramsden eyepiece with one thread parallel to Equator, and two others at an angle of 45° to the first, for general work, as fainter stars can be seen than with the Slade, the photographic film of which has a tendency to obliterate faint stars; but, for taking precise differences of R.A. and dec., the Slade is the more accurate perhaps. The dry battery and switch, with electric light, was provided by an electrician for 15s. With these comparatively simple appliances, I have had very much amusement and instruction from my telescope, which is mounted on a Wray equatorial stand without circles.

E. E. MARKWICK, Colonel.

Devonport, Oct. 23.

[96902.]—**Gas Explosions.**—An explosion of gases travels at a certain rate; that is to say, it takes a measurable interval of time for an explosion to travel from one point to another in the same gas mixture. In a mixture of air and H an explosion travels quicker than in one of air and coal-gas. Suppose two gasholders connected with jets, one containing an explosive mixture of air and H, and the other of air and coal-gas, it would require a greater pressure on the air and H gasholder to prevent the explosion travelling backwards. "L. L. L." will probably find a piece of gauze stretched across the inside of his "gas" burner; this, too, prevents a recurrent explosion in his gas-pipe. With a suitable pressure and such a gauze, "L. L. L." could "burn" his explosive mixture of air and H under perfect control.

M.

[96905.]—**Negatives of Diagrams.**—In all probability your developer did not contain sufficient bromide and pyro. Pin the diagrams so that the lighting is more from the side;—lighting from the front is apt to cause a want of contrast. Of course, the defects and irregularities of the paper are shown less by front lighting. Use slow plates—process plates, if possible, as these are more thickly coated than ordinary plates, although very fair results should be obtained with the latter. Focus carefully with a large stop, and stop down to about $f/32$, rather under- than over-expose, and use a pyro-soda developer, strong in pyro and bromide, and stop development the instant veiling commences. The wet-plate process is much to be preferred for this kind of work.

T. J. LENEY.

[96913.]—**Workshop Lamps.**—Our system of using paraffin-oil is the acme of lighting with paraffin oil. There is no filling of lamps every day, and there is no daily trimming of lamps, as the wick never requires cutting, only wiping off the sediment once a week, or even once in a fortnight, and the light is far superior to gas and the ordinary oil-lamp. It is always a pure white light, without smoke or smell, and no more trouble than gas. The system can be seen in use at Esher, Dorking, and Tulse Hill, London. Shall be pleased to show system to "Jasmine" at any time, and answer any questions through the post, being a regular subscriber to the ENGLISH MECHANIC.

THE ROYAL AUTOMATIC OIL-LIGHTING COMPANY.

Church-street, Esher, Surrey.

[The system appears to be one to supply paraffin-oil from a fixed tank, through pipes to burners. We cannot spare space for the circular sent, and the above reply is very much of the nature of a free advertisement.—ED.]

[96914.]—**Astronomical.**—"Novice," in requesting to be shown how to find in mean solar time the interval during which a star which, rising exactly in the East, remains above the horizon, introduces the simplest of all the cases of finding what is called the "semidiurnal arc." As the essential principles upon which depend our modes of reckoning time, and which are necessarily involved in this simple question, are by no means so clearly understood as one would suppose, I may be excused in answering the above query at greater length than might seem necessary. Two elementary facts may perhaps be taken as generally well enough understood—viz., first, that in the "right sphere" (the conditions at the Equator) all the heavenly bodies appear and disappear during equal times; second, that in the "oblique sphere," such as under our observing conditions, stars having North declination are *more than half* their revolution times above the horizon, while those having South declination are *less than half* their circuits above it. In fact, so much does this hold, that circumpolar stars never set, and stars with considerable South declination never rise here at all. Now, it is evident that just as a ring swivelled horizontally by a diameter has always just one-half of its circle above the plane of its swivels, however much or however little it be tilted, so must exactly one-half of the Celestial Equator be above the horizon in all latitudes. Therefore any body situated in that circle (the

Celestial Equator) must necessarily be exactly for one-half its period of revolution above the horizon, if its motion be uniform. (Of course, we remember that this diurnal motion is due in the star's case entirely to the earth's rotational motion on its axis). The above supposed star of no declination—i.e., Equatorially situated—will therefore rise exactly in the East and set exactly in the West, as these are the *only* points of the horizon where the Equator cuts it; and, further, it will remain above the horizon exactly one-half period of the earth's rotational time—just, in fact, as in solar time the sun does at the Equinoxes. Refraction and other causes prevent these facts from squaring precisely with the above simple conditions *observationally*. The point now is, What relation has our time reckoning to the earth's axial rotation? This rotation appears to be perfectly uniform—at least, to our experience, as uniform as any motion with which we can possibly become acquainted. How, therefore, do we derive *two* entirely different modes of time reckoning from it—*sidereal* and *solar* time? All depends upon the point of reference, from which to mark the rotation. Stars being for this purpose practically fixed, the time which elapses between two consecutive returns of the same star to the same position marks out the period of the earth's rotational time—the sidereal day. On the other hand, the sun moving, in respect to the earth, slowly in the *same* direction (conventionally we may correctly enough speak of this motion of the sun), it necessarily follows that given the sun as a point of reference for the diurnal rotation, the earth must make somewhat *more* than one complete turn, relative to space or to a star, before sun and earth can again be *relatively to each other* in precisely the same position they were yesterday. Hence, whatever units we care to employ, the solar day must be longer than the sidereal day; for, as Loomis points out, "an arc of the Equator, equal to 360° 59′ 8·33″, passes the meridian in a mean solar day, while only 360° pass in a sidereal day," making a difference of 3m. 56·5554s. of sidereal time between the mean solar and sidereal day. The conversion of sidereal into mean solar time, or vice versâ, depends entirely upon introducing the above proportion between them, and the practical conversion is usually done by tables, which are to be found in most works dealing with practical astronomy or navigation—e.g., the *Nautical Almanac*. For our present purpose we have merely to remember that the star supposed to rise exactly in the East must be seen to describe (discounting refraction) one-half the entire circle, or 180° of the Equator, while above the horizon; and that this angular interval in sidereal time is exactly half a sidereal day. Now twelve sidereal hours, by proportions already given, will be found to be 11h. 58m. 2·0453s. in mean solar time, so that for this interval as marked by a mean time clock (the usual article) will a star which rises due East, remain above the horizon. The following equivalents may interest those readers, who, in the absence of tables, may wish to work out "time conversions":—

1h. S.T. =		59m.	50·1704s. M.T.
1h. M.T. =	1h.	0m.	9·8565s. S.T.
1m. S.T. =			59·8362s. M.T.
1m. M.T. =		1m.	0·1643s. S.T.
1s. S.T. =			0·9973s. M.T.
1s. M.T. =			1·0027s. S.T.

Astronomical readers will observe that refinements required in finding a star's true R.A., and which rather interfere with the simple definition of sidereal time, are not introduced in the above. H.

[96918.]—**Scrap Arc-Lamp Carbons.**—The ends of arc-lamp carbons are always useful in making-up Leclanché cells, mixed with the manganese. Otherwise they will do to burn on the fire, being carbon. What possible use can they be? They are only carbon, and will provide fuel. M. T.

[96921.]—**Thin Sheet Steel.**—When the bits of sheet steel are bent into desired shape, drop them into water, and they will probably be as springy as wanted. If the pieces of steel are simply pressed into shape by the dies, they will probably be springy enough if passed into water after shaping. T. L.

[96922.]—**Stylographic Ink.**—Boil pulverised gall-nuts, 250 parts; gum, 125 parts; sulphuric acid, 125; distilled water, 4,000, add a few grains chloride of mercury; pyrogallic acid, 1 part; sifted gum arabic, 3 parts; neutral ammonium meta vandate, 3 parts. Rub together and well incorporate. REGENT'S PARK.

[96923.]—**Heating Tank.**—"Heat" does not state the length of time he has at his disposal in which to raise the temperature of the water to the desired degree. F.I.S.E.

[96924.]—**Artificial Diamonds.**—Pure rubbish—like many another paragraph of the same species. A diamond-like modification of boron may be obtained by heating together to prolonged white heat boric acid and aluminium, or amorphous boron and aluminium, in a crucible surrounded with powdered charcoal. The crystals have the composition $B_{48}C_2Al_3$. Fine diamonds of very inferior quality were artificially produced about twenty years ago by J. B. Hannay, of Glasgow, by prolonged heating together of paraffin spirit, bone-oil distillate, and metallic lithium, but the process was very perilous, and the cost of the artificial stone greater than that of the natural diamond. W. J. G. F.

[96925.]—**Panama Hats.**—The so-called Panama hats are made at a place called "Suasa," in Colombia, South America. They are made of the fibre of a small fan-palm known in the country as "Palmiche." They are not difficult to make when one has learnt to do it; but it is very tedious work, and requires good eyes to make the finer qualities. I have seen men, women, and girls making them. A common or coarse one can be made in about three days, and costs from 3dol. to 5dol. The finer ones take months to make, and may go to almost any price. The natives of Colombia pride themselves exceedingly on the quality of their "Suasa" hats, and look down on anyone wearing a common one. A Colombian would rather go without food than without a fine Suasa hat, and it is not an uncommon thing for natives of the lower classes to pay from 60dol. to 100dol. for one, and the upper classes more. I have not seen one quite as soft as silk, but they can be made exceedingly soft and pliable, and will fold and roll so as to go comfortably into a breast-pocket (I don't know about a waistcoat-pocket). There was one of exquisite fineness exhibited at the last Paris Exhibition, and was sold to a Yankee for £400. QUEX.

[96927.]—**Mercury Gilding.**—If I were that gilder I would change my trade. He will surely die soon if he goes on at it. G. A. HAIG.

[96927.]—**Mercury Gilding.**—G. B. Wood, M.D., &c., "Therapeutics," speaks of the use of the iodide of potassium as of great value in eliminating metallic poisonings, such as lead and mercury, forming double salts, which are soluble, taken up and excreted. Ordinary dose. 10 grains three times a day. Compound syrup of sarsaparilla is a convenient disguiser of the drug flavour. REGENT'S PARK.

[96928.]—**Electro-Magnet.**—The results of winding the two limbs of an electro-magnet for a motor in series with the armature is that the motor will not run at constant speed irrespective of the load, but it starts easier against a full load, whilst a shunt-wound motor will run at almost constant speed, but will not start against a load.

WEBSTER MICHELSON AND CO.,
Dudley. Electrical Engineers.

[96932.]—**Polycistina.**—If you cannot obtain at any naturalist who deals in aquaria, why, inquire of Thomas Bolton, 25, Balsall Heath, Birmingham, or Director, Biological Laboratory, Plymouth. REGENT'S PARK.

[96933.]—**Asbestos Fire.**—A stove fitted with a gas-fire would give out greater heat, per cubic foot of gas consumed into a room, than a gas-fire fitted into an existing coal-fire grate; the latter has the best appearance. The cost of the apparatus itself and the gas per hour will depend upon the dimensions of the room and also the temperature it is proposed to keep it at. The "first cost" would be lowest if the grate is used. A person fixing such apparatus should have experience in that work, else the best result is not obtained. For instance, it is not desirable to permit a large amount of heat to escape up the chimney, and firebrick cheeks should be employed as well as the ball fuel.

161, Albion-road, N. A. CLARKE.

[96937.]—**Electric Light.**—It depends entirely on the facilities you have for generating your electricity. Gas at 3s. 8d. per 1,000c.ft. is practically equal to electricity at 4d. per unit. 1,000,000c.ft. of good gas should give 3,200,000c.p., or say 2,200c.p. every day of four hours. A dynamo to do this work should give 140 amps. at 65 volts pressure;—will cost about £75 and take about 15H.P. to drive. A gas-engine would cost about £125; a steam-engine and boiler about £140. A set of accumulators about £60. With such a set, even burning gas, your electricity should not cost you more than 2d. per unit, which would save you about £54 a year on your gas-bill, so that, reckoning the outlay on plant at £400, and your interest at 5 per cent. = £20, you would be the gainer by £34 per annum. S. BOTTONE.

[96937.]—**Electric Light.**—If "Electric" will give me the following particulars, I will endeavour to give him a fair estimate. As the query now stands, there is no data to work upon:—(*a*) Number of burners? (*b*) How long in use (maximum and average number of hours per day)? (*c*) Has he steam or other power available? (*d*) What is the nature of area already lighted? Take, for example, "Electric" has 60 burners, each consuming 10c.ft. per hour, burning five hours per day, will make roughly the total amount he consumes per year; but the number may be considerably out. The above burners will consume 600c.ft. per hour = 2s. 2d. approx. To replace these burners with sixty 16c.p. lamps will require an engine giving 6B.H.P. If a reliable oil-engine is installed to do this work, the cost for oil will be from 4½d. to 6d. per hour, to which must be added interest, depreciation, &c. With ordinary surroundings, and conditions being equal, "Electric" will find electric light the most economical. If you care to give me the particulars asked for, I shall be most happy to help you, if you advertise your address in the usual column. F.I.S.E.

[96937.]—**Electric Light.**—You could have the electric light far cheaper than your gas-light, as you will see from the last page of our new catalogue (which we shall be glad to send you), where the saving on 100 16c.p. lights is £89 per annum. The figures are there worked out for the consumption of of 1,095,000c.ft. of gas at 3s. 9d. per 1,000. The cost of a good gas-engine and a reliable and efficient dynamo for 100 lights of 16c.p. would be about £80 and £55 respectively.

WEBSTER MICHELSON AND CO.
Dudley. Electrical Engineers.

[96939.]—**Question in Arithmetic.**—I take it that the field is bounded by a gravelled walk 13ft. in width, and that the other two walks are at right angles to each other. If so, the following is the solution—

4,840 × 2½ = 12,100 = number of square yards of ungravelled portion.

$\sqrt{12,100}$ = 110 = length of side of ungravelled portion.

Adding (13 × 3)—

110 + 39 = 149 = length of side of boundary wall.

Multiplying by 4—

149 × 4 = 596 = total length of boundary wall.

Cardiff. D. OWEN.

[96940.]—**Wireless Telegraphy.**—To MR. BOTTONE.—Let your pole be about 10ft. higher than the surroundings. It will be well to have it surrounded by a wall of wire netting, which should be well insulated from the pole, and from everything except one ball of the transmitter. For simply bell-ringing, the Wimshurst is far and away the cheaper and more effective. Of course, you will understand that you arrange the transmitter in circuit with the outside of the jars, and place the prime conductor bells at a distance proportionate to the distance between the transmitter balls. An inch spark gap should be ample for so short a distance. I do not know what facilities you have for making up your apparatus; but as a little guide as to price, it may be of service to you to know that we send out a complete set, with Wimshurst transmitter and receiver, with relay, coherer, decoherer, bell, and batteries for £5 complete. Should you care to write to me as below, I shall be pleased to send you working instructions.

Wallington. S. BOTTONE.

[96944.]—**Laminated Drum Armature.**—To MR. BOTTONE.—Wind the armature with about 2lb. No. 20 d.c.c. in 24 sections, using a twelve-part commutator. Wind the field-magnets with 12lb. No. 22 d.c.c., connecting up in shunt. If you use Manchester type fields, with good wrought-iron cores, about 1¼in. diam., 4in. long, you should get about five amperes at 50 to 55 volts pressure with ease. S. BOTTONE.

[96946.]—**Navy.**—Yes. A year in the engine-room, on the watch, is sufficient, when the candidate can show that he has had three years in a shop where marine engines are made. They need not be marine engines: the real requirement is service on board ship (in the engine-room, on watch). Full particulars can be found in back numbers, or direct from headquarters on application to the Board of Trade. The Government supplies all the information necessary, which can be had on application. Anyone can sit for the examination if he has had a year at sea in the engine-room "on the watch." See p. 256. W. T.

[96948.]—**Launch.**—The Colt Disc Marine Engine, Hartford, Conn., America, give for their make the following dimensions: Diameter pistons, 3in.; total weight, 500lb.; diam. cylinder with over castings, 15½in. Pipe connections—steam, 1in.; exhaust, 1½in. Boat—length, 35ft.; beam, 8ft.; draught, 30in. Propeller—diameter and pitch, two blades, 24in. by 24in. Prices (1887), including reversing gear, thrust-block, coupling, and automatic lubricator, 327dol. Engine occupies small space, runs at high speed, no dead centres, self-inclosed, has few wearing parts, uniform wear, made in best manner and materials, easily operated by one person. See C. F. Kunhardt, steam yachts and launches, effective H.P. at 120lb. 10 to 12H.P. Hurst and Lloyd, High Holborn, have in their window several oil 6H.P. engines adaptable for your purpose; weight from ¼ to ½cwt.; worked by petroleum; price, I understand, about £30 at shop. I do not note in W. S. Hutton's "Practical Engineer's Handbook" anything as to weight, except

as regards crank and half-length of connecting-rod next the crank-pin; but he gives for nominal H.P. with 150lb. pressure per square inch:—Let H P = diameter of high-pressure cylinder in inches; let M P = diameter of the intermediate cylinder in inches; let L P = diameter of the low-pressure cylinder in inches. Then nominal H.P. equals—

$$\frac{HP^2 + MP^2 + LP^2}{5 \cdot 5 \times x}$$

where x = the number of times the indicated horse-power is required to be greater than the nominal H.P., &c. REGENT'S PARK.

[96953.]—**Steam Exhaust.**—Why not put end of exhaust pipe into chimney? G. A. HAIG.

[96955.]—**Stage Thunder and Lightning.**—As regards lightning paper, perhaps this, from W. H. Browne's "Firework-Making for Amateurs" may be handy. He says the chief difficulty is to get rid of all traces of acid (oil of vitriol and nitric acid solution) in which the suitable paper is dipped: there is a liability of spontaneous combustion and explosion by detonation in a violent manner (40 vitriol, 5 fuming N. acid). One plan he advises is to use weak solution of sodium carbonate for last washing (if acid is used), and afterwards well wash to remove soda solution, as latter gives yellow tinge to flame of paper if not removed—a colour destructive to any other tint desired. Advises, if not particular to expense, to try soluble salt of lithia instead of strontium saturated solution for crimson, which he gives for colour. As to colour papers are to be when fired, each paper receives colour effect as follows:—Each sheet steeped for five minutes in warm saturated solution of strontium chlorate (crimson), barium chlorate (green), copper chlorate (blue), potassium nitrate (violet), afterwards hang up to dry. The chlorates may be made sufficiently pure by mixing warm solutions of chlorides of barium, strontium, or copper, with equivalent warm saturated solution of potassium chlorate. After drying small pellet, lighted at one point, thrown into the air, a flame of intense colour is produced. I believe thunder is produced by moving heavy weights about. REGENT'S PARK.

[96956.]—**Glass Silvering.**—Same way as gilding, but more isinglass used, as silver leaf is softer and requires a stronger agglutinant. Thus: Prepare size of 2oz. or more of isinglass in sufficient water to cover it; boil. When dissolved, add one quart of alcohol and dilute to two quarts with water, and filter. Flood surface of glass with size, lay leaf flat on it, scatter whiting previously warmed over whole. Should chalk form lumps in heating, rub fine; but dusting therewith must be delayed till leaf is dry. When leaf is dry dust over with a fine brush, and then back with copal or dammar lacquer. Before doing this last coat, repeat silvering once before. When backing is dry remove superfluous silver by rubbing with moistened finger. REGENT'S PARK.

[96957.]—**Quill Pens.**—Has "Old Subscriber" ever seen a small tool used for making the above? If not, doubtless any cutler will show him one. Mine is marked Rogers, Sheffield. It is in shape somewhat like a pocket-knife, and contains a small blade at one end, and the pen-cutter at the other, which is actuated by pressing down a small hinged lever. It trims and slits at the same time, and certainly does its work well. It is no new thing. To cut the slit in the ordinary way, having trimmed the pen to shape, lay it back down on a block of wood, use on the inside of quill the point of a knife having a thin keen edge, press the knife down on the quill, and at the same time draw the quill away from the knife. Cross-cut the tip after slitting. If you cannot get the slit central, trim the sides to the slit. T. J. LENEY.

[96957.]—**Quill Pens.**—Soak the quills in water until they are soft, and use a short, but sharp, blade to split them. Some years ago, in a shop window in Newgate-street, London, E.C., a man could be seen at work slitting the pens as fast as he could handle them. Not quite sure whether they (the quills) were soaked in water or placed in hot sand. Any way, the quills should be softened by heat, and then slit. Try putting the quills into warm water, and then slitting with a sharp knife. Do it easily by putting the quill into the mouth for a few seconds; but a short and sharp knife is the best tool. S. R.

[96957.]—**Quill Pens.**—Have years ago seen makers using a conical wood plug to form a base for splitting nibs on. REGENT'S PARK.

[96959.]—**Moulding Slag.**—The writer saw several walls in Llanelly, South Wales, a few days ago, with half-round slabs of slag for the coping. The writer will be in Llanelly again in the course of a week or so, and will ascertain, if possible, the information "Constant Reader" desires. F.I.S.E.

[96959.]—**Moulding Slag.**—If the ironworks would run their slag in the molten state into moulds like bricks, but a good bit larger, they would sell well for building, I should think. G. A. HAIG.

[96961.]—**Electrical.**—A zinc copper cell, excited by dilute sulphuric acid, had an E.M.F. of about 0·75 volt. Whether one or fifty couples be immersed in the same cell, the E.M.F. remains the same; but if the couples be placed in separate cells, and coupled in series, the volts increase as the number of cells. The zincs consume less to waste, if amalgamated. S. BOTTONE.

[96962.]—**Multiple Wimshurst.**—The trouble caused to "F. W." is probably due to the "knotting" which he uses to cement the smaller and the larger discs together. I do not know the composition of the knotting; but probably it is this which persistently holds the plates free from excitement by reason of its conductivity. The discs should be fully ⅛th thickness, and then they will be about sufficiently strong to resist bending when under electrical excitement. The cheap, black vulcanite is really more durable, and better for the purpose than is the high-priced brown vulcanite. In buying, I ask for the cheapest, because it is best for the purpose; but I always test it before using it. I have some now which is perhaps eight years old, and it is now as good as when new. A good-condition machine should excite itself with one-half turn of the handle. This in any atmosphere and without warming. J. W.

[96962.]—**Multiple Wimshurst.**—To MR. BOTTONE AND "J. W."—It is very difficult to locate the faults in a Wimshurst without examining and testing it. However, judging from your description, and always presuming that plates 1, 4, 5, and 8 are rotating in the one direction, while plates 2, 3, 6, and 7 are going in the opposite, and that the brushes have been so set as to allow for this (see "E. M." for July 7, '99, reply 96194, for illustration of current brush arrangement), I am under the impression that the fault lies with the "knotting" which has been used to stick down the 15in. discs. This is apparently still wet; and as the narrow ends of the sectors lie in contact with this, all the charge is quietly leaking away to the spindle. The sectors are, to my mind, too few, too large, and certainly too long. Remove the 15in. disc, if possible; clean them and the plates thoroughly with methylated spirits, followed by a polish off with magnesia carbonate cream. Then, replacing the smaller discs on the larger ones, make eight small equidistant holes around the edges of the 15in. discs, reaching through the larger discs, and stitch together with good silk twist, which you can varnish over outside with thick shellac varnish. This will probably set matters right. Provided the neutralising ends make good metallic contact with each other, it does not matter much how. I have tried all qualities of ebonite, and, except when old and perished, find little difference between the cheaper and more expensive kinds. The harder varieties are the best for Wimshursts. I allow 4in. between each pair. S. BOTTONE.

USEFUL AND SCIENTIFIC NOTES.

Largest Meteorite.—The largest meteorite of modern times fell on March 12 this year, close to Bergaa, on the Finnish Gulf. It has recently been recovered from the bottom of the sea, having made a hole in the ice 30ft. in diameter. The meteorite, on reaching the water, burst into a number of small pieces, and it is impossible to form any idea of its shape. The pieces recovered weigh 640lb., the largest having a weight of 140lb.

Monoliths.—Owing to the introduction of rock-drills and channelling machines, the cutting of such monoliths is now an exceedingly simple matter, and a number are now being prepared for the new cathedral of St. John the Divine at New York. These monoliths in their finished state will be 6ft. 3in. in diameter by 54ft. long. They are of granite, and the rough block cut at the quarry measures 64ft. long by 8ft. 6in. by 7ft., and weighs 310 tons. A gigantic lathe is being built to turn it down to its finished dimensions.

Cordite.—The ballistic power of cordite is very nearly four times as great as that of the black powder it has replaced. Thus, 1lb. of cordite fired in the 3in. 12-pounder field-gun is equivalent to the 4lb. of selected pebble powder which used to be the service charge. It has further to be noted that cordite charges cannot be exploded by being struck by bullets, so that there is no danger of the artillery limbers being blown up by hostile fire. A pressure of 120 tons per square inch can be obtained by firing cordite in a chamber which it fills completely, whilst with black powder, under similar conditions, a pressure of 43 tons only is reached. In practice a considerable void space is left in the powder chamber, with a view to keeping down this maximum pressure; and, in fact, a maximum pressure of 16 tons on the bore of the gun is what is aimed at under service conditions. The size of the cords used for guns of different calibres is such as to insure that the burning of the charge is completed in the same time as the projectile takes to travel down the bore.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered, are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last, "Glatton" has replied to 96487, 96496, 96574, 96651, 96659.

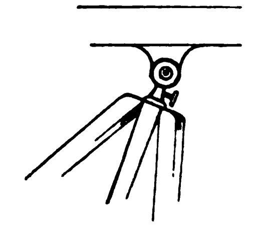
QUERIES.

[96963.]—**Gassner Dry Cells.**—Would some reader kindly give constructive details for the making of a Gassner dry cell? I cannot obtain gypsum. Would plaster of Paris do instead? What proportions should exist between plaster and zinc oxide cell to take a 6in. by 1½in. (or similar size) carbon plate?—VERITAS.

[96964.]—**Typewriter Ink Ribbons.**—Can any reader supply information regarding the method of making typewriter ribbons, and the composition of the ink, and method of applying same to ribbon.—TYPEWRITER.

[96965.]—**Equatorial.**—Inclosed is sketch of my 8in. achro. stand. I would like to mount an equatorial head on it. Unlike one mentioned by Mr. Ellison lately, it has



no screw motions. I would like to know if it is possible for an amateur to apply a driving-clock motion? I am in the clock line, and could easily get a movement driven by weights if I knew how to apply same to a telescope. I would be very glad of any help, and sketch if possible.—EQUATORIAL.

[96966.]—**Selenium.**—From what material and by what means is selenium produced? In using selenium (as in seeing by electricity), will not an induction coil be necessary to transmit the current to any distance? It seems to me that a current produced by this means must necessarily be feeble. What book can I get treating on selenium?—INVENTION.

[96967.]—**Grinding.**—Will someone kindly tell me what power gas-engine I should require to properly drive a 48in. grindstone for grinding new edge-tools after being forged? Also, sizes of driving-wheel and pulley-wheels on shafts and stone would be acceptable, and revolutions stone should make.—SIXTEEN-YEAR SUBSCRIBER.

[96968.]—**Liquid in Toys.**—Would any reader kindly inform me what red liquid is used in children's toys which boils by heat of the hand or mouth?—EXPERIMENT.

[96969.]—**Oscillations of Pendulum.**—Will some reader kindly help me with the following? If l is the length of a pendulum making 1 oscillation per second, and $l + c$ and $l - c$ the lengths of two other pendulums, where c is very small, prove that the sum of the number of oscillations of these two pendulums per day is very nearly $2 \times 60 \times 60 \times 24 \left(1 + \frac{3c^2}{8l^2}\right)$.—TRIP.

[96970.]—**Reversing Arrangement for Oil-Engine.**—Would some readers explain one or two of the best and easiest ways to make reversing arrangements for an oil launch-engine, about 1H.P., either for reversing screw, shaft, or engine? Also, which is the best place to get castings and forgings, and what book is there on making the above engines?—ROLANDO.

[96971.]—**Wind Motor.**—Could anyone give me particulars of a wind motor to drive small dynamo sufficient for lighting a small house? I am carpenter by trade, and understand sufficient of electricity to fit up dynamo and accumulators if the method of making motor is described. I should prefer it of wood, or most part. I live on a hill, and get plenty of wind.—H. BRAND.

[96972.]—**Motor Cycles.**—To "THE WRITER OF THE ARTICLES."—I intend constructing a light four-wheel car, after style of quadricycle described, but without the tricycle framing, sprocket, pedals, &c., the car to carry two persons. Would you kindly supplement your excellent articles with details of frame, steering and driving gears? I think it would interest a great many readers of "E.M." In any case, I would like information and sketch. Is motor sufficiently powerful for the above? Only moderate speed required.—M. H. B. C.

[96973.]—**Sand-Blast.**—Can any of "ours" give me particulars or any information of the sand-blast apparatus? I should like to know the pressure of air, and how produced, and if power is required.—M. A. P.

[96974.]—**Acetylene Gas Generator.**—Can any reader inform me how to make an acetylene gas generator? I am making a small motor, and am rather at a loss.—J. W. Drury.

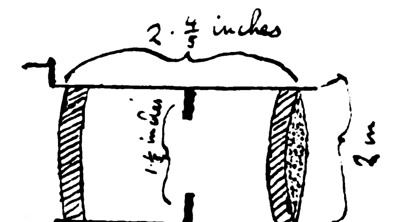
[96975.]—**Fishing Lines.**—Would be glad to learn of a good dressing for fishing lines.—Angler.

[96976.]—**Kieselguhr.**—Is there any preparation by which I could solidify or harden kieselguhr?—W. M.

[96977.]—**Varnishing Calico.**—Can any reader give me particulars for varnishing calico, for the purpose of making a small gas balloon?—W. M.

[96978.]—**Nervous Affliction.**—Can any reader advise a remedy? I am a young man, 25 years of age, with taste for study. When I was 15 I made study my only recreation, and this caused me a peculiar headache all day long, sometimes between the eyes, and at others at the back of the head and neck. This went on until I was 20, when the headaches left me, and in their place I was left with a very peculiar cramping seizure in the head, just as I was dozing off to sleep, and now I never go to bed but I have about 20 or 30 seizures, never lasting more than three to six seconds in duration. Muscularly speaking, I am as strong as a bull, and a model of strength and physical development, and I feel quite well and strong during the daytime—in fact, never feel the slightest weakness until I try to sleep; then I have these seizures, which render sleep impossible for about two hours every night. If I once get to sleep I never have another seizure on going to sleep a second time during the same night. About one night a month I sleep without seizures. Is it not a peculiar case? Can anyone advise?—W.

[96979.]—**Lens for Lantern.**—I have a portrait lens 8¾in. focal length to cover 5 × 4 plate. Can anyone tell



me (1) if it could be used with condensers for an ordinary-sized magic lantern, (2) the size of condensers, (3) the arrangement of lens and condensers, and shape and position of reflector, and (4) how to arrange two or three acetylene gas-burners in the lantern?—K. O. S.

[96980.]—**Turning Taper Rollers.**—Would some reader kindly inform me the best way to turn taper rollers 8ft. long 1½in. diam. at large end, to ⅝in. at small end?—H. D.

[96981.]—**Barometer.**—I am interested in your series of articles, "Some Meteorological Instruments and Their Uses," and would like to make a large barometer worked with oil. What would be the best to use—linseed-oil or glycerine? I thought of making the tube siphon-shape in lead tubing, and with the largest part of the bottom length of glass. Could you tell me how to fasten the glass tube to the lead tube, what length of tube I should need, and in what manner I could fill with oil or with glycerine so that I should get the top part free from air?—R. Weigley.

[96982.]—**Noisy Wimshurst.**—What is the reason of my Wimshurst machine making this peculiar noise? I find that after having revolved the plates round for about two minutes I hear a hissing noise at both jars.—E. G. Woodhouse.

[96983.]—**Steam Motor Waggon.**—I am desirous of making a waggon. I have a vertical engine and boiler, boiler works to 100lb., engine 3in. cyl., 4in. stroke, single, very compact. I should like to know how the mechanism is made for allowing the back wheels to turn corners, and how can I make a two-speed gear, two miles per hour and six miles per hour? Engine runs about 600 per minute, back wheels 3ft. diameter, chain drives. Also, how is the front lock worked in a heavy waggon, assuming the waggon to weigh, when complete, with water, oil, &c., 30cwt. about? What load could I take up gradients of one in six? If I compounded the engine, what extra load could I take up the same incline? I may say I have the facilities for doing all the work required. I should be pleased for the name of any books that would help me.—E. D. T.

[96984.]—**Plugging Holes in Steam Jackets.**—A cast-iron (1in. thick) steam jacket has some square holes, 1in. area, in same, and I propose driving from the inside of jacket some hard wood plugs to fill up the holes. The steam pressure will be, at the highest, 55lb. Will this be successful to stop the leakage? Plugs will be carefully dried.—Raglus.

[96985.]—**Condenser.**—I want information how to make a little condenser to suit a 20ft. steam launch, in order that salt water may never be required to enter the boiler. I understand that some steam must necessarily be wasted, but that the bulk of it can be easily condensed, and so used over and over again with the addition of a make-up supply of fresh water to be carried in a small tank. I think many other small launch owners, who have their boats on salt water would appreciate the information.—Old Colonial.

[96986.]—**To Mr. Reginald A. R. Bennett.**—I have made a phonograph, but cannot get it to act, so now I have converted it into the working on your principle. I got so far, but now I ask: Does the needle have any cutting edge, or is it like an ordinary-shaped needle? And I have a brass cylinder, upon which I make my covers (records), but I find they stick to the brass cylinder, and I have difficulty in removing them. Can you explain the reason, and is it necessary to have a zinc cylinder to leave a thin stratum in place of a brass cylinder? Could you give me a little information?—A Tryer.

[96987.]—**Series.**—Will some mathematical reader kindly sum the following infinite series?—

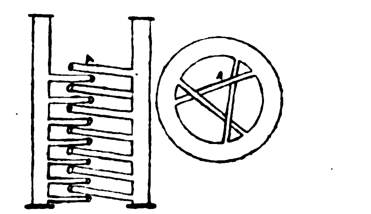
$$1 + x + \frac{x^2}{|\underline{2}\;|\underline{2}} + \frac{x^3}{|\underline{3}\;|\underline{3}} + \&c.$$

—Factorial.

[96988.]—**Zither Construction.**—Will any reader kindly give me information on the above subject, but more especially the best method of finding the correct position of the frets on the finger-board, the size and place for the sound-hole, and the position and number of the bridges inside the body of the instrument? In what way does the depth of the instrument affect the quality of the sound, and what is the best proportional depth?—Kohu Kohu, New Zealand.

[96989.]—**Polish for Brown Shoes.**—Recently some recipes were published for the above in the "E.M." I tried several of them. I tried for the tints annatto, phosphine, leather-brown, Bismarck-brown, alkanet-root, &c.; but I do not get a tint matching Propert's brown-boot polish. Can any reader inform me how to bring that colour? Also, how are the Universal creams (white) made for all kinds of leather?—Krishnalal Nanabhai.

[96990.]—**Boiler for Motor-Cars.**—Can someone kindly give an opinion of a boiler similar to sketch?



A, brass tubes slightly rising with the ends riveted to inner iron pipe, and so arranged to give most heat and strength.—A Cornishman.

[96991.]—**Cutting Mitre Wheels.**—I have to cut a pair of six greater diametral pitch wheels, with 21 teeth. I have the dia. 3⅝in. Will someone please tell me how to find the correct angles? Is there a formula for finding the width of space? I have a universal milling machine (Cincinatti No. 1½). How must I set it to cut taper on sides of teeth?—C. G.

[96992.]—**Petroleum Drinking.**—I have seen it asserted in print that petroleum drinking is at present prevalent in Paris. Can any reader of the English Mechanic give the information—(1) Why it is taken? (2) In what form is it used? (3) What are its effects?—W. A. D.

[96993.]—**Coil.**—Will Mr. Bottone kindly inform me the distance up to which a 2in., also a 6in., coil will work for wireless telegraphy? Also the height to which the vertical wire must be carried in each case? Is there any book treating on the subject suitable for an amateur?—C. H. K.

[96994.]—**Motor Cycles.**—Could "The Writer of the Articles," or some other well-informed reader, give us a definite answer with regard to the long cylinder bolts? I am about to start work on one, but would like to know about this first.—E. M. S.

[96995.]—**Great Central Newspaper Express.**—Can any correspondent give particulars of the actual running of the new early newspaper fast train to Manchester over the Great Central route? No need to waste a lot of space in useless details, as I only desire times of arrival at the stopping stations, and average speed between them.—A. S. L.

[96996.]—**Bone Bearings.**—Some time ago our friend "Jack of All Trades" advocated bone bearings for high-speed machinery. Will he kindly say what kind of bone, and how it should be prepared for, say, a 5in. lathe mandrel? Does he mean ivory?—Marrow Bone.

[96997.]—**Dynamo.**—I have a compound-wound dynamo, 110v. 16a., and when running the casts get hot and the voltage falls 10 volts in a very short time. I have tried running the dynamo with mains, pilot lamp, and voltmeter all disconnected, and it still gets hot. I should be glad if anyone would kindly explain the reason.—M. S.

[96998.]—**Accumulator.**—I have a small 6-volt accumulator which I charge from a 105-volt main, using a 100-volt 16c.p. lamp as a resistance. If I charge it for three or four hours and then light up a 6-volt lamp with it, the light only lasts about 15 minutes; but on giving it a rest, it will again light up, and so continue for about a week, a few minutes at a time. Will someone kindly say where I am at fault? Is the resistance I am using suitable?—M. S.

[96999.]—**To Mr. Bottone.**—In your "Guide to Electric Lighting" you describe a modified form of Bunsen battery, using a mixture of nitrate of soda and sulphuric acid in the carbon department. Please say the proportion of this mixture, and also the strength of the exciting fluid.—L.

[97000.]—**Armature.**—Will any electrical reader kindly say how I can find out the correct amount of wire and gauge output in amps. and volts for an armature 3¼in. long, 1⅞in. diam., armature 16-cog drum.—H. E. Woodhouse.

[97001.]—**Collodion Cotton.**—I have some collodion cotton that I want to dissolve into a gelatinous mass. I have tried camphor and methylated spirit, but without effect. I shall be thankful if any reader can inform me how to dissolve the cotton.—W. C.

[97002.]—**Nasmyth's Locomotives.**—In the life of James Nasmyth, the fact is recorded that he built engines for the Great Western, Bristol and Gloucester, and London and Southampton Railways. Can any of your readers give particulars of any of these, and say how many engines have been built at Partricroft works from 1838 to the present time?—Inquirer.

[97003.]—**Rothwell's Engines.**—According to several old railway books, it seems that in early years a firm of Rothwell made many locomotive engines. Can one of your readers oblige by giving the place where their works were situated, and also say when they began to build engines, and if the old firm exists now?—Inquirer.

[97004.]—**Wireless Telegraphy.**—To Mr. Bottone.—I have a 4in. coil and an exhausted Marconi coherer 1½in. by ⅛in. outside, gap 1/16, and two 2in. brass balls. (1) What distance should such a coil communicate, and is the coherer up to it? (2) What wire and core for the relay? (3) What sized Leclanché for this circuit? (4) Should wings be of thin brass, and what size should they be, and at what height for the greatest distance coil is capable of?—Dies.

[97005.]—**Physiology of the Brain.**—Can any reader give me the origin of the following paragraph, which I found in a paper that does not quote its authorities? "The more advanced of modern physiologists now claim that the back lobes of the brain are the seat of the highest intellectual faculties, a theory which is in direct opposition to that of the phrenologists and to popular opinion as well, the latter being that a high forehead is a proof of superior intelligence. An anthropologist of high repute points out that a man, of all creatures, has the most highly developed back lobes, and that the ablest men and races have them in the highest perfection. Idiots and confirmed lunatics, according to his investigations, have these imperfectly developed or in a very bad state."—T. P.

[97006.]—**Metallurgy.**—How was cast iron converted to wrought before the invention of puddling?—M. C.

CHESS.

All communications for this column to be addressed to The Chess Editor, at the Office, 332, Strand.

PROBLEM No. 1699.—By C. A. Gilberg.

Black. [8 pieces.

White. [7 pieces.

White to play and mate in two moves.

(*Solutions should reach us not later than Nov. 13.*)

Solution of Problem No. 1697.—By A. F. Mackenzie.

Key-move, Kt-K 4.

NOTICES TO CORRESPONDENTS.

Problem No. 1697.—Correct solution has been received from Whin-Hurst ("Recent events must make the disappointment keener"), A. Tupman, J. E. Gore, T. Clarke, Rev. Dr. Quilter, Richard Inwards, A. E. Stokes, W. Peters, J. Mason, F. B. (Oldham).

The specific inductive capacity of guttapercha is 2·46, of rubber 2·34, of paper nearly unity. The average capacity of a telephone cable should be 0·080.

All standard Russian railways are required to equip their goods waggons and engines by January 1, 1903, with the Westinghouse air-brake. The order involves the equipment of 300,000 waggons, as well as a large number of locomotives, 60,000 of which are to be fitted with air-brakes, and 240,000 with air-pipes and couplings, inside of three years.

There is an outcry in Philadelphia against the extending use of bituminous coal, which is rendering the city "as sooty as any western soft-coal city." Previous to 1890 practically all this coal burned in Philadelphia was included in the 250,000 tons annually consumed in making gas. Ten years ago bituminous coal began to be used for other purposes, and in 1893 the total consumption rose to 900,000 tons; in 1897 and 1898 it was 1,600,000 and 1,450,000 tons respectively, according to the Government reports on mineral resources for these years. While the increase in the use of bituminous coal in Philadelphia has been 2,034,977 tons in the period 1893-98, the increased consumption of anthracite coal only amounts to 50,468 tons.

INLAYING.—V.

IN Fig. 96 is seen a flowing frieze ornament that can be adapted for single or duplicate uses, or with slight modification it forms an excellent centre-piece when used singly. By the addition of a centre at the right hand, and reversing the flow of the ornament, we gain a long frieze. Fig. 97 is similar to the above, but a trifle more difficult to execute; can be converted into a long frieze by adding a centre, as before stated. Fig. 98 can be repeated *ad lib.*, and will convey our meaning with respect to reversing the flow of the ornament.

The above can be cut in white holly in almost any ground colour; but if coloured ornaments are used, particular care should be bestowed to gain the desired effect without resorting to glaring contrasts. Judicious cutting up will permit of very effective shading. Or the same will look exceedingly well if the ornament is cut in German silver or brass; but silver is far superior, and when well engraved it will give satisfaction for the trouble taken. The metal will look well if the groundwork is rosewood, coromandel, or violet ebony.

The basket of flowers, as shown in Fig. 99, has a pleasing effect if cut in a rich mahogany. The addition of a spray at both sides tends to enhance the utility. A scroll ornament springing from the basket will not look out of place, providing the additional ornament is not too pronounced.

A few progressive studies of panels are given, as at Fig. 100 and Fig. 101. They will look well in almost all the grounds in vogue at the present time. They have a very pleasing effect, if the ornament is cut of dark mahogany, and the groundwork of satinwood, Hungarian ash, or bird's-eye maple.

The other panels (Figs. 102, 103, 104, and 105) illustrate the progressive stages of ornament. They will bear considerably enlarging, and can be cut in white holly or in coloured woods, as in the Pompeian style of ornament.

Our next stage will be the working together of brass and shell (tortoise), the latter being tinted. Different colours look and, not least, wear well.

The saws in use for metals should be purchased ready for use. A careful touch of the superfine file after a little use will prolong the life of the saw; but remember our warning: not to cut any one tooth lower than the other. It is fatal to the work and saw as well.

Figs. 106 and 107 are two friezes that can be cut in brass and tortoiseshell, silver and engraved, and in leather.

The brass used for our purposes should be the best annealed E metal. The German silver is also annealed, but still somewhat harder than brass. The tortoiseshell can be purchased ready split, but its future preparation has yet to be explained. There is also in the market a fairly colourable imitation made from the hoofs of animals, and this can be purchased in such substance as can well be employed for our purposes. Whether the imitation commands the taste of the reader matters not. We certainly prefer the natural shell, which looks what it is, and is far superior, whether coloured or not.

As the shell when purchased is invariably thicker in the middle, it must be reduced by scraping. A bent tool is the most convenient. A 1½in. plane-iron bent at right angles at the end of the slot is the best, but an ordinary piece of steel, hardened and tempered to the same degree as an ordinary cabinetmaker's scraper, will bear filing and setting in the same manner as the scraper.

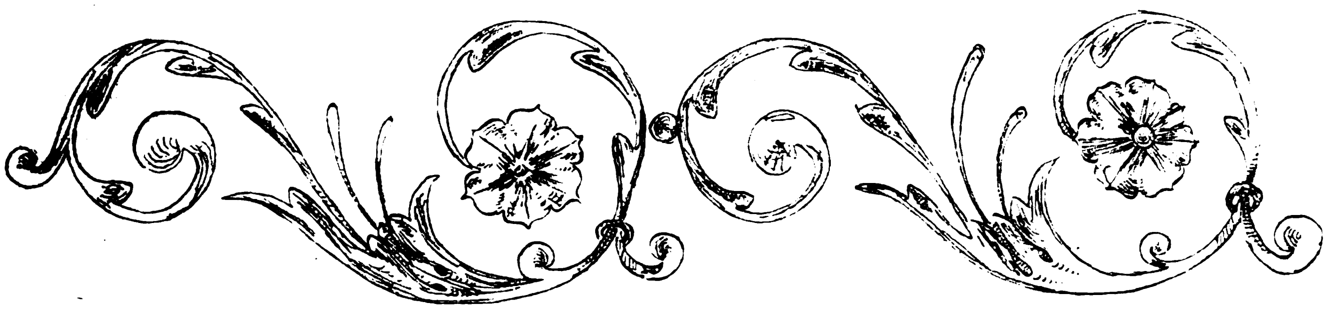

FIG. 96.

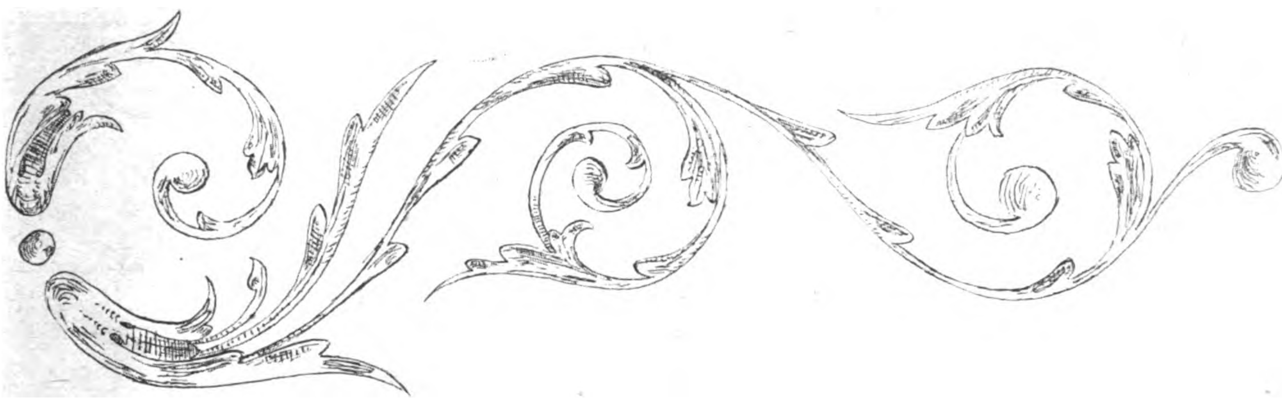

FIG. 97.

FIG. 98.

FIG. 99.

It being next to impossible to obtain a perfect equal thickness, as in the case of the metal, we have to pack up, so to speak, with paper *absolutely free from grease*, upon which we spread our colours. Vermilion is used for red reflections, arsenic for green; bright ultra-

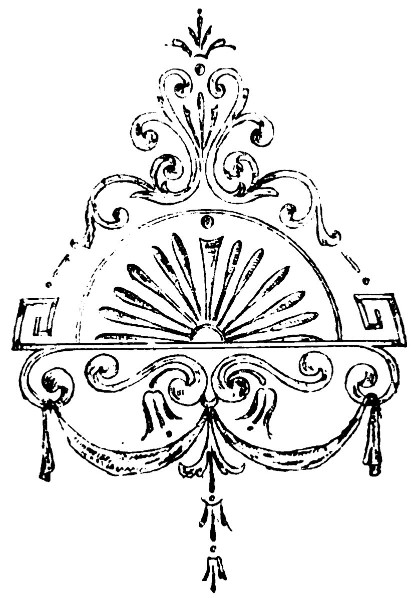

FIG. 100.

marine, gamboge, and carmine each for their respective colours.

An equal quantity of the best gelatine is added to the best Scotch glue in like proportion. When thoroughly mixed or "blended," the chosen colours are added

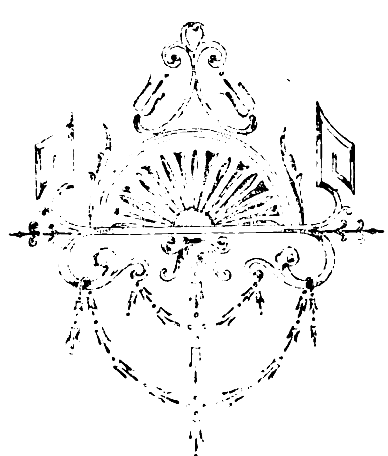

FIG. 101.

until a thick paste is obtained. The colours can be either brushed in or laid with an ordinary palette knife. The secret of success lies in having the paste well hot, and as consistently thin as will leave a good body of colour, free from lumps, and allowed to dry before a second or third coat is added if found necessary. We say necessary advisedly, because some pieces of shell may just possibly be very thin; consequently less opaque. They will show the colour up more—a fault that cannot well be remedied—but by judicious matching too glaring a contrast will be avoided.

Having chosen a sufficient number of pieces of shell for the object in view, they should be cleansed by scraping. The coloured paste will then adhere better, and the scraping tends to leave a fine surface free from blemish, where scratches or marks left in would reflect up and through the transparent portions of the shell, and thus mar the work beyond repair. The matching and piecing together is got by cutting with a pair of scissors, so that a number of irregular pieces when jointed together (and it matters not how or what form the pieces assume) will form one sheet of shell sufficiently large to cover our design, and of as near uniformity of colour as it is possible to obtain. Upon the outer face is glued the pounced design. The sheet of shell can now be tacked with fine pins, or glued upon the sheet of metal in use. If pins are used, they necessitate the drilling of the metal. A good plan is to bind the edges all round with brown paper. These directions apply particularly to work that will not take more than 6in. in width, as that is the general size the brass is rolled, although sheet-metal can be got almost any width, but it is an open question if the annealing is as perfect in the wider as in the narrow metal; but if found necessary to joint up the brass, a plan will be explained

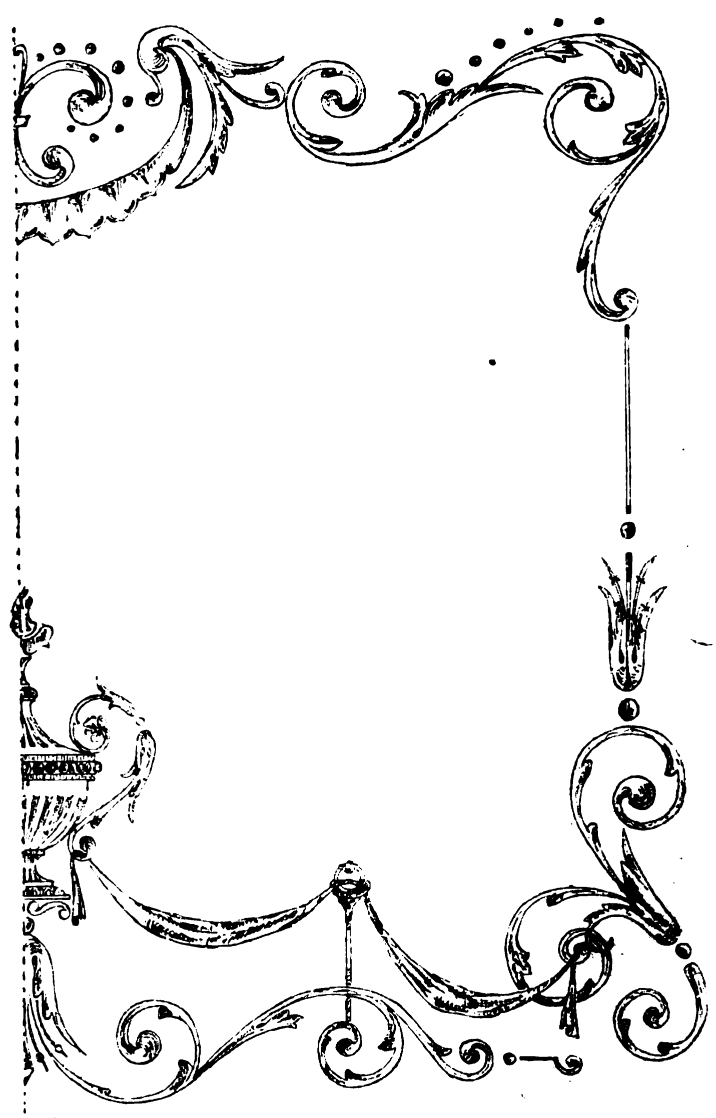

FIG. 103.

FIG. 102.

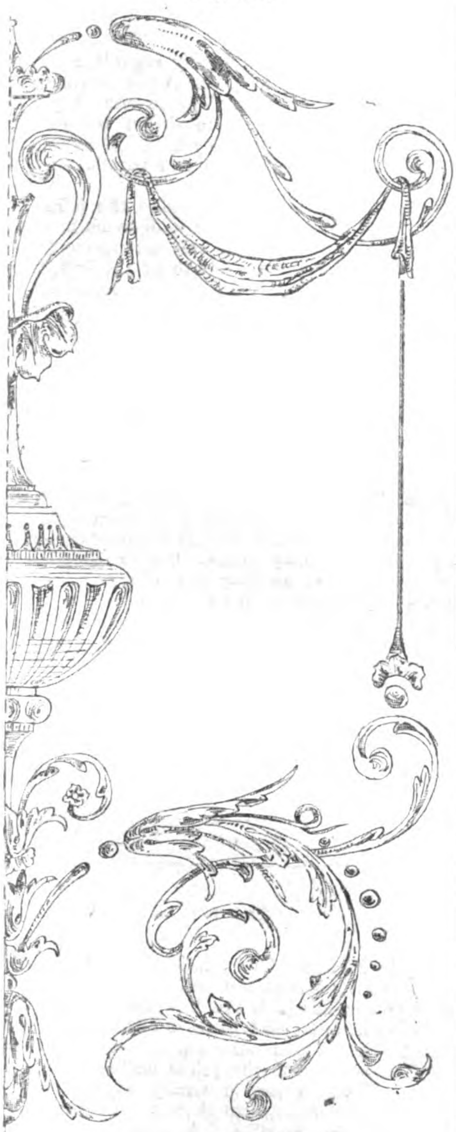

FIG. 104.

whereby the joint will not be so prominent or prone to show.

Another method is to joint up the shell on stiff brown paper (of course, after the reducing process is done), giving a touch of glue here and there to retain the whole

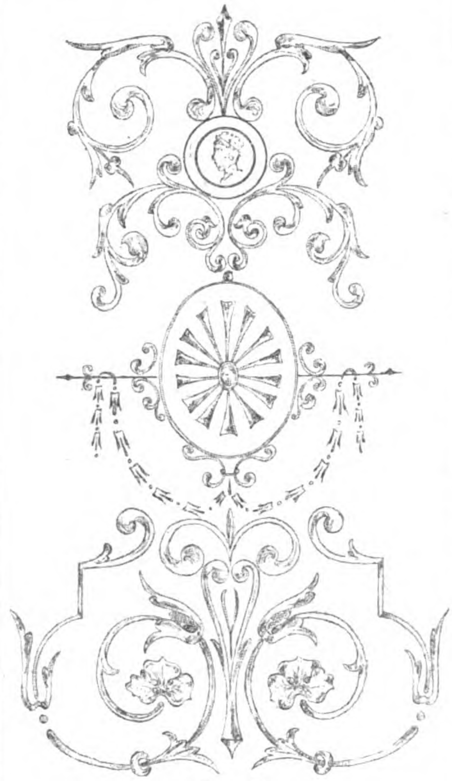

FIG. 105.

fairly firmly together. The colour can then be applied in thin coats, until the requisite density is obtained. When the coloured portion is thoroughly hard, the shell can be cut alone, using a backing of cheap stuff, as before explained. Cutting the brass by itself in either one or two thicknesses may be absolutely necessary, either because a large design demands it, or because a number of smaller pieces can be cut more economically. Again, by having four thicknesses of metal, a four-part design can be cut to great advantage, both in material and exact similarity of form.

Our work would be somewhat incomplete unless we gave means of laying our work after cutting. The difficulty lies not so much with woods that have fast dye colours, but with our work just touched upon. We therefore describe the process now.

Taking for granted the groundwork or body upon which it is intended to glue, veneer, or superimpose the cutting is ready, the first care is to tooth the face of the ground or body; next, to spread an even coat of glue, covering all parts. It should now remain for awhile; and then, when just tacky, the cutting can be laid gently, and in the exact position it is required to remain. To prevent any after-slipping, a few veneer pins should be driven in to fix it safely, but not into any light woods. Driving the pins on the edge of the cutting, and turning a portion over on to the veneer, will in many cases be sufficient. In no wise should holes be made in light wood; the result will be black spots.

The cutting being now in position, it remains to have in readiness a stout piece of mahogany about 1in. thick, named a "caul." The caul is gently heated, and should be of such heat as to cause a given quantity of glue to be exuded when even pressure is put upon the whole, allowing the work to remain under pressure until the remaining glue is thoroughly set. But, in the case of buhl-work, a slightly different course is pursued. It should have been stated that it is usual to have one or two thicknesses of ordinary paper between the cutting and the caul. We also want the paper in this instance, and a layer of some elastic material, such as a piece of felt carpet. Its uses are twofold. Firstly, when pressure is put upon the caul, the inequalities of the shell will have a better chance of being soundly glued to the groundwork or body. Secondly, it prevents the heat of the caul acting too directly. In gluing buhl-work, ever aim at gaining a good heat and no more. If the caul will permit the hand to be placed upon it, it will be about right.

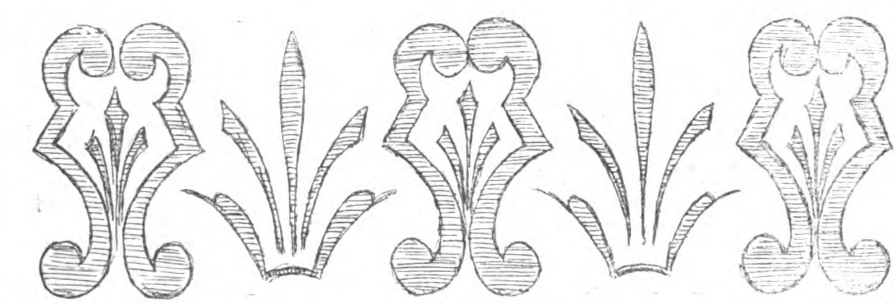

FIG. 106.

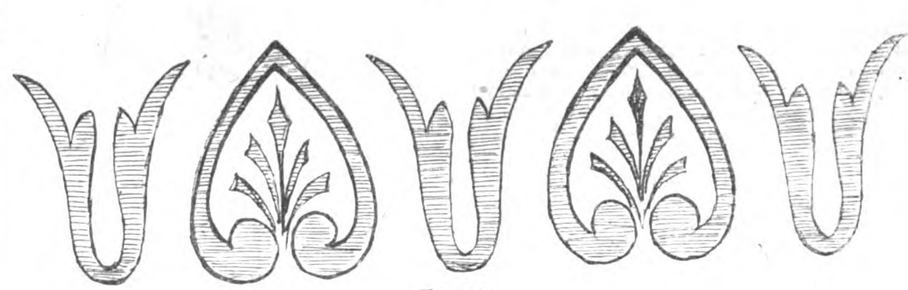

FIG. 107.

MILLWRIGHT'S WORK.—XVI.

THE fastenings of belts are very important details, because the joint is weaker than the solid material, and its strength depends upon the manner in which it is made. There seems scarcely a limit to the modes of jointing which have been adopted. Yet the old-fashioned lacing holds its own still, and is hard to beat. Though it seems to be used less than formerly, yet, when employed by a competent and experienced man, it is most efficient. The difficulty in its use is how best to arrange the lacing to obtain the maximum strength. Some slight projection, too, of the lace and of its ends is unavoidable, notwithstanding the free use of the mallet or roller. But this does not amount to

much in the hands of a neat strapper. Moreover, the process of lacing occupies some time, and must be done neatly if the belt is not to jump as it runs on the pulleys.

Metal fasteners have come largely into use of late years, and divide favour with laces. The objection to them is not non-efficiency, but that

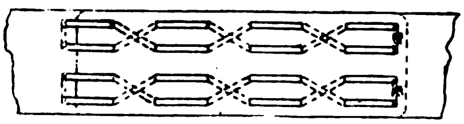

FIG. 87.

many are not flush on the outside, and caution has to be exercised lest the projections come in contact with anything, or lest the clothing of attendants should be caught by them. From this point of view the flush lacing has the advantage. Joints in which the ends stand up cannot be used with binder pulleys, neither can they be used on drives in which both surfaces come in contact with pulleys. Many of these fastenings, therefore, while efficient in holding power, do not fulfil an engineer's idea as to

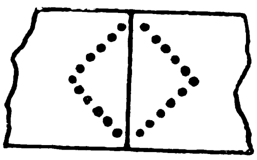

FIG. 88.

safety. All belts which are united in such a way that edges or fastenings stand up cannot be recommended for general use, though they are suitable for situations in which the belts are inclosed, or in which the duties of the attendant do not bring him into close proximity to them. A slight projection in a high-speed belt is liable to catch clothing, and for that reason should be discountenanced for general service.

All belts are built up by jointing short lengths of leather. This is done permanently by the manufacturers. Scarf joints are cut and cemented,

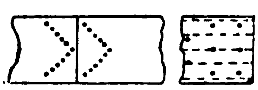

FIG. 89.

and lacing or riveting are added to make a permanent joint. In the shops the length of belting is usually connected in a temporary fashion, because joints have to be made afresh from time to time, in consequence of the inevitable stretching of the belts by the constant tension of service. Hence the joints made in the shops are not often cemented, because that takes longer in making than a temporary lacing. Tullis and Son, however, recommend, when possible to dispense with lacing in favour of cemented joints, and carry it out in their practice.

Belts are joined temporarily with butt, or

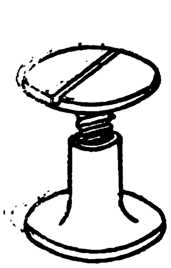

FIG. 90.

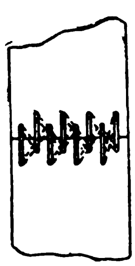

FIG. 91.

with scarfed ends. There are objections to both. The scarfed joint is probably the more common. If made neatly, it permits the belt to take the curves of the pulleys better than the ends of a butted joint. If badly made, it is open to the objection of being either too thin and weakened, or too thick and bunchy. In these details nearly everything depends on the strapper. For this reason none but a qualified man or men should be allowed to meddle with its.

A neat scarfed joint is made by shaving the leather as truly as possible off to a feather-edge, then punching holes with a hollow steel punch,

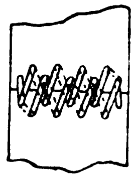

FIG. 92.

through which the laces will be thrust, and pulled taut.

Punching the holes weakens the strap by breaking its continuity. This cannot be helped,

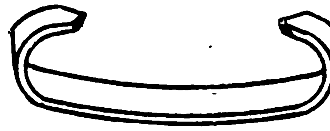

FIG. 93.

and therefore the strength of the belt is estimated across the weakened joint section. Though punching is usually adopted, yet in leather and in woven belting an awl can be used, in which case the material is not cut, but thrust aside, like the grain of wood by a bradawl. The degree of weakening of a belt, however, depends very much on the arrangement of the holes, which is the reason why so many devices are seen in belt-joints.

It is popularly believed that holes made by an

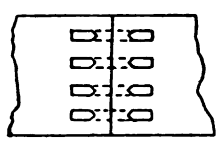

FIG. 94.

awl in leather permit of the full strength, or nearly the full strength, of the belt being retained. Experiments have proved that this is incorrect, and that leather is less liable to tear through when a clean hole is punched. This

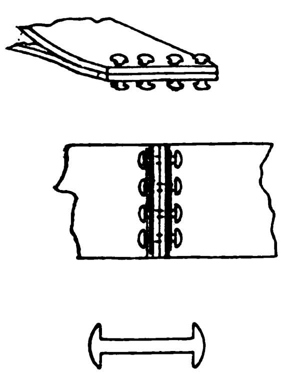

FIG. 95.

seems analogous with the fact that drilling a clean round hole at the ends of an incipient crack in a plate is the best means of preventing its extension. A hole bored with an awl makes a vee'd opening, which is more conducive to an extended

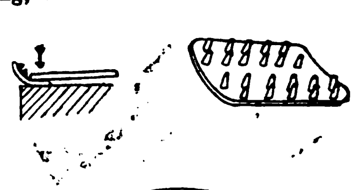

FIG. 96.

rent than a clean round hole. The leather then gives way first, the lace cutting it out.

The best form of hole is probably that which is punched with an *oval* punch, the long direction of the latter corresponding with the length-way of the belt. Another point which experiment has determined is, that there is little advantage in doubling the rows of holes in a butt joint. When

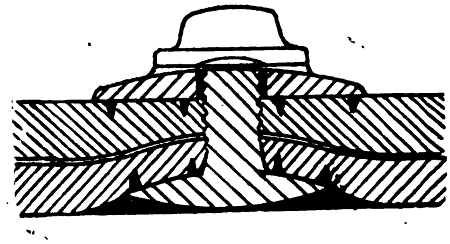

FIG. 97.

a single row of holes is exceeded, the lace holds and the belt fractures.

The common forms of permanent leather-scarfed joints made by the manufacturers are done in the first place by cementing. One type is then laced, the other riveted with copper rivets. I do not know that one is better than the other. The temporary fastenings of belts are so numerous

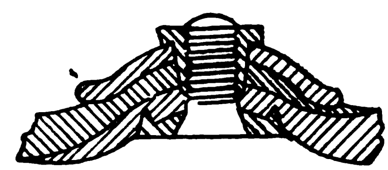

FIG. 98.

that one is often in a difficulty regarding which to select for a given purpose. A common method of temporary lacing, as done in the shops, is shown in Fig. 87, the side shown being that which goes against the pulley face. The straight portions of the lacing then run parallel on the pulley.

Tullis and Son prefer to make the joints of belts, when not cemented, in a diamond fashion (Figs. 88 and 89), because this arrangement retains nearly the whole strength of the belt, two holes only being in line across in any location.

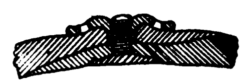

FIG. 99.

One drawback to splicing is the feather-edges of the splice, which are not kept down well by the laces. Herein lies one advantage of cementing even temporary joints. Copper clasps are used to assist in keeping such edges close, the clasps being driven in and riveted over.

For scarfed joints I think next, perhaps, to a good lacing, the steel screw fasteners (Fig. 90) are the best. It has been said that their edges cut the leather, but the fact is they wear themselves out first against the pulleys. They have the advantage of being quickly fitted, lie flush, and hold securely. A butt-joint fastening is

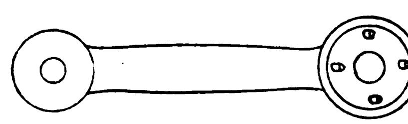

FIG. 100.

shown in Fig. 91. The parallel lines of lace are those which go next the pulley. Fig. 92 is an arrangement in which the lace does not cross on itself, with consequent increase of thickness, but runs in parallel diagonal lines.

We now come to the joints made with metal fasteners, which are generally applied more quickly than laces, and that is their chief advantage. The clip type of fastening is shown in Fig. 93, and the joint in Fig. 94. It is simple, and that is all. Holes are punched near the ends of a butt joint, the clips or hooks inserted, and turned over. Such a joint would fail under a light stress by tearing out of the belt holes, or by straightening of the clips, or by both. The joint

might be strengthened by staggering the hooks and inserting a larger number, which would be the best arrangement possible with this mode of fastening.

A common form of fastening for light belts is that shown in Fig. 95. The ends of the belts are laid face to face, the yellow metal hooks inserted in their holes, the belt straightened and flattened, leaving the ends standing up. Another form of fastener, Fig. 96, consists of a curved plate, with prongs. When applied, the belt is laid on one-half and hammered over the prongs, and turned over and riveted. Then the other end is closed similarly. When the belt and plate are straightened, the teeth bend over, inclining inwards, clipping the belt firmly to the plate.

There are several belt fasteners which are modified forms of the common belt screws; but they are used chiefly in the cotton and canvas

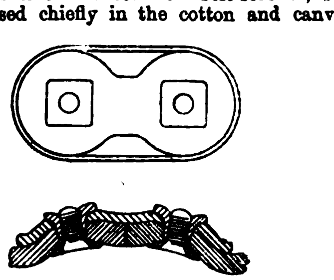

FIG. 101.

belting. Baxter's lock-nut belt fastener, Fig. 97, is a modified screw fastener, but much improved. The top face of the washer has a convex projection, over which the lock-nut fits, and is thereby prevented from slackening back. The head and the washer are well provided with prongs to stick into the belting. Jackson's patent fasteners are neat, the nuts being neatly dished and rounded. The nut sinks into the belt on both sides, its friction relieving the holes of strain. The nut is turned by means of a tommy-like key, which enters into holes in the nut. Fig. 98 shows the oval fastener, Fig. 99 the button fastener, Fig. 100 its key, and Fig. 101 the plate fastener for heavy belting. J. H.

COWPER-COLES SOUND LOCATOR AND PROJECTOR.

THIS instrument is for the purpose of readily locating sound, and for projecting sound long distances. The instrument consists of a reflector which is made entirely by electro-deposition mounted on an arm which can be readily turned on its centre, and depressed or elevated by the operator. When it is desired to ascertain the exact direction from which a sound emanates, the apparatus is turned on its axis, and as soon as the reflector is opposite the source of sound, it is heard much intensified in the receiver.

When it is desired to carry on a conversation between two distant ships or points, two instruments are used, so that the beam of sound is thrown from one reflector to the other, and focussed in the receiver of one instrument. One operator speaks into the flexible tube, while the operator working the other instrument places the tube attached to the receiver to his ear. Conversation can thus be carried on at long distances without unduly raising the voice.

Some experiments have recently been made at St. Margaret's Bay near Dover with this instrument. The ticking of a watch when placed in the focus could be distinctly heard 20ft. away, even with a strong breeze blowing across the line of direction of sound.

PEARL INDUSTRY OF NEW CALEDONIA.

THE pearl and oyster industry of New Caledonia is as yet in its infancy. To those who are familiar with these products, which have been supplied for the last half-century and more from the coral reefs of Torres Straits, Tahiti and Samoan groups, and, later still, from New Guinea, in all of which localities the trade in pearl-shell and pearls has obtained the distinction of a regular European market quotation, it may be surprising that the resources of the vast seaboard of New Caledonia and its dependencies have not ere this become known and seriously worked. Acting-Consul Erskine is of opinion that the oversight may be accounted for by the fact that the great mineral wealth of the colony has no doubt drawn off the attention of the commercial community; but since the advent of the present governor, great encouragement has been given to the development of the other industrial and commercial resources of the islands—hence large concessions having been granted by the French Government. Syndicates were formed for the working of pearls and pearl-shells on the coasts of New Caledonia and the adjacent islands, with the result that at the present moment extensive prospective operations are being carried out to determine the existence and locality of shell banks. There are now two separate parties of concessionaires. The syndicate occupying the whole of the east coast of the island as well as the Chesterfield, Wallis, and Belep groups, is busily engaged in exploring its concessions with the aid of a patent submarine apparatus, which is said to be capable of descending to the depth of 100 fathoms, although 40 or 50 fathoms will be all that is required for the present. This machine is carried by a small ketch of about 38 tons, and it appears from the reports received to be working admirably, and discovering large banks of shells, especially off the north end of the island. Some 12 banks of large extent have been discovered and chartered, one of them, according to Consul Erskine, being about four miles long by about 100 yards wide, at a depth of 25 fathoms. The company working the concessions on the West coast, whose headquarters are at Paris, is stated to be making valuable finds. From 1lb. weight of pearls and upwards are said to be exported monthly. Large numbers of these pearls are sometimes found in each shell, which is mostly of a small size, and called in New Caledonia the "Pontadine," and apparently of small value for trade purposes. The shell banks found on the north coast of the island lie principally in shallow waters, and the oyster is collected by the Loyalty Island boys, who are employed for this purpose by the company at a wage of 30 francs (24s.) a month and rations. It is, however, proposed to import native divers from Tahiti, as they are more experienced at the work than the natives of the Loyalty Islands. Very little export of pearls and shells has so far been made, though parcels of a few tons of shells are occasionally despatched to Europe, and fetch from £40 to £60 per ton. Some of the pearls are valued at from £20 to £120 each. The concessions already mentioned are granted for a period of ten years, with the option of a further extension of ten years to the concessionaires, who must be of French nationality. Consul Erskine says, "If my information can be relied upon, it seems likely that the pearl and pearl-shell industry of New Caledonia has a very successful future before it, and will, no doubt, establish a reputation equal to any of the celebrated pearl fisheries in these latitudes."

SULPHIDE ORES.

AT a meeting of the Society of Engineers, held at the Royal United Service Institution, Whitehall, on Monday evening, a paper was read by Mr. Sherard Cowper-Coles on the "Electrolytic Treatment of Complex Sulphide Ores."

In introducing his subject, the author gave particulars of the present concentration system adopted at Broken Hill, so as to produce an argentiferous lead concentrate sufficiently low in zinc to be available for the ordinary lead smelting furnace. He then proceeded to give some particulars and figures of the cost of distilling zinc from its ores, the cost of producing a single ton of zinc, including coal, labour, pottery, and stores being usually not less than 80s. He pointed out that the present process is primitive and very wasteful, about 16 per cent. of the metal being unextracted from the ore, and 10 tons of coal being required in many instances to produce one ton of zinc. Reference was made to experiments for producing zinc in a blast furnace.

The author then recounted some of the chief characteristics of sulphide ores, and gave analyses of various samples. A historical sketch of the investigations undertaken by various workers in this field then followed, and particulars were given of Watt's, Dieffenbach's, Ashcroft's, Siemens and Halske's, Hoepfner's, Mohr's, and Swinburne's processes. The author then described in detail a number of experiments he had made on a practical scale on sulphide ores, and enumerated the difficulties that had been encountered, and how they had been met. Information was given as to the crushing of the ore, the roasting, and details of the type of roasting furnace employed. The next operation described was the leaching out of the zinc with sulphuric acid, and purifying the zinc solution obtained by passing it through epuration tanks, the purified solution then being circulated through electrolysing cells, and the zinc deposited in a metallic form. The advantages of aluminium revolving cathodes were then considered, also the best material for the anodes.

The effect of impurities in the electrolyte was described, and an analysis given of a sample of zinc sponge, also particulars as to the cost of depositing zinc. A diagram was exhibited showing the actual weight of zinc deposited as compared with the

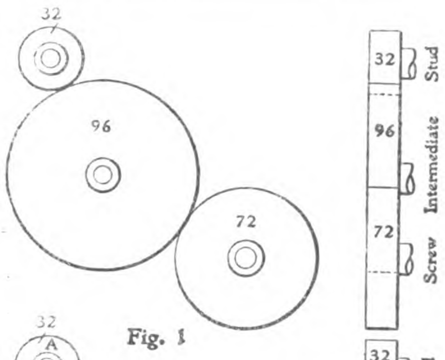

Fig. 1

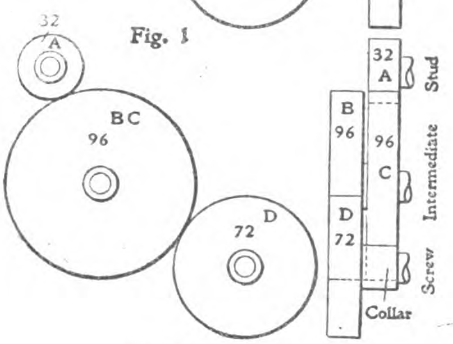

Fig. 2

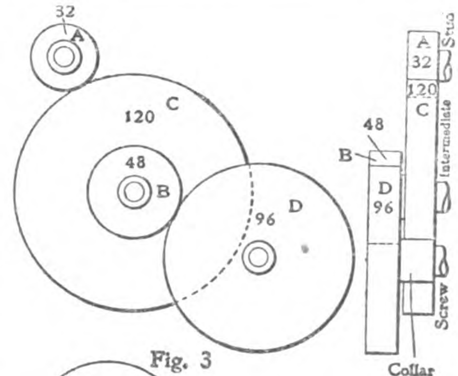

Fig. 3

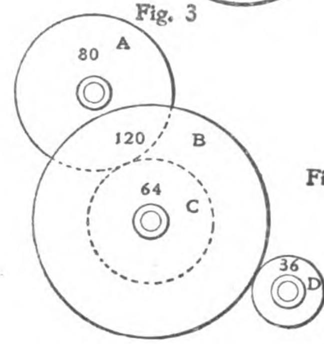

Fig. 4

theoretical, with varying current densities. The process of manufacturing zinc white and zinc sulphate from zinc-bearing ores, and the leaching out of the lead remaining in the ore after the zinc has been extracted were described in detail. The cost of electro-depositing the lead was also given, the cost being far less than that of zinc. The author stated that the current which would deposit one ton of zinc would deposit three tons of lead. The theoretical amount of electrical energy required to deposit one ton of lead was stated to be 263·5 kilowatts, which, at $\frac{1}{4}$d. per kilowatt, equals 11s. per ton of 2,240lb. of lead deposited. Particulars of a process for the manufacture of litharge and white lead direct from lead-bearing ores were also given. The author then described the final operation of leaching out the silver and depositing the same from a cyanide of potassium solution. The paper was illustrated by diagrams, and a large number of specimens of crude sulphide ores and their products were exhibited.

COMPUTING COMPOUND GEARS.

THE following remarks on the method of computing gears for cutting threads are extracted from an article in the *American Machinist*, by Mr. Morris Fulton, of Philadelphia:—Say that we have a screw-cutting engine lathe arranged for using the gears either simple or compound, with a lead-screw having a pitch of four to the inch, and the following list of gears: 24, 32, 36, 40, 48, 56, 60, 62, 64, 66, 69, 72, 78, 80, 84, 96, 120. This may not be the best possible selection of gear numbers, but they will answer our purpose. There are, of course, two gears alike for cutting the same pitch as the lead-screw, and there is also a gear for cutting $11\frac{1}{2}$ threads to the inch for wrought-iron pipe and fittings.

Fig. 1 shows one of the simplest cases of single or direct gearing. Assuming here that the stud turns at the same speed as the lathe-spindle, then if the gears on the stud and on the screw were of the same size, or had the same number of teeth, they would both turn at the same speed, and the thread cut by the tool would have the same pitch as the lead-screw. In this case, however, the driving-gear on the stud and the driven gear on the screw have not the same number of teeth. The number of teeth on the screw being the greater, the screw will, of course, turn slower than the stud or spindle, and the tool will cut a thread finer than the lead-screw, or will cut a greater number of threads to the inch. The ratio of the lead-screw pitch to the pitch of the screw that is cut will be the same as the ratio of the gear on the stud to that on the screw. To find, then, the number of threads to the inch that these gears will cut we have the simple proportion:—

$$32 : 72 :: 4 : 9.$$

Here, of course, the operation is $72 \times 4 \div 32 = 9$, or the number of teeth in the gear on the screw multiplied by the pitch of the screw, and the product divided by the number of teeth in the gear on the stud gives the number of threads to the inch that the gears will cut.

If, instead of this, we wished to cut a certain number of threads to the inch, we would first select some gear for the stud, remembering generally that if a fine thread is to be cut, a small gear will be required, while if a coarse thread is to be cut, a larger gear must be used. Say that we want to find the gears for cutting nine to the inch. We select 32 for the stud, and we have this simple proportion:—

$$4 : 9 :: 32 : 72.$$

That is, after selecting the stud gear, we multiply it by the pitch that we want to cut, and divide the product by the pitch of the lead-screw. If we had taken 40 for the stud, then the operation would have been:—

$$4 : 9 :: 40 : 90;$$

but as we have not a 90-tooth gear in our list, that would not do.

In simple or direct-connected gearing like this, the diameter, or the number of teeth in the intermediate gear, need not be considered, as the intermediate gear merely transmits the motion, tooth for tooth, from one gear to the other. In the compound gearing on the engine lathe there are two gears on the intermediate stud which revolve together, instead of the single gear. In the compound train shown in Fig. 2 these gears both have the same number of teeth, and it is evident, without computation, that the result is precisely the same as in Fig. 1. Compound gears are, however, frequently necessary, to enable us to cut either coarser or finer threads than would be possible with the simple gearing, and in some cases they enable us also to cut fractional threads that are not at either extreme as to pitch. In Fig. 3 the train shown is for cutting fine threads, and the train in Fig. 4 is for a coarser thread than the lead-screw.

In these trains the gears A and B are designated as drivers, and C and D as driven gears. The ratio of the pitch of the lead-screw to the pitch of the screw that is cut will be the same as that of the product of the drivers to that of the driven gears. To ascertain the number of threads to the inch that will be cut by the gears in Fig. 3, we have the proportion:—

$$32 \times 48 : 120 \times 95 :: 4 : 30.$$

That is, we multiply the driven gears together, and this product by the pitch of the lead-screw. We also multiply together the two drivers, and use this product as a divisor of the previous product, the quotient being the pitch required.

The pitch resulting from the combination shown in Fig. 4 is obtained by the following compound proportion:—

$$20 \times 120 : 64 \times 36 :: 4 : \frac{96}{100}, \text{ or } {\cdot}96.$$

This last result must not be misunderstood. The pitch of the thread is not $\frac{96}{100}$ths of an inch, but it means that $\frac{96}{100}$ths of one thread will be contained in one inch measured on a line parallel with the axis of the screw. The total measure of one thread along this line would be $1\frac{4}{96}$in. or $1\frac{1}{24}$in.

Returning to Fig. 3, say that we have to find the gears to cut 30 threads to the inch. The difficulty in the matter is that we here have to assume, or to "select at random," three of the four gears, when we may easily compute the fourth. It will generally happen that the gears first picked out will not do, and others must be selected and another computation made. In this case we know that, as the thread to be cut is a fine one, the drivers must be comparatively small and the driven gears large. We first take, then, say, the two smallest gears on the list for the drivers, and the largest gear on the list for one of the driven. Then, to find the other, we have this proportion:—

$$4 : 30 :: 24 \times 32 : 120 \times x.$$

Then $(24 \times 32 \times 30) \div (120 \times 4) = 48$, the other gear. That is, we multiply together the two drivers and the pitch of the thread to cut, and divide this product by the selected driven gear multiplied by the pitch of the lead-screw, the quotient being the number of teeth for the other driven gear. We now have the full set of gears for cutting the required thread; but when we try to connect them on the lathe we find that they will not reach. It is evidently necessary to use some larger gears, so we start again with 32 and 48 for drivers, as in Fig. 3, and 120 for one of the driven, as before, when the other driven gear is found to be 96, and these connect all right. In this case it was not necessary to restate the proportion and go through the whole computation again. We have simply taken one driver, 24, and one driven gear, 48, and multiplied each by 2, giving us 48 for a driver and 96 for the driven gear. A simple case that might be quite likely to come to us would be to cut a screw of one thread to the inch. In this case we know that we have to speed up the screw, so we take big gears for the drivers, and we have the proportion:—

$$4 : 1 :: 120 \times 96 : 32 \times x,$$

and we find that the other driven gear will be 90, making the complete series: drivers, 120 and 96; and driven gears, 32 and 90. When we come to connect these we find that they are too large, so we take the 120 driver and the 90 driven, and subtracting a third from each, we get, instead, 80 and 60, which have the same ratio as 120 and 90, and our set of gears is then: drivers, 80 and 96; and driven gears, 32 and 60. There is still an objectionable feature about these. The driven gear, 32, is too small, and will not drive as well as a larger one. We take 40 instead, and in making this larger we have to make the other driven gear smaller, to keep the product of the two the same, so we multiply together the driven gears, 32 and 60, and divide this by 40, and the quotient will be 48 for the other driven gear, and our set then becomes: drivers, 80 and 96; and driven gears, 40 and 48, which should be a satisfactory train for cutting one thread to the inch.

THE STEAM TURBINE.

AT a recent meeting of the Institution of Junior Engineers, the Hon. C. H. Parsons said he had been requested by the retiring president and the committee to deal with the subject of turbines, with which his work had been specially connected. The first engine deriving its motive power from fuel was recorded in the Pneumatics of Hero of Alexandria about 200 B.C. This engine was a crude form of steam turbine; but from that time the principle had been allowed to lie dormant until A.D. 1629, when it was suggested again by Bianca in another form. About 15 years ago he (Mr. Parsons) was led to investigate the subject of improving the steam turbine and its application to the propulsion of vessels. The first vessel fitted with steam turbine machinery was the *Turbinia*, begun in 1894 and completed in 1897. She was estimated to have attained a speed of $34\frac{1}{2}$ knots; she had been out in very rough weather, and was an excellent sea boat, and at all speeds there was an almost complete absence of vibration. The turbine principle was being applied successfully to torpedo-boat destroyers, and in regard to larger ships the conditions appeared to be more favourable in the case of the faster class of vessels, such as cross-Channel boats, liners, and cruisers. In such vessels the reduction in weight of machinery and economy in coal consumption per horse-power were especially important, and the absence of vibration was also a great advantage. A boat 270ft. long, 33ft. in beam, of 1,000 tons displacement and $8\frac{1}{2}$ft. draught, could be constructed with spacious accommodation for 600 passengers, and with machinery developing 18,000H.P. such a vessel would have a speed of about 30 knots, as compared to the speed of 19 to 22 knots of the present vessels of similar size and accommodation. It might be interesting to examine the possibilities of speed attainable in a special unarmoured cruiser—a magnified torpedo-boat destroyer of light build, with scanty accommodation for a large crew, but equipped with an armament of light guns and torpedoes. Assuming dimensions double those of the 30-knot destroyers, and plates of double thickness, specially strengthened, there would be two tiers of watertube boilers, and eight propellers of 9ft. diameter, revolving at about 400 revolutions per minute. The speed would be nearly 44 knots. She could carry coal for this speed for about eight hours, but she would be able to steam from 10 to 14 knots with a small section of the boilers more economically than other vessels of ordinary type and power.

THE total quantity of coal brought coastwise to the port of London last year was 7,378,000 tons.

BORING-TOOLS.

HAVING read a number of articles of recent date on boring-tools of various descriptions, I would like to describe a tool of my own make, which I believe is original. At the time this tool came I was employed in a shop in the central part of Ohio. This shop at that time was building turret-lathes. It being a new venture, and the shop employing but few men, it could not support a blacksmith, and every machinist had access to the forge, where he did his own forging and tool-dressing. There was a portable forge in the basement, and a boy to do what striking was necessary.

Having been given the job of finishing the cones for these lathes, Fig. 3, which were turned all over, I placed one of them in a chuck and trued it ready for boring. My next job was to find a boring-tool long enough to bore through the cone, and, finding none, I proceeded to the basement and forged a tool, to the best of my ability. The tool was so long and slender I was unable to get below the scale on the casting. At last, giving up in despair, I went to the foreman and told him my troubles. He said he didn't see any reason why the tool would not work if it was properly ground, and tried it, to satisfy himself, but with the same result. I then approached him with the subject of making a tool and holder. I explained my idea to him, and told him I was sure such a tool would do. I could not convince him, but he at last consented to let me make the tool. I got a pattern made, and then the casting for the standard, Fig. 4. This I planed with a tongue on the bottom to fit the top of the rest, and secured it by a bolt in the centre. The hole for the tool I drilled near the size, and then bored true with a small bar on the centres, and put in the two $\frac{5}{8}$in. set-screws. I made two bars of 1in. round steel, one bent and the other straight, and of the right length. The nose was cut away taper on the two sides, and two $\frac{1}{4}$in. holes were drilled obliquely, as shown, and crossing each other in the centre, where I had a $\frac{1}{4}$in. set-screw to hold the little tools that did the cutting, and when I had these all lipped and ground I was ready for business.

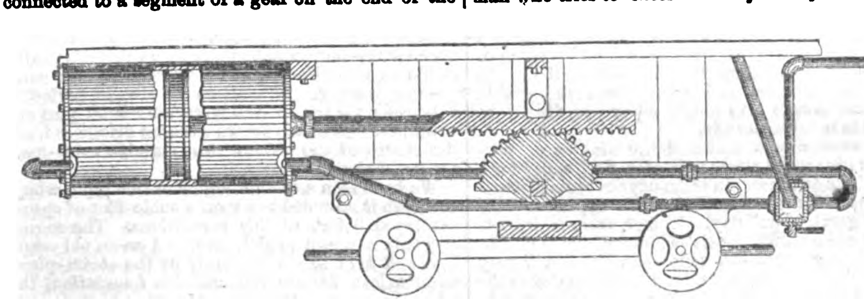
With the tool in the position B I did the boring, and that and turning the inside of the cone was all I had calculated to do with the tool. With the cutter in the same position I turned surfaces marked I and M, and faced K. I then changed the tool to A, and turned and faced the hub and turned the large step F. I then used the bent tool, Fig. 2, and with D I turned O and faced G, also that part of H that was not held in the chuck, and faced N.

I had thus finished the entire cone, except the small part in the chuck. I then went at the task of convincing the foreman that I had a good tool; but he would not be convinced. To give him his just dues, however, when I left there that was the only tool that he would allow to be used for turning cones.—A. F. HORTON, in *American Machinist.*

A VERY active programme of shipbuilding on the Great American Lakes is being inaugurated. The Carnegie Steel Company have ordered five steamers, each 475ft. long.

WELDING-MACHINE OPERATED BY AIR.

THE illustration shows an appliance which has been attached to the Debombourg welding and upsetting machine used in the Erie shops at Galion, Ohio. The machine was originally operated by a lever 7ft. long, and required from one to four men to operate it. It is now operated by the valve shown in sketch. The cylinder is 12in. by 27in., and has a rack on the end of piston-rod. This is connected to a segment of a gear on the end of the eccentric shaft. This appliance was gotten up by Mr. A. A. Arnold, machine foreman, under the supervision of Mr. A. W. Ball, master mechanic, and is one of the many air appliances used in the Erie shops at Galion, Ohio.—*Locomotive Engineering*, N.Y.



AN APPARATUS AND METHOD FOR PREPARING AGAR.

IN the April, 1898, number of the *Journal of Applied Microscopy*, Miss Marion H. Carter, of Cornell University, published a method for preparing agar for the cultivation of bacteria. Being impressed with its simplicity, I determined to give it a trial, inasmuch as it promised to save considerable labour. Repeated trials have proved that much of the drudgery connected with the preparation of this important medium may be avoided by employing Miss Carter's method. The object of the present article is to emphasise this fact, and to describe an apparatus which I have devised for employing the method. The apparatus consists mainly of an ordinary 9in. copper funnel, with an inch-wide perpendicular wall round the top, which may be obtained ready-made at the shops. To it are added a cover, and three legs having a spread equal to the greatest diameter of the funnel. The spout may be closed by means of a rubber stopper, or a cap may be soldered on. In the former case the funnel will be found useful in other directions. A funnel of this size will hold a gallon, and gives ample room for work.

If one litre of medium is wanted, place about 900cc. of bouillon in the funnel, 10 or 15grm. of pulverised agar, according as a 1 per cent. or a $1\frac{1}{2}$ per cent. solution is desired, to the other 100cc., and mix thoroughly by rubbing up in a mortar or a beaker. Place the mixture thus made in the funnel, and stir thoroughly. If the agar is in the stalk form, it may be put directly into the funnel after having been cut up. Now place the funnel with its contents in a 11in. by 13in. can, containing sufficient water to last for two hours, and boil. An Arnold steriliser may be used instead of the can, if desired. After boiling for an hour, turn off the gas, remove the covers, and stir the agar solution, especially that in the spout of the funnel. Replace the covers, and boil another hour. Turn off the gas, and allow the whole to cool, taking care not to disturb the solution at this time. After solidification has taken place, remove the funnel, invert it on a glass plate, and the agar will come away as a mould. That portion from the spout will be found made up of the insoluble materials which ordinarily interfere with filtration, and which usually amount to about 1 per cent. of the whole mass. It is to be sliced off and thrown away. The remaining portion will be sufficiently clear for ordinary purposes, and may at once be remelted, distributed, and sterilised. Should it not be sufficiently clear, it may be clarified by the usual method. Filtration may then be readily accomplished, since most of the foreign and insoluble matter has been removed by the sedimentation process. As might be supposed, the nutritive qualities of agar thus made are in no way interfered with. Over fifty different species of bacteria have been grown upon it with perfect success by the writer.—CHARLES F. DAWSON, M.D., Washington, D.C., in the *Journal of Applied Microscopy*, N.Y.

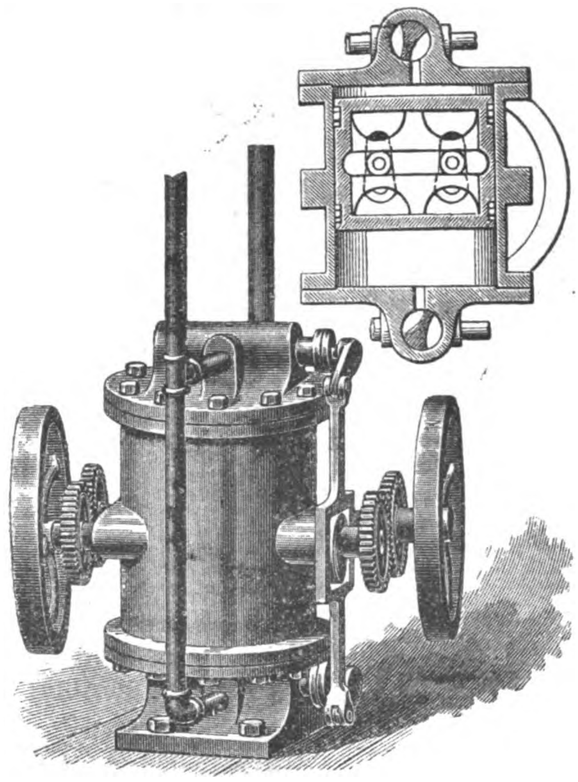
LANTERN SLIDE-MAKING FROM THE SPECIALIST'S POINT OF VIEW.

IN these days of high-pressure work, the truth of the proverb, "Jack of all trades, master of none," is more than ever apparent to everyone, and especially to photographers. When we see an amateur exposing on anything that comes in his way, be it landscape, architecture, animal or figure study, or what not, we generally class him in that wide and extensive species of beings known as "wasters." Whatever class of science or skilled work you take, you will see that the men whose works are looked on as standards of excellence are those who have struck out on some well-defined line and gone ahead solely in that direction. A man who tries to excel in every or any direction is bound, sooner or later, to have to give it up, and concentrate his energies on one particular class. So in photography. The men who are known as leaders in photographic circles are not all-round men, but those who have striven in one particular direction. Figure studies, landscape, sea studies, architecture, portraiture, and various other special classes of photography all have their leaders.

There is also another class of specialists. We find some workers devote all their energies to one particular printing process. It may be platinotype, or carbon, or it may be lantern slides. But these are not the kind of specialists which we are here considering. It is the first class of specialists which we are discussing.

It is obvious that an architectural photographer will work for a different result to a man who is making figure studies his *forté*. The architectural man will generally find that a black tone is one which suits his subject best, and therefore he must regulate his exposure and development in order that the colour of the deposit may be of an appropriate shade. As a general rule, he will have no need for the special tones which his *confrère* who goes in for landscape, portraits, or figure studies may often require. Different shades of greys and black will be the prodominating colours in his collection of slides.

In the case of the landscape photographer, however, the case is altered. Different atmospheric conditions, and various other things, will be found to be more accurately conveyed to the observer of the finished slides by means of a variety of tones, not only of different shades of reds and blacks, but even in some cases by a blue or green. It therefore behoves a photographer of this class to be able to obtain these various tones at will. He should be expert in toning to any of the colours



which he knows are of use in rendering his various subjects correctly, and in regulating the different processes through which the slide passes, in order that, when finished, it will express in the fullest possible degree the sentiments which it was intended it should convey to the observer. In this branch of photography perhaps I ought to mention one class of subject which seems to be particularly adapted for lantern slides. I refer to those views in which it is endeavoured to convey the idea of a moonlight or sunset scene. In my opinion, there is nothing which shows so well the artistic value of a lantern slide as a well-rendered moonlight scene or a sunset picture. Here we have a wide field open to the photographer and slide-maker, and one in which the results will amply repay you for all the trouble taken over a slide.

The worker who makes figure studies or portraiture his special study will also find a use for a large range of tones. In these days of sepia platinotype, the red tones for portraiture appear to have gained great popularity. In fact, from an inspection of some professionals' windows, one would be led to believe that this tone runs the black very close. To these workers, then, such plates as the Ilford Alpha and others of that description will be valuable tools, whilst, as I have said before, the specialist in some branches of the black art will hardly ever require them.

Seascapes and wave studies are also very suitable subjects for lantern-slides, and the photographers who devote themselves to these subjects will find plenty of work for the winter evenings, which should result in slides worthy of the title "pictures." The worker in this class will also find that he wants a long range of colours for his slides, and, therefore, he must be able, when the opportunity occurs, to produce a blue or a black or any other tone that will set off his slide to the best possible advantage.

These are only a few instances of how an amateur must work to secure results to fit in with his own special branch; but everyone will find that his slides will have some particular characteristics in accordance with the branch which he has adopted which would not be suitable for a slide of a different class of subject.—"ALEX," in the *Photographic News*.

HOYT'S HIGH-SPEED ENGINE.

A SIMPLE form of engine, which would occupy but little space, and which, nevertheless, would develop considerable power, has long been sought by manufacturers of automobiles and launches; for the motors at present in use are not only very bulky and heavy, but are often too complex in construction to be readily controlled. We have recently had the opportunity of inspecting a small high-speed engine, invented by a mechanical engineer, Mr. Gabriel P. B. Hoyt, of Jamaica, Borough of Queens, New York City, which will probably find its broadest field of usefulness in automobiles and launches, in which, as we have already remarked, high-power engines of small size are of the utmost importance.

The engine in question comprises essentially a cylinder in which a reciprocating piston is mounted, provided with a slot into which the wrist-pins of two crank-arms extend. The crank-arms are carried by shafts, which at their extremities are provided with gear-wheels meshing with each other. When steam or any other motive agent is admitted to the ends of the cylinder a continuous rotary motion is given to the shafts by the action of the slotted piston on the crank-arms and wrist-pins. The two shafts being geared together, a uniform rotary motion is obtained without vibration, especially when the piston starts on the return stroke, as the two shafts rotate in opposite directions by reason of the connecting gearing. The piston is always perfectly balanced; for the oppositely-turning wrist-pins are at all positions of the stroke at equal distances from the centre of the piston. Any suitable valve-gear can be employed.

We have seen a double engine of this type, which although it occupied less than a cubic foot of space, developed 6H.P. at 600 revolutions. The engine was only a rough model, mounted on an old soap-box, and held in place merely by the steam-pipe; nevertheless, despite the unstable foundation, the vibration was hardly perceptible either to the eye or touch.

By changing the construction of the valves the engine can be converted into a gas-engine, in which form it will probably be especially serviceable in launches. The lack of vibration, the large power which is condensed within a small space, and the simplicity of construction, in which the usual cross-heads and guides have been dispensed with, are the chief points of interest in this new engine.—*Scientific American*.

"THE HEAVENS AT A GLANCE" for 1900 is Mr. Mee's useful card almanac or celestial diary, which amateur observers have appreciated in former years. It is published by the author at Penhill, Cardiff.

ARTIFICIAL paving-stones are being successfully produced in Germany. The process of manufacture is to mix coal-tar with sulphur and warm thoroughly, and then add chlorate of lime. After cooling the mass is broken into small pieces, and mixed with glass or blast-furnace slag. This powder is then subjected to a pressure of 200 atmospheres, and reduced to the forms wanted. The resistance to wear and tear in use is fully half as great as that of Swedish granite.

SOME of the western railways of the United States have in use a weed-burning apparatus, one of which worked over 900 miles of road last year at a cost of less than 2½dol. per mile. The apparatus comprises a lamp using oil vapour. This vapour is kept close to the track by a shield over it. The intense heat burns the weeds between the rails. Once at work, the shield is lowered within 4in. of the rail, and when not in use it is raised to 18in. above the rail. The operation is somewhat slow, only about 1¼ mile an hour being covered.

SCIENTIFIC NEWS.

THE Leonid meteors are expected on the nights of Nov. 13 to 16, but the probable time is the early morning of Nov. 16, the middle of the shower, according to calculation, being about 6 a.m., Nov. 16. It is certain that many observers will be "on the watch," and it is to be hoped that they will not be disappointed, but it is possible that they may be—just as they were last year. Still, all who have the time and the desire to observe should look out for the meteors and record what they see, in their own words, but being particular as to the time, which should be G.M.T. if possible. It is possible that the shower will not be seen in its greatest display until 1900. For "astronomical" purposes the determination of the "radiant" from visual observations is the most important. This is a class of observation that requires practice and previous training, and an intimate knowledge of the sky. It is required to know not only the radiant point or radiant area for the entire shower, but also the position of the radiant at short intervals of time—at every half-hour, for instance. This is an observation of extreme importance, as from it can can be learnt if the radiant shifts during the progress of the storm, or, in other words, if the attraction of the earth influences the position of the swarm's orbit, and in what manner it does so. On this depends our power to predict the history of the shower in the future. Prof. E. C. Pickering, of Harvard College Observatory, has issued a circular giving directions for observing, and any notes of the meteors seen may be sent to Mr. W. F. Denning, the director of the Meteoric section of the British Astronomical Association.

The Leonid meteors are to be observed (if possible) from a balloon which will ascend near St. Denis on Nov. 14-15, and the following night. Probably the most successful observations last year were those made at Paris by means of a balloon when the city was covered by a fog or black cloud. Dr. Janssen, director of the Meudon Observatory, will make all the arrangements, and if the Leonids come in numbers over Paris and its environs, they will be certainly captured photographically.

The Gresham lectures on astronomy will be delivered by the Rev. Edmund Ledger, M.A., F.R.A.S., on Nov. 14, 15, 16, 17, commencing at 6 p.m., at Gresham College, Basinghall-street, E.C. The subject is "Sidereal Astronomy in Relation to the Constellations of Cygnus, Lyra, and Hercules."

A reproduction of one of Dr. Isaac Roberts's photographs of the stellar regions appears in *Knowledge* for this month. It is a photograph of the nebulæ surrounding D.M. 1848 Monocerotis, and is of especial interest, because it is new. Dr. Roberts says: "The surfaces of these nebulæ are strewn with numerous stars besides the nebulous condensations which are doubtless involved in the nebulosity; but it is probable that the stars are not involved, and are placed either behind or else in front between the earth and the nebulæ."

The Hampstead Astronomical and Scientific Society has a small observatory erected on the East Heath, in which the members can have an opportunity of using a reflector with a mirror of 10¼in. Mr. P. E. Vizard will commence a series of five lectures on Nov. 20 in connection with the society, to be continued on following Monday evenings.

It is stated that the following gentlemen will be nominated for election on the new council of the Royal Society at its anniversary meeting on the 30th instant: — President, Lord Lister; treasurer, Mr. Alfred Bray Kempe; secretaries, Sir Michael Foster and Prof. Rücker: foreign secretary, Dr. T. E. Thorpe. Other members—Mr. Horace Brown, Captain Creak, R.N., Prof. Dewar, Prof. E. B. Elliott, Dr. Gadow, Dr. Halliburton, Prof. W. A. Herdman, Sir John Murray, Sir Andrew Noble, Prof. Reinold, Dr. Stoney, Mr. C. J. Symons, Mr. Teall, Prof. J. J. Thomson, Dr. Tylor, and Sir Samuel Wilks, Bart.

Suggestions have from time to time been made that the British Association should occasionally go further afield than the United Kingdom for its annual meeting, and twice this great gathering of scientists has taken place in Canada. The council has recently received an invitation from Ceylon to fix an early date for a visit by the

Association to that island. It is, however, very improbable that the council will see its way to accepting the invitation. The time required for the double journey would be an obstacle to the attendance of many members, so that nothing like a full meeting could be expected, while the season at which the Association usually assembles is also a serious consideration in connection with a proposal for going to a Tropical climate. It is probable that a visit to Ireland may be arranged for the year 1902.

The session of the Royal Geographical Society commences on Monday, Nov. 13, when the president, Sir Clements Markham, will give a short opening address, which will be followed by a paper by Mr. W. Rickmer Rickmers on his "Travels in Bokhara." The paper at the following meeting, November 27, will be by Mr. Vaughan Cornish on "Desert Sand Dunes." At the December meeting, Colonel Sir John Farquharson will probably give an "Account of the Past Twelve Years' Work of the Ordnance Survey," from the directorship of which he has recently retired. Other papers expected to be given during the session are: "An Ascent of Mount Kenya," by Mr. H. J. Mackinder; "The Work of the Yermak Ice-Breaker in the Spitzbergen Seas," by Admiral Makaroff; "Travels in Central Asia," by Captain H. H. P. Deasy; "Travels in the Region of Lake Rudolf and the Sobat River," by Captain Wellby; "Travels in Abyssinia," by Mr. H. Weld Blundell; and "Anthropogeography of British New Guinea," by Prof. Haddon.

At the Royal Victoria Hall, Waterloo Bridge-road, on Nov. 14, Mr. W. J. Pope will deliver a lecture on the "Uses of Distillation." On Nov. 21 Dr. J. W. Waghorn will lecture on "Bad Contacts in Their Application to Telephones and Wireless Telegraphy"; and on Nov. 28 Mr. Michael Sadler will lecture on "A Brother of the Birds."

The Reader in Geography at Oxford University has returned from East Africa, and Mr. Mackinder has, it appears, accomplished the ascent of Mount Kenya. Mr. Mackinder's expedition included five Europeans besides himself, two of whom were Alpine guides from Courmayeur, two natural-history collectors, and Mr. C. B. Hansburg, a skilled amateur photographer. The journey to the lower slopes of Mount Kenya was full of interest, the route lying for some distance through one of the most thickly-populated and most highly-cultivated regions in Africa. According to the notes in the *Scotsman*, Mr. Mackinder established his base camp on the Sagana River, and then with his guides and his collectors set out for the exploration of Mount Kenya. He has succeeded almost beyond his expectations in mapping the entire mountain and its immediate neighbourhood, having not only ascended to its summit, but made a journey round the shoulders of the mountain just below the glacier level. He has thus been able to establish that there are no fewer than fifteen glaciers on Mount Kenya.

The death is reported of Dr. E. J. Petri, Professor of Geology and Ethnography in the University of St. Petersburg. He was formerly professor at Berne.

Mr. Frederick Wilkinson, the inventor of several useful appliances in connection with the machinery used in the textile industries, is dead. He invented the revolving-disc carding engines, and a few years ago devised a means of case-hardening the tips or carding points of card wire.

M. Berthelot has been making some investigations into the phenomena of hydration and oxidation at the expense of organic substances under the free influence of oxygen and light, and he concludes that such substances as the sugars, carbohydrates, glycerides, are affected by simultaneous hydration and oxidation—in nature. M. Berthelot's experiments were carried out on the slow oxidation of ether in the presence of air and water, and were presented in a memoir to the Paris Academy of Sciences.

Lyddite is one of the high explosives which are now in use by all the great Powers, and, in fact, by some of the minor States. It is so named from the experiments having been first made at Lydd, in Kent; but although there is some secrecy about its manufacture, it is well known that it is practically the same as Mélinite, écrasite, and other explosives. The base is picric acid, which is brought into a dense state by fusion, but when "fired" burns violently, and therefore "explodes" with terrific force. Picric acid has been used for many years in the dyeing industries, as, amongst other tints, it produces beautiful yellow dyes.

An invention that is much wanted is a "recording" instrument for the telephone, so that some evidence may be available as to what was actually said to the telephone. According to a technical serial an interesting invention has been made by a young Danish engineer, purporting to connect a phonograph of special construction with the telephone. In case the person for whom a telephonic communication is intended is absent, the phonograph will receive it in his place, and repeat it to him on his return. The phonograph is without a wax roller, and is based upon a system totally different to and decidedly less complicated than that of Edison's. A steel band is used instead, and from this a conversation can be wiped off as can a chalk drawing from a slate.

According to recent reports, the submarine boat *Holland* has made some very successful trials in New York harbour. The vessel ran a mile in nine minutes at a depth of 10ft. It would be interesting to learn how long the vessel can remain submerged.

USEFUL AND SCIENTIFIC NOTES.

Messrs. Green and Boulding, of Bunhill-row, E.C., have issued a neat catalogue, the principal feature of which is the Buffalo automatic injector, which takes either hot or cold water.

The construction of a light railway through the Isle of Sheppey will shortly be commenced. The starting-point will be at Queenborough, on the London, Chatham, and Dover Railway, and the terminal station at Leysdown, with intermediate stations at Fowler's Corner—near the halfway houses—Minster, and Eastchurch. The new line will, it is expected, be completed in twelve months.

The *National Geographic Magazine* states that various sites within a radius of twenty-five miles of Washington are being examined by parties under Dr. Bauer's direction for the determination of the best location for the Coast and Geodetic Survey Observatory. The examinations thus far made have disclosed some interesting regional disturbances, especially in the vicinity of Gaithersburg. In order to determine what influence such regional disturbances have upon the variations of the earth's magnetism—such as, for example, the diurnal variation or the secular variation—it is proposed to mount a sensitive Eschenhagen declinetograph at Gaithersburg, with the aid of which the variations of the most sensitive of the magnetic elements—the declination—will be continuously and automatically recorded.

Copper-coated Zinc Plates for Process Blocks.—Coppered zinc plates combine the advantages of copper and zinc plates. They can be made as follows:—An alkaline galvanic bath is first made containing distilled water 1,000cc. (1oz.), copper acetate 200gm. (88gr.), ammonia 100cc. (50 minims), potass. cyanide 500gm. (220gr.) The copper acetate is first dissolved, the ammonia added, and the precipitate which results dissolved in the potassium cyanide. An acid galvanic bath is likewise made by dissolving copper sulphate in water up to saturation. The zinc plate to be coated is cleaned thoroughly with a potash solution, and placed in the position of the cathode in the alkaline bath, a copper plate forming the anode. A current of about three ampères per square centimètre is used. After about five minutes the zinc plate is removed and polished with chalk. The copper image is not affected by this treatment, if conducted carefully. The zinc plates are next transferred to the acid bath, and submitted for about four minutes to the action of a current of about one ampère per square centimètre. If necessary, the plate, on coming from this second bath, is again polished. The sensitising solution contains: water 100cc. (1oz.), fish-glue 20gm. (88gr.), albumen 20gm. (88gr.), ammonium bichromate 3gm. (13gr.) The coating, drying, exposure, and development of the plates is carried out as usual. The back and edges are then coated with asphalte varnish, and the plate is ready for the etcher. The etching-bath is a 40 per cent. solution of ferric chloride, which is allowed to act for about two minutes—a sufficient time to lay bare the zinc. The plate is washed well, cleaned by a vigorous rubbing with a brush and pumice-powder. For the second etching a bath of three per cent. nitric acid is used for five minutes; this acts only on the exposed portions of the zinc. Should deeper etching be required, the plate must be inked in the usual way, powdered with asphalte, and heated. In this case the etching-bath may be five per cent., and the period of etching ten minutes.—*The Process Photogram.*

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor *of the* English Mechanic, *332, Strand, W.C.*

**** In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

VARIABLE STAR OBSERVATIONS, OCTOBER, 1899.

[42988.]—R Aurigæ is now below 13·0 magnitude, and beyond the reach of the Rousdon telescope. It was last looked for October 30, when no trace could be seen, though the air was very clear.

U Orionis has again come into a convenient position for observation, but it is very faint, being 11·8 magnitude October 28. The minimum will probably occur about the end of November, and by the beginning of 1900 it will be an easy object.

T Ursæ Majoris has fallen about six magnitudes in the last four months, and was a very minute point, 12 2 magnitude, October 30. The minimum will probably occur some time in December.

S Ursæ Majoris is now about minimum, and was a very faint point, 12·2 magnitude, October 30. The rise is sometimes very rapid, and observations during the next two months will be of great interest.

R Camelopardi passed a minimum, 13 6 magnitude, September 26, when it was a most unique point, barely seen with power 132, and about the limit of vision for this telescope. The interval since the previous minimum, January 6, 1899, is 296 days.

S Herculis passed a maximum, 6 4 magnitude, September 21, and has been a bright, well-defined yellow or pale orange star for the last six weeks, during which time the light has varied but little. It was observed 7·1 magnitude October 30.

Instrument in use 6·4in. equatorial refractor. Weather has been very favourable, and observations were made on 16 nights, on several of which the sky was remarkably clear. C. E. Peek.

Rousdon Observatory, Lyme Regis.

THE MOON AND THE WEATHER.

[42989.]—In the singular article by Prof. Hazen on this subject (p. 227), referred to by "F.R.A.S." in his letter last week, the writer, from certain *à priori* considerations, is led to say: "We see how absurd the notion is that the moon does influence our weather." He then sets himself to demolish the three ideas that the moon influences (1) pressure (appreciably), (2) cloud, and (3) temperature; all which, of course, ministers greatly to the satisfaction of "F.R.A.S.," who has so long maintained, in season and out of season, that the moon has nothing to do with the weather. Here is a high meteorological authority, whose dictum should effectually quiet the "lunatics."

Very good. But there is a little paragraph at the end of Prof. Hazen's paper which "F.R.A.S." seems to have overlooked, and which fairly takes one's breath away? "Just what influence," he says, "the moon may have upon the electrical condition of the atmosphere may be considered in doubt." Is it, then, possible, that one idea of the moon influencing weather may, after all, be rationally entertained and considered? The words seem to imply that there is some such (electrical) influence; we have only got to define it. But the professor is more explicit, for he presently remarks: "There seems good evidence to show that there are more thunderstorms during new than full moon." Here, truly, is a dilemma for us. It is absurd to think the moon affects weather; it is *not* absurd to think so. The moon has no influence on weather; the moon *has* an influence on thunderstorms. And one of the highest authorities saying both these things, almost in the same breath! Nor is it easy to see how the moon can affect the number of thunderstorms without affecting pressure, temperature, and other things. So that (I take it) the edifice built up by the professor, not very strong at the best, falls to pieces, as every incoherent and contradictory statement is bound to do. This idea of the sun having an influence on thunderstorms seems to be gaining force. Not only does Prof. Hazen accept it. Two eminent meteorologists, Ekholm and Archimus, have recently read a paper to the Swedish Academy, proving that both Polar lights and thunderstorms are under lunar influence. And not long ago, if I remember rightly, a paper connecting thunderstorms with the moon was read in the French Academy. Perhaps some faint ray

of this new light of science may even, in time, penetrate the bigotry (in meteorological matters) of "F.R.A.S." ! A. B. M.

o^1 CYGNI—15 CEPHEI, &c.

[42990.]—If Mr. Espin will refer to the "E. M." for June 21, 1878, he will find a diagram of o^1 Cygni by "S. W. B.," including more stars than his own sketch. The pair *d* is double on this diagram. Mr. Espin has misplaced the companion on sketch: it should be immediately preceding. The *comes* to o^1 is also on "S. W. B.'s" map; there is also a star *s.p.* A rather nearer than Mr. Espin's *a*, and a triple and pair betwixt A and C.

With regard to 15 Cephei, I am at a loss. Mr. Espin gives the old companion as at 200 6° 11″. Now I have repeatedly observed this star with 6½in. some years ago, and I have it as 295°, 300°, 297° at various times, but certainly never at 200°. Is there a misprint? Distance estimated at 10″ to 12″; easily seen with 4in. stop. Perhaps Mr. Espin will examine again. Possibly he may be right; but I think there is an error.

Mr. Burnham's sketch of *o* Cygni was made with the 18½in. refractor of the Dearborn observatory.

Can Mr. Espin tell me how to lay down additional azimuth curves on Peck's cover for his star-map? If they were drawn more closely, they would furnish a means of turning R.A. and D. into azimuth and altitude. What is the principle upon which these curves are drawn, and best means of drawing them?

γ^2 ANDROMEDÆ.

[42991.]—The small companion to γ Andromedæ has constantly attracted attention since its duplicity was discovered by O Σ in 1842 down to even recent numbers of the "E. M." And, singularly enough, the discrepancies as to the colour of the components and as to angle and distance date from the discovery, and also continue at the present date. Observers are flatly contradictory as to which is the smaller star of the pair. Sm called them yellow and blue, De both blue, while Dawes seems to have fluctuated in his appreciations from "both blue" through "both green exactly alike," "green and deeper green," "pale yellow and blue" to "greenish yellow and bluish green." The only safe conclusion is that the colour ascribed depends on the colour corrections of the o.g. used in combination with slight variation in focussing, or is largely atmospheric, and so far as it is inherent is not very pronounced or distinct.

From 1842 to 1850 O Σ thought there was no change in angle or distance; but the evidence for either change or permanency rests on rather unsatisfactory grounds, since in the year 1842 the angle was measured both as 126·6° and 100 2°; and in 1847, as 111·3° and 117·9°; in 1873, 109·2° and 95·9°; while in the previous year it varied from 87·7° to 113·7°. The distance in 1842 is variously stated at 0·51″, 0·15″, and 0 31″, and in later years the variations are considerable, and point to nothing very satisfactory. We may conclude that the stars were too close for any real measures of either position or distance, and that they are no more than rough estimates, although made with micrometers.

The discrepancies continue in recent years. Burnham in 1889, found 98·2°, 0·09″. In 1890 he was doubtful of any elongation, and says "Decidedly less than 0·1″," and in 1891 found slight elongation only with 36in., and power of 2700, "Less than 0·05, and angle 312 6°." One admires the angle given to decimals of a degree with stars only suspected of being out of round. If the observations can be accepted, the stars occulted about 1890, and a considerable error in angle occurred on one or other occasion. But other observers with smaller, but probably more perfect, instruments claim to have completely divided this pair in recent years, although the angle assigned (in one case 113°) is quite irreconcilable with Mr. Burnham's estimate, as his estimates are with older observations. It does not appear that we have as yet any data accurate enough to serve as a basis for even an approximate orbit; but it seems very singular that only Gregorian reflectors have been able to divide, and Newtonians of 12in. and greater aperture, as well as refractors of 36in., have only spoken with uncertain voices.

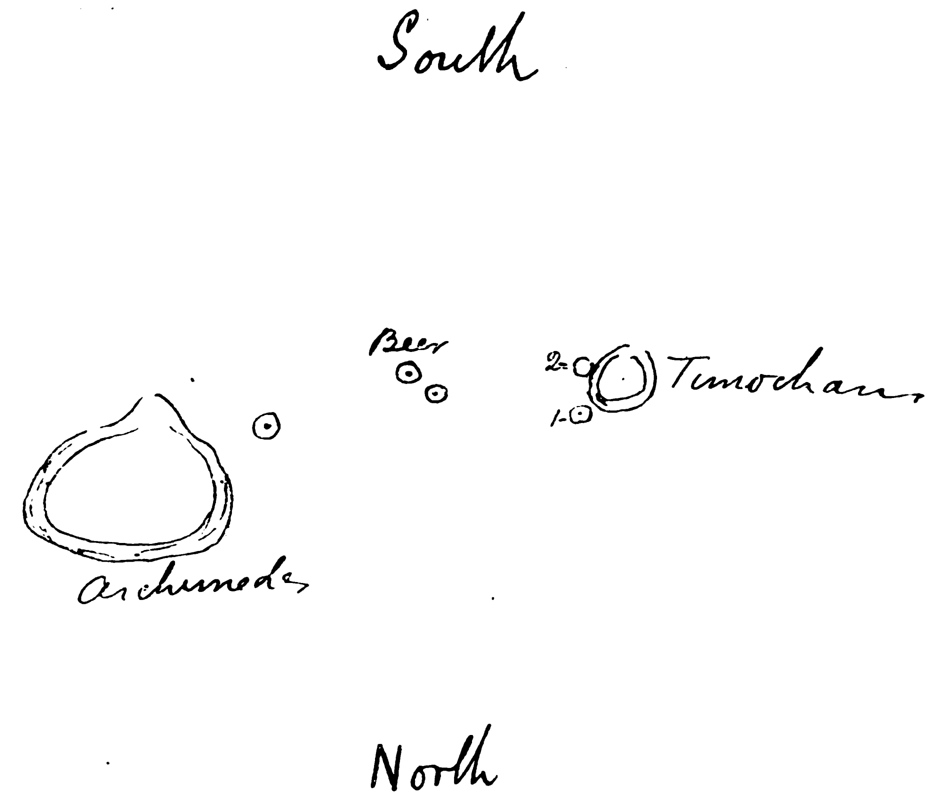
CRATER NEAR TIMOCHARIS.

[42992.]—I am obliged to "F.R.A.S." for his reply to my letter in your issue of 20th ult., and to "E. D." for his letter (42950). I do not think I made any error in orientation; but to make the matter plain, I send a small sketch showing the positions of the crater I see on the photo, lantern-slide, and of the one shown in Elger's map in his book on the Moon, which is not on the lantern-slide. The crater in Elger, and not on the lantern-slide, I have marked 1; the crater which I see on the slide, and is not shown by Elger, I have marked 2. It is much smaller than indicated in the sketch; but through a good magnifier quite clear and distinct. At the bottom of the plate there are the words "Lick Obs., Sept. 52, 1890, Moon's age 8d. 4h." The crater I refer to is rather to the south of an imaginary line drawn from Beer to the centre of Timocharis. R. P.



OBSERVING THE LEONIDS.

[42993.]—Although the paucity of Leonids observed last November and in November, 1897, does not lead us to expect anything like a record display this year, and though the brightness of the moon, so near the full, is unfortunate, it is none the less to be earnestly hoped that the greatest diligence should be employed in using to the greatest possible extent any opportunities for observing the meteors which may be afforded us on the present occasion, and the following simple hints may therefore be acceptable.

Dr. Johnstone Stoney and Dr. Downing give 6 a.m. on the morning of Thursday, Nov. 16, as the probable time of the centre of the shower. The radiant will then be nearly on the meridian, the moon will be low (near her setting), and the morning twilight will have commenced.

The experience of last year rather suggests that this is a late time to fix, and a watch should certainly be kept both on the nights of the 14th and 15th from 10h. 30m. in the evening until daybreak the following morning.

The observations to be made may be roughly classed under those which may be undertaken by persons unaccustomed to meteoric observation, and those which should be made by well trained meteor observers. The principal work to be done by members of the former class is meteor counting. A considerable portion of the sky should be chosen, either one of which the well-known radiant in the centre of the hook of the Sickle in the head of Leo is the centre, or one just bordering on the radiant. The area should not be too large to be easily held at a single view, and its corners should be marked by well-known stars. The counting should then be carried on as suggested by Prof. E. C. Pickering. "Once an hour, or better, once every half-hour, observe and record the time during which ten meteors appear. This is most easily done by noting the time by a watch, and at exactly the beginning of a minute looking at the sky, giving it undivided attention, and counting the meteors seen. If great numbers of meteors appear, it may be better to count a larger number, as twenty, or even fifty. If the interval between the meteors is long, the number to be counted may be reduced. These observations should be repeated until dawn, or over as long an interval as possible. Between these observations the observer may rest, or may make special observations of individual meteors. Thus, when a meteor is seen, record the hour and minute, the brightness on a scale of stellar magnitudes—2 equals the brightness of Jupiter or Sirius, 0 Arcturus or Vega, 2 the Pole Star, 4 the Pleiades, 6 the faintest star visible; the colour, B = blue, G = green, Y = yellow, W = white, and R = red; the class, L = Leonid, if the path prolonged would pass through the radiant point; N = other meteors. Thus, L 5 Y, 12h. 36m., indicates that a Leonid, magnitude 5, yellow in colour, was seen at 12h. 36m.

Observers who are accustomed to meteoric work should lay down on a star-map as accurately as possible the path of the meteors seen with respect to the stars. The time and duration of the appearances should be most carefully noted, and also the time of any special outburst or explosion that may occur to a particular meteor. From these there can subsequently be deduced the radiant positions for different intervals during the night. This class of observation is a most important one, as from it may be learnt, through the shift of the radiant, the influence of the earth's attraction on the swarm.

A third method of observation is by photography, and here again the work may be divided into two classes, according as the camera is either rigidly fixed, or else mounted equatorially and driven by hand or clockwork. In neither case should a long exposure be given, since the moon is so nearly full that it may fog the plates. Probably a quarter of an hour should not be exceeded, and the times of opening and closing should be most carefully noted. So also the observer should, as far as possible, watch the region of the sky covered by the camera, and note the time and direction of any bright meteor crossing it. The camera may be pointed on the radiant or on the zenith, or on some star conveniently placed between the two.

A portrait lens or rapid rectilinear lens should be used with a fixed camera; a wide-angle lens with one which is made to follow the stars. It will be much less necessary to note the time of the passage of the meteors in the latter case, since the stellar images would be dots on the plate, not trails, as with the fixed camera. Hence the direction of motion of a meteor can be determined without knowing the time of its passage.

Since the colour of the meteor streaks is usually of a greenish or bluish colour, it would be advisable to use a red lantern to illuminate the notebook and the face of the chronometer. Still more important is the need of securing accurate time. Both before and after the observations the error of the watch or chronometer used should be determined, and the correction applied to the observed time.

THE NUMBER OF STARS NOT INFINITE.

[42994.]—In the current number of *Knowledge* will be found an article in which I have stated very briefly the reasons which have led me (contrary to the current opinion) to believe that the number of fixed stars is finite. In the following letter I shall give my reasons in somewhat more detail.

The point from which I start is that the total amount of light received from the stars is a certain very small quantity, variously estimated, but cer-

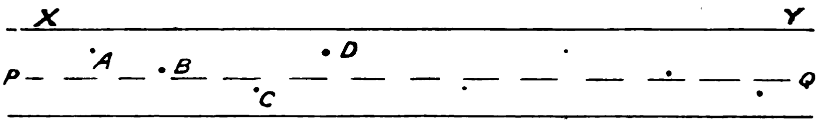

FIG. 1.

tainly not exceeding one-tenth of the light of the full moon, or 1-8,000,000th of the light of the sun; whereas if the number of stars were infinite, the whole of the sky would shine with a brilliancy comparable with that of the sun itself.

That this would be the case can be shown most easily from the theory of probability. Let X Y, Fig. 1, be a tube of uniform cross-section in which a number of objects, A, B, C, D, are scattered at random. The tube is supposed to be of infinite length; but the distance between any two adjacent objects is supposed to be finite, and the objects themselves to be of sensible size. Let an infinite straight line, P Q, be drawn through the tube.

Problem.—To determine the probability that the line P Q will ultimately intersect one of the objects.

Solution.—Let a be the area of the object A projected on a cross-section of the tube, b that of the object B, and so on. Also let s be the area of a cross-section of the tube. Then—

Probability that P Q will miss A is $\frac{s-a}{s}$

do. do. do. B is $\frac{s-b}{s}$

do. do. do. C is $\frac{s-c}{s}$

and so on. Hence we get the probability that P Q will miss A, B, *and* C

$$= \frac{(s-a)(s-b)(s-c)}{s^3}$$

$$= \left(1-\frac{a}{s}\right)\left(1-\frac{b}{s}\right)\left(1-\frac{c}{s}\right)$$

If there are n objects, we have a similar expression with n factors. Suppose, now, that the smallest of the n objects has an area q. The product of the n factors $\left(1-\frac{a}{s}\right)\left(1-\frac{b}{s}\right)$ &c., will be less than $\left(1-\frac{q}{s}\right)^n$ By hypothesis, q is finite; consequently $\left(1-\frac{q}{s}\right)^n = 0$, when n is infinite. In other words, the probability that P Q will ultimately meet one of the objects is a certainty. The above is a formal proof, but the conclusion appears to me sufficiently obvious without mathematics.

Now, let us apply the above to the stars. P is the eye of an observer looking through a telescope in the direction P Q. The objects A, B, C, D, &c., are stars. It follows that the line of sight will ultimately meet a star; at least, it will do so if we adopt the hypothesis that the stars are scattered indiscriminately at finite distances from each other. Since P Q will ultimately meet a star in whatever direction it is drawn from P, and since the superficial brightness of an object is independent of its distance, it follows that the brightness of the sky would equal that of an average star if the stars extended infinitely in all directions.

The above reasoning is clearly conclusive against the hypothesis that the stars are infinite in number and scattered throughout all space indiscriminately. We may, however, imagine that the stars might be distributed on some system which would render the conclusion invalid. We shall examine this supposition separately.

Let P, the eye of the observer, be the apex of an infinite cone having a small vertical angle (Fig. 2). Let this cone be divided into compartments by equidistant planes A, B, C, D. Let all the stars in the cone from P to A be projected on A from P as the point of projection. Let the total projected area be a. In the same manner let b, c, d, e be the projected areas for the stars in the other compartments, and let s be the area of the base of the cone P A; also let P A = r. Then the solid angles subtended by the stars in each compartment will be $\frac{a}{r'}, \frac{b}{4r'}, \frac{c}{9r'}, \frac{d}{16r'}, \frac{e}{25r'}$, &c. Now we know by observation that the sum of this series is finite, and much smaller than s. The number of terms must consequently either be finite or they must continually diminish, and become ultimately evanescent. Now it will be observed that each term in the series represents the density of the stars in the corresponding compartment, for the area of any plane D is

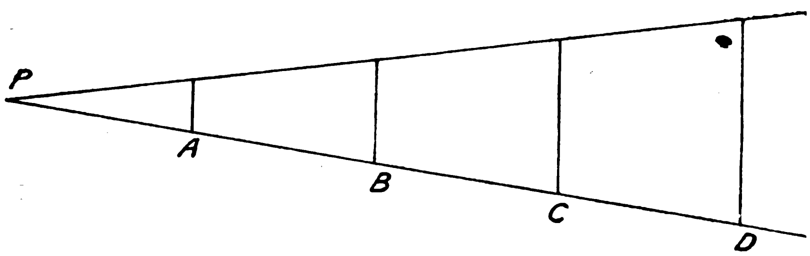

FIG. 2.

proportional to the square of its distance from P. Hence, if the number of terms is infinite, the density of stellar distribution becomes ultimately evanescent. I submit that this only differs mathematically, and not physically, from asserting that the number of terms is finite. Perhaps the matter may be put a little more clearly. Thus: The sum of the series must be greater than $n x$, where n is the number of terms and x the smallest term. Hence, if n = infinity, x = zero.

I see no escape from this conclusion. The method of distribution will not affect it. The result will be the same if we imagine the stars to be collected into systems, the distance of the stars apart in the system being small compared with the distance between the systems. To affect the result, the distance of the systems from each other would require to be infinite.

In the above, it has been taken for granted that there is no absorption of light in its journey through space. If there be a medium in space which intercepts light, the conclusion will no longer hold. Hence we have to consider the probability of the existence of an intercepting medium. I reserve this for another letter.

Gavin J. Burns, B.Sc.

"THE MENACING COMET."

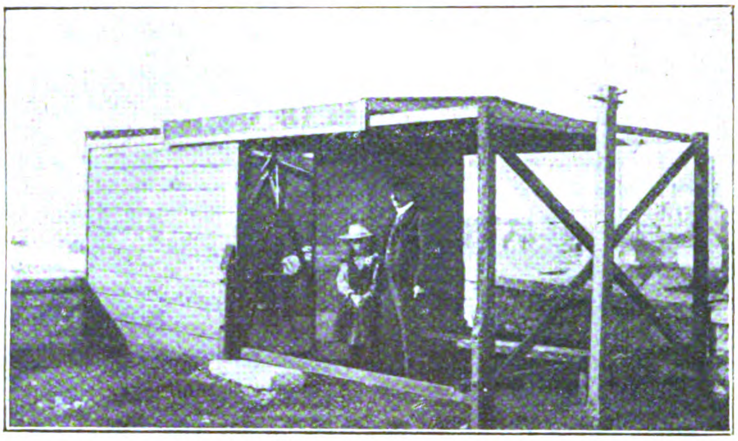
[42995.]—On the 1st inst., the *Daily Mail* may have startled the ignorant and those who fear to die by announcing, under the above heading, the return of Biela's comet.

"This announcement was all the more alarming, because Biela's comet has threatened the destruction of the globe before, and because Prof. Rudolf Falb foretold in 1897 that the end of the world would come 'on November 13, 1899, at nine minutes past three o'clock.'

"Yesterday, however, the Astronomer-Royal at Greenwich assured a representative of the *Daily Mail* that, as far as Biela's comet is concerned, the end of the world would not take place on either the 13th or the 28th of the present month."

It is now the 3rd inst., and the clock of terrestrial time is ticking on, measuring the same motion of the earth, at the same rate, as it has always done in the memory of man. By the time this is in type, we shall be close upon the fatal "nine minutes past three o'clock of the 13th inst., and the 28th," for there seems to be some discrepancy of calculation. In fact, Prof. Falb is slightly out in his figures and time. Only slightly, but sufficiently to remind one of the Byronic lines in one of miscellaneous poems, describing the red nose of the chancellor, which startled the devil into momentarily thinking it was the general conflagration. Of this we may be sure: the clock will sublimely tick on, and it will not be Biela's comet that will give the earth any such infernal jolt in its orbit round the sun. Now, I am far from imagining that celestial collisions may not take place, and that "such occurrences, though rare in time, may not be frequent in eternity." The whole thing was supremely absurd, put as the *Daily Mail* put it. If a comet's orbit so intersected that of the earth that it was certain to strike us, it is but reasonable to suppose that it would be visible for some time previously, and keep on getting bigger until it put us all in a sweat; unless it suddenly came round a corner in the heavens, and there are no corners in infinite space for any comet to play us such a joke. Having said this much, I now wish, with your kind permission, to submit to your many astronomic readers some ideas, the results of years of study, in relation to comets in general; and perhaps they will give additional interest to the comet, Biela's or whatever name it bears, which seems to be a part of, or involved with, the stream of Leonid meteors.

I will begin with the startling assumption that gravitation is caused by motion. I have studied Newton's "Principia" years ago, and in none of his works, not even in his "System of the World," have I been able to discover that this world-renowned philosopher explained of what gravitation consisted. Having, in the absence of any other explanation, assumed that the cause of the smaller body falling to, or towards, the larger body is because the larger one is in rapid motion, it naturally follows that no planetary body in infinite space can, properly speaking, have any such thing as weight. To suppose the earth in space has even the weight of a feather, is equivalent to supposing that something can be made out of nothing. It is as ridiculous as supposing that a thing can hold itself up. It may be safely assumed that the laws of motion which apply to one comet may be taken, in a sense, as applying to them all, although they may apparently not all be acting in the same manner. Hence, a little consideration of Halley's comet may help us to understand, perchance, something about the portentous threatening of Biela's. Halley's comet was a queer thing, upsetting all the schools of thought or systems of astronomy which were taken as accepted facts beyond question. So ruthlessly did this comet act in the provoking way in which it travelled in utter defiance of all preconceived ideas of motion, gravitation, and force, that it upset everything and made philosophers endeavour to account for it by supposing a palpable absurdity. Sir John Herschel had a suspicion that the phenomena of this comet did not cover the laws of the gravitation of matter as propounded by Newton. He saw and stated that "the comet's envelope and tail could not be a figure of equilibrium under the laws of gravitation." It must be borne in mind that the behaviour of the tails of comets is a phenomenon utterly incompatible with our ordinary notions of gravitating matter. If they are material, where is the force which can carry them round in the perihelion passage of the nucleus in a direction pointing continually from the sun, in contravention of all the laws of planetary power and motion? The "repelling force" which Herschel was constrained to imagine, if it exists, destroys *in toto* his own and Newton's gravitation theory. It did not dawn on his mind what Newton had left unexplained—viz., *the cause of the smaller body falling to the bigger one.* Herschel acknowledged that he could not in gravitation find the cause for the extravagant sweep of the tail of Halley's comet, which was far beyond the earth's orbit. The "repellent force" was an idea equivalent to making a wheel turn both ways at once and at the same time. The present popular idea that our world in infinite space has weight, the millions of trillions of tons of which are capable of being calculated, resolves itself into confusion worse confounded, and the wildest absurdity. What, then, is a comet? My answer is—it is unknown. The spectroscope gives us some information, but not much. The use of amateur instruments, such as are in the reach of mechanics, 3in. refractor or possibly a stray 5in. mirror, is disappointing, so much has to be left to imagination. The most important statement emanating from an observatory that I have read for some years, was that emanating from the St. Louis Observatory. It was stated that the astronomer fixed the telescope in such a position that a comet, which was so far off that none but a cyclopian instrument could see it, would pass the field of view at midnight. In place of the eyelens he put on a fine plate of selenium at the back of a spectroscope, which is a mineral highly sensitive to electrical action, to which he attached some fine electrical wires connected with a bell in his bedroom. The spectrum of a comet is unlike that of any other heavenly body, and the moment it passed over the selenite plate it violently rang the bell in the bedroom. I believe this was a true report, inasmuch as I never saw any contradiction. It was certainly one of the most marvellous things I ever remember reading, for a comet, countless millions of miles off, invisible to all but an immense refractor, had the power to excite or exert sufficient mechanical power to violently ring a bell. Of the nature of cosmic force we know next to nothing. The recent photographic discovery that the well-known spiral nebula is not spiral at all, but consists of consecutive rings of nebulous matter, would seem to show that rings of meteoric matter ultimately condense into planetary globes. The question arises whether the great band of Leonid meteors, of which Biela's comet appears to be a part, is of this nature. Probably if it is so, the erratic movements and broken-up condition of the nucleus may be accounted for by the repeated impact of the earth in rushing through the stream. Evidently this would, by its disturbing force, prevent its consolidation, without which it cannot assume its planetary orbit, but must remain

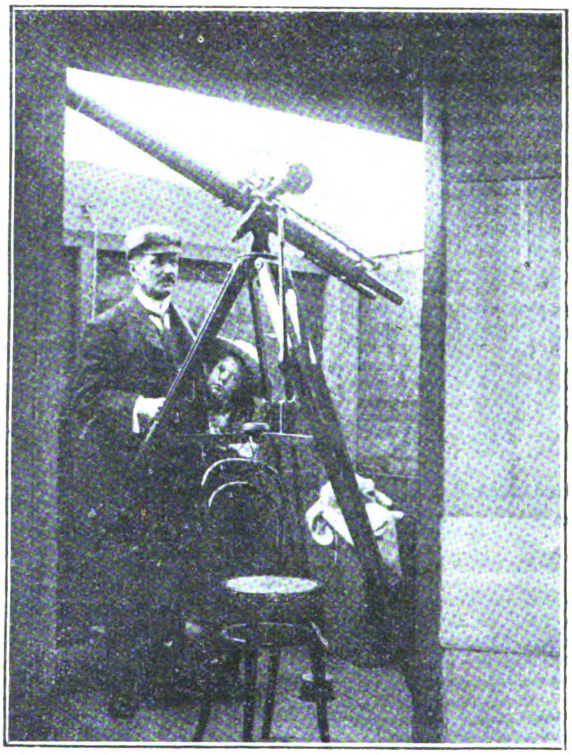


an ever-widening ellipse, ultimately becoming a comet detached from our Solar System, yet repeatedly visiting it by reason of the affinity of its elements and unknown laws of motion.

A Constant Subscriber.

AMATEUR'S OBSERVATORY.

[42996.]—I INCLOSE two photographs taken by my son of a little observing house I have lately put up which turns out very satisfactory in practice. The pictures (if they come out clearly on reproduction) more or less speak for themselves. The exterior



view shows the sliding roof (which is covered with canvas) half-way off. It runs on small brass rollers, and is slightly ridged to allow the rain to run off easily when the building is closed. A wooden plank will be observed in the middle of the area occupied by the skeleton frame exterior to the observatory. I walk along this when pushing the roof along. Without it the roof could not be moved so easily, owing to its height from the ground. The angle between two low walls was utilised as a site for the erection, which is firmly clamped to the former by two iron bands, the situation being high and exposed to all the winds that may blow. The post to the right with wooden pins has nothing whatever to do with the observatory, being occasionally used to suspend a line for drying clothes on.

The other picture shows the interior. A weather-board can be seen which can be lowered when required, giving a clear view just down to the horizon. The glass is a 2¾in. refractor on a Wray equatorial mounting without circles. The legs of the tripod rest on three iron pipes driven into the ground and filled with cement. Boards of floor cut round these, so that motions of observer cannot shake the glass.

I had the slow motion in declination brought down by a wooden handle to near eyepiece, which the picture shows. A small dry battery rests on the crosspieces of the tripod, and from it the wires run up to the electric lamp fitted in the tube on the opposite side to the counterweight.

One corner of the little house has a sloping desk for writing, and two shelves below for eyepieces and other paraphernalia.

The whole was put up to my general design by someone a little more skilled than the oft-quoted "village carpenter," but the latter could no doubt put up just as good a house under proper supervision. If anyone requires further details, I should be pleased to furnish them on application. The door, I should say, faces east, roughly. My little daughter is included in the photo.

E. E. Markwick, Colonel.

H.M. Gun Wharf, Devonport, Oct. 29.

REDUCING INTENSITY OF LIGHT—ASTRONOMY (?)

[42997.]—LET Mr. Ellison disabuse his mind of the notion that I had him in the least in my eye while writing letter 42816. I now apologise for having failed to acquaint myself of the fact that the "various devices" I reviewed (I can scarcely be said to have criticised them) had all been rediscovered by him, in this way making them, as he designates them, "*his*." Therefore would it be most unjust of me to accept his "duly grateful" thanks.

It will be found, I think, that as I indicated I should do, I added "my little quota"; but neither did I claim any originality for myself, nor deprive anyone, I hope, of the honour of their inventions, the authorities I named having long been known.

The question as to the relative amount of disturbance of vision caused by flat glasses of equal perfection placed so as to be influenced by reflection as compared with refraction, or placed in front of eyepiece lenses as compared with a position in the parallel rays of the convergent pencils behind them, is far too important to bear condensation here, but must lie over. But the very serious error made by the writer of 42948, when discussing a suggested improvement on "dark-glasses," makes it imperative that, emanating from so influential a source, its misleading effect upon less accomplished readers should be neutralised. In 42948, we are told that "it does not require much mathematics, after all." Certainly not; but all the same Mr. Ellison's plan is anything but an improvement on the plane glass if inserted in the position he advises. The suggestion is to make the surfaces of the dark glass of radii which have the central point of the image at the solar focus of the object-glass as the centre of both, thinking as he does, in fact stating, that "all rays from the o.g. would be perfectly normal to both surfaces, and would suffer no change whatever." The error here, which must be evident to the merest beginner in optics, and which is indeed of the same kind as that made some time ago by a learned contributor while discussing images formed by reflection, lies in fixing the attention solely upon the mathematical point which forms the axial part of the image. The slightest attention shows that while no doubt for the above point all rays from the o.g. would be normal, the conditions of the lateral rays passing to every part of the image other than the single axial point, are far different. No mere concentric arrangement of curves, watch-glass-like, can possibly prevent very considerable disturbance. Were this otherwise, many problems in practical optics would become very simple indeed, which theory and experience alike prove to the contrary. Indeed, in Mr. Ellison's suggested case, a glass curved as he advises would cause still *more* serious disturbance than a plane one, as the simplest projection of the conditions will demonstrate without any mathematical calculations whatever.

As is well known, such a dark-glass, if properly figured, would require to be made to suit each separate eyepiece, and even then there would be a margin of compromise. So much for the ultimate benefits of non-mathematical optical pottering. Fortunately, such a position for the dark-glass as Mr. Ellison suggests is not a necessity.

It is not my intention to advert, even shortly, to anything 42816 did not contain; but I may be excused in pointing out again that such "devices" as entire telescopes set apart for solar observations alone—e.g., Sir J. Herschel's reflector with unsilvered mirrors (the so-called helioscope), or even telescopes kept partly in that condition, formed, like the many complicated and expensive designs for like purposes, avowedly no part of my purpose in reviewing the various simple methods cited in my letter on this subject. On this account, keeping, as I said I should do, to such simple appliances as could cheaply and easily be used upon any telescope that should always be readily available for every kind of observation, I failed to see the bearing of certain criticisms made on my letter, because it did not happen to refer to methods I, on stated purpose, left out.

But, after all, perhaps my main object in bringing this subject forward again is to point out the fact that the writer of 42948 has, apart from the scientific error already alluded to (an error easily excusable in one unaccustomed to deal in such matters), made a literary mistake which might have been very easily avoided—a mistake which is particularly distasteful in destructive criticism—I mean the attributing of certain responsibilities to the wrong source.

I find I am credited with having led your telescopical amateur into the trial of methods which led to thorough disappointment—methods which gave results that might be said to be "magnificent," but which could not be called "astronomy." I suppose by a "perforated stop" (a term I do not remember having used) your correspondent means "perforated screen," and he states broadly enough that in the form in which he used it (a piece of perforated zinc, of hole size unknown) he followed my recommendation. Let me correct this upon three points. First, by looking again at 42816, *he* will find I merely go the length of saying "I can quite substantiate Mr. Dawes's opinion of the screen as already quoted second-hand in your pages from Chambers's 'Handbook,'" adding that "there Dawes is stated to have found this expedient to be capable of producing a sharpness of definition he considered to be very marked." Secondly, perforated zinc, which, personally, I have never found in hole, and especially in solid reticulum, so fine as the "'cardboard,' such as that employed in Berlin-wool work," which Dawes is said to have used, was not a fair trial material; and, thirdly, while "substantiating" Mr. Dawes in my letter, I took care to mention the fact that "my *own*-experience has been in favour of fine net," and further that different telescopes require different sizes of mesh, fine muslin being mentioned as having served well to bring out on some apertures, and under certain powers, the intense black zone

immediately surrounding the bright stellar point, or points, and in which zone faint or close companions were most favourably seen. In none of the above three particulars does Mr. Ellison's trial follow even the recommendation imputed to me, and in so far as the screen he did attempt to use (perforated zinc) is concerned, no one can tell whether or not its grade suited his telescope so as to be able to compare his results with those of Dawes. Indeed, the question becomes simply one of comparative proficiency in manipulative skill, in knowing what to look for, in sharpness of eye, and in general observing experience, between Mr. Ellison and Mr. Dawes, whose method he has followed much more closely than my modification of it. The latter has probably found a successor more famous than himself — but we are a "hard-hearted" and somewhat "unbelieving generation." The resplendent display of remote diffraction images of the star, which has attracted Mr. Ellison's attention so much in comparison with the dark inner zone, are just such phenomena as an experimentalist not very sure of what he was to see would fasten his eye upon. Of course, to observe the comparatively tame central phenomena of this diffraction spectacle, requires *rather* more skill than to write up a spectacular peroration upon the supposed failings of a brother contributor, who is no longer to fill, it would appear, the place of "guide, philosopher, and friend in matters astronomical" to your correspondent "any more."

Any more? Why, I have all along been in unhappy ignorance that I ever filled any of these posts to anyone—at any rate, there is now a vacancy.

But, after all, what astonishes me most is the fact that so learned a correspondent as the writer of 42948 should consider the subject matter of my letter (and his also, for that matter) as "astronomical" at all. To some amateurs, no doubt, these trifling physical and optical elements, along with the "fun," as some express it, of pottering among pieces of lacquered brass, or its humbler substitutes, may go a long way in standing for "astronomy," especially when backed up with occasional trials of sight as to who can see the faintest star with the most unsuitable means, or with occasional entries, in official-astronomer-like form, of such valuable details as "just glimpsed so-and-so," "good seeing at 11h. 50m.," &c. "Mere instrumentation" was a phrase several times heard by me, as expressive of the value placed upon the above style of "astronomy" by a late very high official in these matters.

Does one find almost anything of this species of "astronomy," or even the trace of some of its most popular developments, in such works as Airy's "Popular Astronomy," or in Herschel's "Outlines"? Let anyone who despises mathematics in such subjects read the latter's introduction, where is found the following:—"Admission to its sanctury (Astronomy) is only to be gained by one means—sound and sufficient knowledge of mathematics, the great instrument of all exact inquiry, without which no man can ever make such advances in this or any other of the higher departments of science as can entitle him to form an independent opinion on any subject of discussion within their range." (The dozen last words seem right.)

Regarding Vega, Webb says that as a test object the companion may be seen *in favourable weather* with a $3\frac{7}{10}$in. refractor, *sometimes*. He adds, with significant want of vigorous belief, "*it is said to have been* perceived with $2\frac{1}{8}$in." When I can afford time, I am going to run up to Dublin to experience the wonderfully favourable conditions there for seeing this star with still smaller an aperture than that so strongly doubted by Webb, but reported in 42948. H.

"IGNORANCE."

[42998.]—It is rather surprising to find so intelligent a correspondent as Mr. Schucht (p. 276) writing about a "grand and enjoyable hobby." Perpetual motion underwent post-mortem many years ago, as can be found in Dircks's "Perpetuum Mobile." and it is now past mention by passed mechanics, just as one o'clock is p.m. To us the motion of the heavenly bodies is perpetual; but that is the nearest we can get to it, for the vision of a machine of the kind is only a dream which comes at past midnight. P. M.

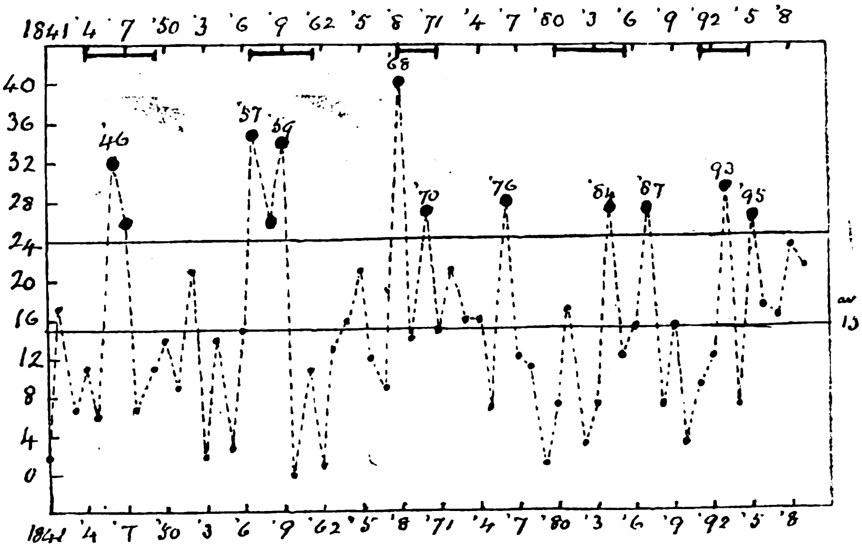
FIFTY-NINE LONDON SUMMERS.

[42999.]—A short time ago I gave, by your kind permission, a curve of London winters. Herewith I send you a curve of our summers for the same period—since 1841.

The item here considered is not, as in the former case, the mean temperature of a group of months, but the number of days in each year on which the temperature reached or exceeded 80° (at Greenwich). This number varies, it will be seen, from nothing in 1860 to 40 in 1868; the average is about 15.

I think it is worth noting (*pace* "F.R.A.S.") that nearly all the hottest summers in this period have occurred about the time of growth and maxima of the sunspots. Those with more than 24 of those hot days are marked with a bigger dot than the others; there are 12 of them. At the top of the diagram will be noticed five short horizontal lines. Each of these is drawn from the first year after a sunspot minimum to the first year after the next maximum. And it will be seen that 10 out of the 12 are in the time covered by those lines; the exceptions are 1876 and 1887.

Alex. B. MacDowall.



SELF-ACTING SURFACING.

[43000.]—I send you this suggestion for self-acting surfacing for a lathe fitted with overhead motion. I am about to fit it to my screw-cutting

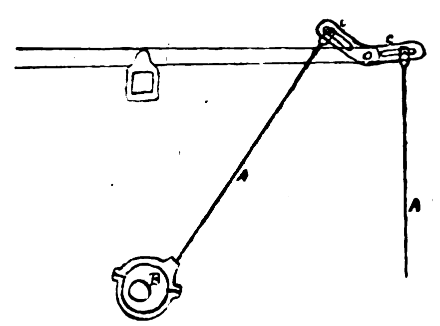


Fig. 1.

lathe, but would be pleased to hear criticisms or improvements on it first. It is the same kind of feed as is commonly fitted to shaping and milling machines, but I have not seen it applied to lathes before. The sketches, I hope, make it plain. In Fig. 1, A A are rods (about ¼ square Bessemer steel) to convey motion from eccentric B on overhead

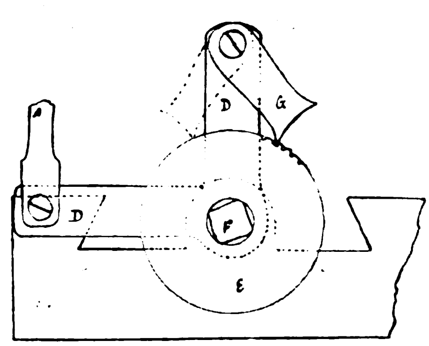

Fig. 2.

shaft to pawl on cross-feed screw. These rods are connected by means of the slotted plate C, fixed to tension shaft, which must be locked in position. In Fig. 2. shaft A moves plate D, which is free to turn on feed-screw F. On the square end is fitted a cogwheel, E, all in one with a winch-handle for hand feed (not shown). Pawl G moves wheel E, and direction can be reversed by turning G over to the other side, as shown by the dotted lines. The rate of feed can be altered by moving studs in the slotted frame C (Fig. 1). Fig. 2. is half-size.

H. W. Allingham.

PROF. BONNEY ON THE AGE OF THE EARTH.

[43001.]—Prof. Bonney has published a most wonderful "Story of Our Planet," near 600 pages, and in the index there is no such word as *comet*. It is true that by following the references given under "meteors," we find at p. 331 that "at intervals more rare the comet gleams like a pale torch among the brighter sparkles." At p. 335, "the comets, attenuated as is their substance . . . . consist apparently of hydrogen with various compounds of carbon—possibly chlorine and some other terrestrial substances." For the only visible bodies that can ever encounter "our planet," this pair of sentences out of 600 pages seem ridiculous. Comte, the Positivist philosopher, saw that the comets were simply the *only* bodies, besides sun and our satellite, that interest us terrestrials at all.

In discussing the "age of the earth," he fixes this at something between 100 and 500 million years. That would involve meeting or being overtaken by at least 400 to 2,000 comets, of which he has not a syllable but the above three lines!

Without hinting at the probability of the earth being older than the sun, he relates Laplace's Nebular Theory in such a way as to make the sun the last body to appear (p. 337), and supposes the earth to solidify while the sun was "possibly augmented in bulk by the matter which is now condensed into Mercury." As the said matter is not a forty-millionth of the sun's, this augmentation was hardly worth mention. I know of no reason for thinking the sun as old as the Permian strata.

We have witnessed in the Andromeda nebula the birth of an earth, but at no time that of a sun. We may venture to predict that if mankind ever witness such a birth, it will be in the same nebula. So, too, if an event like the destruction of Sodom is ever witnessed, it will be in the morning of some 15th of November, or in the next century 16th, and so on. E. L. Garbett.

OLD TIMES.

[43002.]—Seeing "Jack of All Trades" answering questions again takes one's thoughts back to the early days of the "E. M.," when Mr. Bottone taught us chemistry, and "Sigma" (Mr. Sprague) contributed his work on electricity; when "E. L. G.," with many adjectives, anathematised the decimal system, and introduced us to his pet Deluge and Watery Comet; when Mr. Hampden and "Parallax" would not be convinced that the earth was round, and Mr. "H." did not feel inclined to pay his wager; when W. Tonks told us all about small mechanical matters, and "Seconds Practical Watchmaker" taught us how to repair watches; when Thos. Fletcher, J. Lancaster, and R. A. Proctor were regular contributors, the latter with his column of Paradoxes; "The Harmonious Blacksmith" and "Fiddler" discoursed sweetly, and the letters of "Eos," from various Tropical places, were always such good reading (I wish they could be reissued in book form); when Fred Carre and "Frontiersman," "Saul Rymea" and "Todleben," "O. S." and "J. K. P.," and so many others gave us the benefit of their experience. When the illustrations were woodcuts, and the "Sixpenny" Column contained about a dozen advertisements; when in answer to an inquiry as to a machine for turning over the leaves of a book to be used by an engine-driver who had lost both arms, a subscriber built a machine, and sent it to him; when "Garrison Gunner" (Capt. Battersby) told us about the West Indies, and so many others who, alas! have joined the majority! There were giants in those days.

Talk about an encyclopædia—a set of the "E.M." is the only one that covers the ground in regard to

mechanics and applied science, and is a mine of information on almost every subject, and some very queer ones have appeared. We had our Medical Column, which was stopped on a point of etiquette, and the Legal Column ditto. When that interminable series of articles appeared on Organ-Building, which is, however, the most complete ever written on the subject, and Dr. Allinson taught us to drink hot water (and a very good thing it is) and eat whole-meal bread. Thirty years ago I bought a number of "E.M.," and never missed a week since. It is curious to notice how a certain lot of inquiries turn up at regular intervals, and how frequently perpetual motion is discovered. Perhaps the best series of articles were those on Zoology by the late Dr. Aveling. Would it not be possible to have another series in continuation to bring them up to the higher mammals? And why not a little human physiology?—surely there is no machine better worth describing than the human body.

West Didsbury. M. Cole.

A SIMPLE WATER MOTOR.

[43003.]—The following description of a simple water motor, which may be readily constructed with very few tools and little difficulty, may be of service to Mr. River (query 96845), and other readers of the "E.M." The motor is intended to operate off the ordinary house supply, and will give from one to two man-power, according to available pressure.

A glance at Figs. 3 and 4 will show at once the method of construction, and the principle on which the motor works. The first thing required is a wooden disc 8in. in diameter and 1¼in. broad, mounted upon a ⅝in. steel spindle. The central portion of the spindle is to be left of full diameter for a distance of 5in., each end being turned down to ½in. diameter. If the operator be not the possessor of a lathe, the nearest blacksmith will do the necessary turning for a few pence. Care must be taken to leave sufficient length at the side to admit of a pulley being afterwards attached. The wooden disc should now be firmly keyed on to the spindle, and if possible turned up true *in situ*. However, if carefully made otherwise, this is not an absolute necessity. Finally give the wood a good coat of tar. We now require thirty little buckets of the form shown in Fig. 1, 4in. by 4in. The simplest way to prepare these is to model one carefully in wax. Well oil a small sheet of glass and also the wax pattern, and place the latter hollow side downwards upon the glass. Mix up some plaster of Paris to a stiff cream and pour it carefully over the pattern, afterwards working it up carefully with a flat paper-knife or similar tool, taking care to leave a good margin round the pattern. Allow the plaster quarter of an hour to harden; then take it up, and, with a sharp penknife carefully cut away any plaster which may have found its way into the hollow face of the pattern. With the point of the penknife also bore three conical holes in the plaster margin. Again, well oil the face of the mould and pattern, and proceed to form a plaster-lid in the same manner as before. When the plaster has hardened this lid will be found to lift away quite readily from the body of the mould, whilst the three little conical pegs fitting into the conical holes serve as guides, and insure its being replaced in exact position. The wax pattern may now be removed from the mould. If necessary, it can be melted out, and the mould should be set aside in a warm place to dry thoroughly for a day or two. Across the face of the mould a bell-mouthed groove must be cut through which to pour the metal, and on each side of it a small groove to permit of the escape of air when pouring the castings. The castings may be made of an alloy of two parts of lead to one part of zinc, and the mould may be held together under gentle pressure in a vice whilst making each casting. After the required thirty have been cast, two small holes should be drilled or punched in each, as shown in Fig. 1, and the buckets fixed at equal distances round the periphery of the wooden wheel by means of long French nails.

To make the bearings, procure some mandrel-drawn brass tube ½in. internal diameter. Cut off a short piece about 1½in. long, and round it form the body of the pattern in wax, allowing about ¼in. of the tube to project at what will afterwards be the outer end of the bearing, and keeping the other end flush with the face of the flange. Place the oiled pattern and flange downwards on a sheet of oiled glass and form a plaster mould as before, first closing the ends of the tube with wax plugs to prevent the plaster entering.

When the plaster has hardened, turn the mould over, withdraw the brass tube about a quarter of an inch, and form a plaster cover as before. The mould will now show in section, as in Fig. 2, the prints A A being formed by the brass tube. When casting the bearings, well tin a short piece of the brass tubing with solder, place it within the mould as a core, and cast the body of the bearing round it in zinc-lead alloy. The result will be a bearing requiring no further treatment save the drilling of an oil-hole. Two bearings are required. The wooden case for the motor may be made from ½in. deal, the inside dimensions being 4in. by 12in. by 15in. high. In the bottom board must be cut a hole about 3in. in diameter to allow the waste water to escape, two straps being also secured to the bottom to raise it about an inch from the ground, and by means of which it may be firmly screwed or bolted down if required. The nozzle is formed from a short length of ⅝in. lead piping. One end is knocked up until the bore is reduced to about $\frac{3}{16}$in., and to the other is soldered the male screw of an ordinary hose junction. A lead flange by which it may be screwed in position should also be soldered on. When putting the machine together, care must be taken to get the bearings in perfect alignment. A slight tendency to bind may be corrected by sinking the bearing a little bit into the wood on one side or the other. The pulley may be roughed out and afterwards turned to shape with the machine running. Connection may be made with one of the house taps by means of an ordinary hose, and the motor either placed in the kitchen sink with a heavy weight on it to hold it steady, or fastened down over a grating. It will be found most useful for driving small dynamos and similar light work.

W. J. G. Foreman, C.E.

CALCIUM CARBIDE.

[43004.]—No one can keep more than 5lb. of calcium carbide on his premises without a license, and the railway companies treat the carbide as if it was an explosive, and have special rules and rates as in the case of cartridges, gunpowder, &c.

Everything that can possibly be done to kill a most promising industry by rules and rates is being done by the Board of Trade and the railway companies, and an industry *can* be most effectually killed by absurd and restrictive regulations, as witness the melancholy example of the motor-car. It is no exaggeration to say that the ridiculous regulations of the Board of Trade have lost this country many millions of pounds, and have strangled it in its birth the most promising new industry of modern times. The more free and enlightened French are miles ahead of us—the victims of a narrow, bigoted, and autocratic bureaucracy.

I have seen it stated that eighteen hundred townlets and villages in France are lighted by acetylene. In this Board-of-Trade-ridden country are there one hundredth as many? Lancastrian.

ELECTROID GAS.

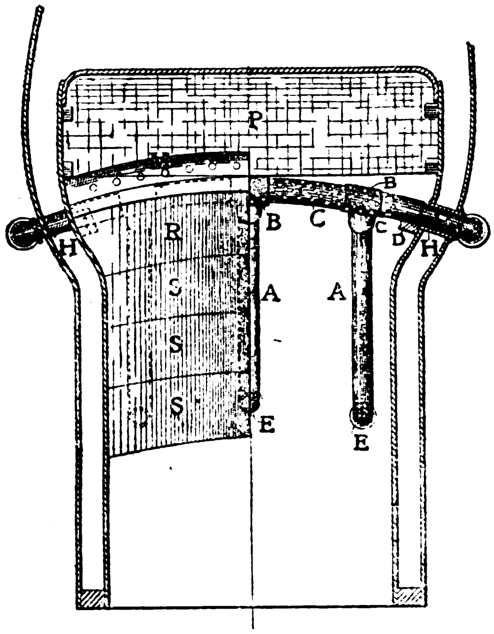
[43005.]—The name "Electroid" is a misnomer. I should say an ignorant and absurd misnomer. The gas is only our old friend Acetylene plus two volumes of atmospheric air. The acetylene generator used by this company is on a good principle, and makes a very pure gas, as is always the case when the carbide is thrown into a large excess of water, heating and polymerisation being thus avoided. By an automatic arrangement the carbide is thrown into water as required, and without interrupting the action of the apparatus. The gas passes to a purifier to remove phosphorus—the worst impurity—and then to a mixer, where it is automatically mixed with two volumes of atmospheric air. The resulting acetylene light is singularly white and beautiful. I have thoroughly inspected and investigated the apparatus, and its working, of the Electroid Gas Co., and believe it to be a most safe and excellent arrangement for the production and consumption of acetylene.

Wm. Hardman, M.B., &c.

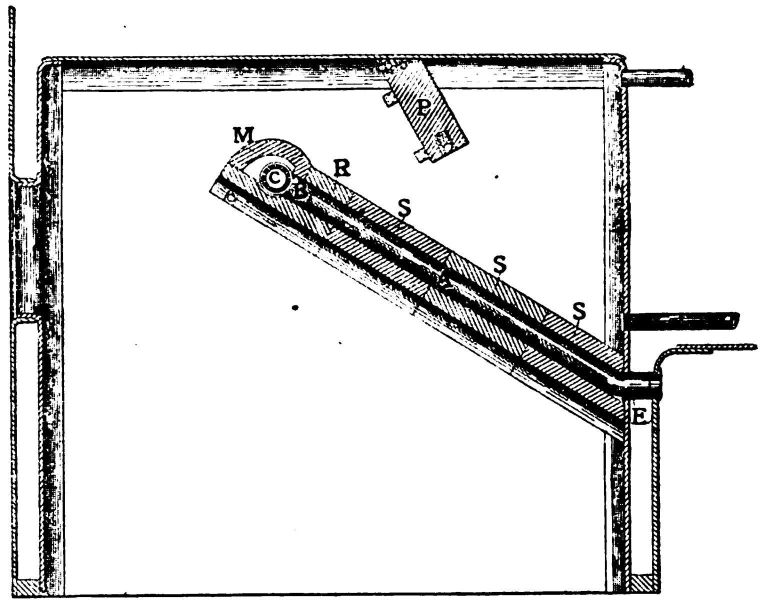
MORE PERPETUAL MOTION.

[43006.]—With regard to the letters by Mr. Baker and others *re* the above subject, I would like to have a few words with those interested, partly because having been through the mill myself, I can quite appreciate what Mr. Schucht says about its being a fascinating subject; but that is about the only fact in his letter with which I can agree.

Has it never occurred to Messrs. Baker and Schucht that the simplest perpetual-motion machine is embodied in a bicycle wheel with a heavy valve at one spot on the rim? If the wheel is placed free to revolve, and the valve just started from the top on its downward journey, it should gather enough energy during its downward movement to drive it right up the other side and over the top. But it will *not*, simply because the friction of the bearings and air (small as it is) absorbs exactly as much energy as would otherwise suffice to lift the valve the slight distance by which it falls short of a complete revolution. Any device introduced to obviate this must of necessity introduce more friction, and thereby defeat its own object. Mind you, this energy is not destroyed, but is converted into heat in



Cross Section.



Longitudinal Section.

the bearing (infinitesimal it is true, but it is just enough to upset the balance the wrong way).

Concerning the latter part of Mr. Schucht's letter, I think he has made a great mistake, in that a man striving after perpetual motion has not reached, let alone passed, the elementary stage of applied mechanics, because one of the very first maxims this involves, and upon which half the problems are based, states that: "Action and reaction are equal and opposite," and one does not get much further in it before he finds that by doubling the length of a lever you do *not* double the power, although you may halve the distance. What you do double is the stress at the further end, and it is just this failure to appreciate the difference between power and stress, energy and work, velocity and momentum, mass and weight, together with a lack of the faculty of seeing that "power" is but a measure of the *rate* of doing work, and not a measure of work itself, which accounts for such a large amount of deep thinking, which might be usefully applied to practical schemes, being wasted over this mirage of perpetual motion.

Mabel.

THE LIGHTNING FLASH.

[43007.]—Some statements of "Constant Subscriber" (letter 42985) in your issue of last week need, I think, some further explanation. Your correspondent considers that we are surrounded by an illimitable infinitude of liquid air, but goes on to assert that it must be "imponderable" and "unelemental." If it be imponderable and unelemental, it cannot be liquid air, nor, indeed, any material substance whatever, for as long as air exists its atoms and molecules must possess mass, and under the influence of gravitating forces, weight, and if the elemental nature of the constituent atoms could be destroyed, then the material would no longer exist as air. From the latter portion of "Constant Subscriber's" letter, and from the variation in the spelling, I conclude he does not set aside the wave-transmitting "all-pervading æther," but merely superimposes on it his liquid-air ether. Now would not the frictional resistance offered by such a material substance in space, however attenuated, have long ago, considering the infinitude of past time, reduced all celestial motions to a standstill. Moreover, would it be possible for wave motions such as those of light and heat to be transmitted over vast regions of space, as we know to be the case? Your correspondent does not discuss the causes which operate in breaking the continuity of the intra-terrestrial and outer liquid air—ether of space. In the instance given of the two persons killed by the flash, one of whom was reduced to ashes and the other unburnt, was there any evidence that both received the discharge in equal intensity? Might not one have perished from the disruptive action of the lightning, and his companion from the effects of shock? With regard to the difference in temperature in the blood of reptiles and the mammalia, it seems to me the fact is explained chemically on the ground of the comparative rate of oxidation, as effectually as on any magnetic hypothesis. Physiologists have shown that the nervous system is of epiblastic origin, whereas the blood vascular is mesoblastic. How, then, does "Constant Subscriber" consider the nerves to be "a continuation of the venal system."

C. S. H.

SMOKE FROM LOCOMOTIVES.

[43008.]—Referring to the letter of "Loco." on p. 277, I would say that surely he knows efforts have been made for many years to consume the smoke from locomotives, which is not considerable, as the steam "washes" it, and it is not much of a nuisance. It is a great nuisance on board steam-vessels, especially to those passengers who are "abaft the funnel," and there is no doubt the Admiralty would take up any useful device, for smoke betrays the position of war-vessels. Here, however, is a device for dealing with smoke in locomotives, taken from a recent number of *Locomotive Engineering*, a paper published in New York, which may interest your readers:—"In 1884, while master mechanic of the Eastern Railroad, Mr. A. Pilsbury, now superintendent of motive power of the Maine Central, got out a form of brick arch providing for air admission through the arch, coming out at the top. He took out a caveat for the invention, but never had it patented. The invention was applied to an engine on the Eastern Railroad, and gave excellent results, having been in service over a year. The matter was not carried further because Mr. Pilsbury left the road, and several official changes subsequently took place on the Eastern Railroad, and among them the device was neglected and afterwards forgotten; but its usefulness and utility were substantially established.

"We have received from Mr. Pilsbury a blue-print of the device, from which the annexed engravings were taken. It will interest some of our readers to know that Mr. A. M. Waitt, now superintendent of motive power of the New York Central Railroad, was chief draughtsman for Mr. Pilsbury when this form of arch was designed, and he made the drawing from which the blue-print referred to was taken.

"The brick arch is supported on lugs, D. There are three air-tubes, A, fitted into thimbles at the front end of the firebox at E, and terminating at the upper ends of the tubes in T fittings at B. The T's B and thimble E form slip joints, which admit of and provide for all the movement necessary and required by expansion.

"It will be noticed that the cross-pipes connecting the upper ends of the T's are perforated, and in turn covered by perforated curved firebrick, so that the air is delivered at the point and manner most suitable for aiding in consuming the gases. The deflecting arch P is not an essential part of the arrangement, and was not used in engine fitted with the device."

Your readers know that there is very little smoke (visible smoke) when a locomotive is running; but it is always desirable on the score of economy to consume smoke, and it is especially so on board steam-vessels for the benefit of the passengers—the sailors don't count. Anyone who could do away with it would make a handsome fortune.

S. R.

[43009.]—In the year 1845 Parliament passed an Act requiring locomotives to consume their own smoke; but it was known then and it is known now that it is impossible to avoid making *some* smoke, and consequently the law has remained practically a dead-letter.

Locomotives all have the brick arch, deflector, and blower, and I know of nothing better, but still all the smoke cannot be avoided. The London County Council did on Aug. 1 last decide to prosecute some railway company and its men in a police-court. However, the matter would not end there, as the companies have decided to carry such a case right up to the House of Lords, and the societies to which the drivers and firemen belong will defend their members up to the highest court.

Under these circumstances the County Council is very slow in putting its resolution into force. Indeed, it is already stated that probably nothing will be done beyond that the resolution of the Council will "go off in smoke."

Clement E. Stretton, C.E.

Saxe-Coburg House, Leicester, Nov. 4.

WHEN WERE YOU BORN?

[43010.]—I should be very pleased to thank Mr. R. A. Lawson for having shown an incorrection in the formulæ kindly published on p. 211, if I could indeed find anything incorrect in it. On the contrary, I feel obliged to answer that Mr. L. has misunderstood the whole thing.

In fact, the results of Mr. L.'s calculations ought precisely to be read: 2nd day of 2nd month of 54th year, and not, as he says, 20th day, &c.

Mr. L. has only failed to observe that, as the ordinal number of a month can happen to be expressed by two ciphers, two places must be left for them in the final number.

Thus, in Mr. L.'s example, 20254 should be read 2·02 54, just as in mine 30980 has been given by myself as 3 09·80.

I can neither thank Mr. L. for the two (out of six) easier solutions he proposes. If he wants to see how truly they are *scarcely correct*, I would invite him to follow me in the application of any one of the two to the case of a person born 2/10/54—

Day of the month	....	2
× 1,000	=	2,000
+ 10 × 100	=	3,000
− (45 + 1)	=	2,954
+ 100	=	3,054

which doesn't mean anything.

Mr. L.'s formulæ, if it had to improve mine (which, by the bye, is not mine at all), ought to be slightly modified by multiplying by 10,000 instead of 1,000 in the first operation: the result would then be the same as the one I have given.

But for that, should it be an improvement? Is rapidity, as the result of the employment of a smaller number of figures, to be much considered in a trick of this kind? I do not think so. It seems to me that the more you oblige the person asked to jumble his numbers, by successive operations, is the better, as it busies the mind of that person, and prevents him from knowing your little game.

Those two solutions of Mr. L. must anyhow be turned aside; but as he says that he has kept four others of them in store, we may hope that he will have the goodness of producing them, and that at least one out of the four shall be of some value.

Milano, Oct. 29. Hunot.

MOTOR CYCLES.

[43011.]—Referring to Mr. Sangster's letter (42960) in your issue of the 27th ult., I think that your readers would have had a much better grasp of his figures had they been given in English

measure and not in the metrical system, as this latter is not known to all. But mayhap this Mr. Sangster overlooked—inadvertently, I hope. His first quoted figures refer to no bearings in particular, and are therefore unintelligible to me, and I doubt not to other of your readers.

The rest of Mr. Sangster's letter is a personal attack that I fail to understand after his compliment on the "able" way in which I had criticised motors, both the De Dion and the Ariel—which, by the way, was not at first named by me in this journal. Mr. Sangster is perfectly right as to the authorship of "Monty's" letters; but that is no justification for a coarse personal attack, in which truth is distorted to suit his spleen. What interest can it possibly have for your readers to know Mr. Sangster's history of this writer? Being anonymous to them, though not to the Editor, they will not care one brass farthing so long as they get a *veracious* account from an English mechanic of motor-cycle work and its practice. And I claim that *I am* an English mechanic, one who has been through the whole curriculum — fitting-shop, drawing-office, and all—has served on shore and afloat, under others, and as his own master, during which time an inquiring mind and a ready hand have gained him an experience that Mr. Sangster has admitted in a letter that I hold.

But I must tell your readers that my descriptions of motors are not of prehistoric vehicles, but of the latest product of as late as August last. It might surprise Mr. Sangster to know that "Monty" has just been asked to inspect and test, on owner's behalf, a new motor tricycle, at present under construction by the Cycle Components Manufacturing Co., when he will then be able to note all the latest possible mechanical improvements on which Mr. Sangster has dwelt. The world is full of "possible mechanical improvements," and progress is always welcome, or should be; whilst, on the other hand, nothing is gained by a petty spirit when palpable faults are pointed out and remedies suggested.

I am *not* in the motor-tricycle business now, nor am I with a gentleman who is *wholly* engaged in the motor business. Mr. Sangster misquoted me.

Mr. Sangster knew my pseudonym; but I have written thereunder to this Journal for some years, and I prefer still to sign myself **Monty.**

[This must end the discussion so far as the personal element is concerned, which we think should not have been introduced by Mr. Sangster. —Ed.]

PHOTOGRAPHY—GELATINE PAPERS.

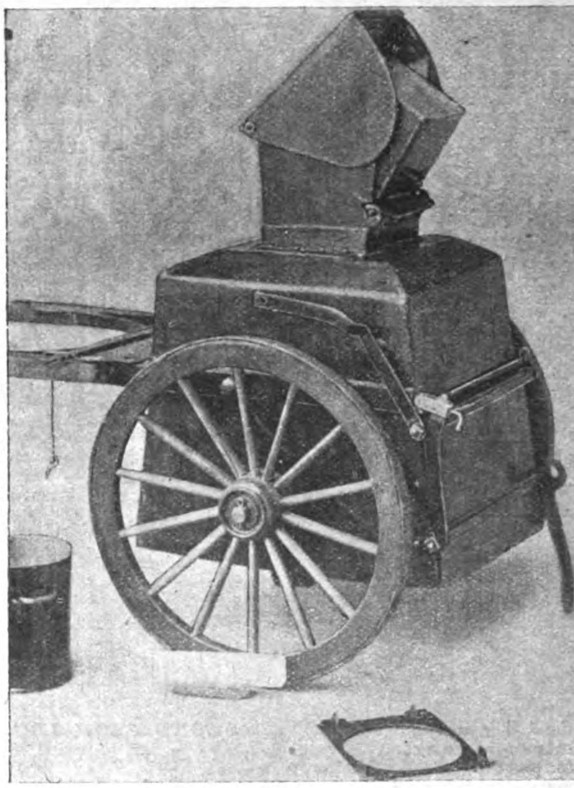
[43012.]—It will be admitted that the great drawback to the use of these papers is the troublesome amount of washing both before and after toning, which the makers seem to insist upon as a *sine quâ non* to successful working. Now, presuming alum is not used—and many experienced photographers find it unnecessary—there seems to be no theoretical reason for so much washing, or, indeed, any at all, and practice has in my hands confirmed this view, for I find that excellent results may be got by simply placing the prints dry, and, without any previous washing, to remove the free silver into the usual sulphocyanide bath. From thence, when of the required tone, they are removed direct to the fixing bath. In this way no washing is required until after the prints are fixed. In my own practice I have mostly used the Ilford paper, and the only modifications required are to print somewhat deeper than usual, and to use a rather weaker toning bath;—the Ilford formula, diluted witih one-third part of water, answers well. It is advisable to place each print into the toning bath separately, and to keep them constantly moving to insure even action. There is, of course, nothing new in the *modus operandi;* but from the amateur who has little time to spare for the practice of his favourite hobby, and who has wisely discarded the use of the uncertain combined bath, it will, I think, meet with due appreciation.

Whitstable. **H. C. Parlow.**

MODEL SANITARY DUST-CART.

[43013.]—The inclosed photo. was taken of a model sanitary dust-cart designed by me at the instigation of your paper. The principal features about the cart are that it can be loaded by one man from the ground, and that it will hold as much (60c.ft.) as an ordinary tip-cart. The shoot is arranged to prevent all dust from blowing about. As soon as a bucket is put up to the shoot, it opens a flap in front; the bucket is then pushed right in, lifting with it the hood, until it comes to a stop; the bucket is emptied, and brought back. All closes automatically by its own weight; no springs are used. The cart is a low tipping-cart with a door at the bottom, which, when unfastened, can be pulled open by a lever at the side, or, when tipped, will open itself. The shoot can be worked from the back or at the side. The stuff, owing to the shape of the cart, trims itself.

Being an employé of the London County Council, I cannot work this invention, but want the Council to take it up, and have asked them to have one built from my specification, which I doubt.



I have taken out the patent for the shoot (completed); the door, &c., is provisionally patented. I had to obtain permission for the shoot. The cart and door is as much the Council's property as it is mine, until they give me permission.

E. J. Hitchcox, Hydraulic Engineer.
South Pontoon, Woolwich Ferry, L.C.C.

THE ESSEX FUNGUS FORAY.

[43014.]—The following rather extraordinary account of the annual fungus foray in Epping Forest appeared in a halfpenny London morning paper:—"The members of the Essex Field Club made a successful week-end raid on the fungi of Epping Forest. In the woods the most striking objects were the clumps of the gaudy fly agaric, with tall white stalk and brilliant scarlet top. When incorporated in the humble 'catch-'em-alive,' as its name implies, it deals death to greedy insects. When taken in moderation by the human subject it causes a form of drunkenness that is indulged in by the people in the north of Russia, yet such are the ways of nature that the grubs of beetles may flourish on its substance. In the open grew the oak fungus that, as it ages, turns to a fluid once used for printing Bank of England notes. The blackness is due to the tiny spaes [?] that play the part of seeds, and under the microscope their absence from a note would show a forgery at once. Nor must the bracket-like form be forgotten that grows from trunks of birch-trees, and claims close kinship with the 'beefsteak fungus,' nor yet the 'candle snuff' that marks the spot where other trees have fallen. Nearly 140 kinds were distinguished by the experts, Dr. M. C. Cook and Mr. George Massee. It is to the former veteran fungologist that lovers of nature owe so much for his many delightful books on plants, while the latter is, perhaps, the greatest living authority on the minute forms of fungal life. Two species not hitherto found in the forest were recorded, and the experts characterised the collection exhibited as the best they had seen for ten years."

The "gaudy fly agaric" is the *Agaricus* (*Amanita*) *muscarius*, but it is news to learn that it has anything to do with the "humble 'catch-'em-alive.'" Dr. M. C. Cooke says: "It is found most commonly in birch woods, and not very plentifully in Britain. A decoction of this fungus has been employed as a fly-poison; whence its vulgar name," but that has nothing to do with "catch-'em-alive." It is perhaps the most handsome of all fungi, and it is possible that it is used in Russia, but it is doubtful whether it is the true Fly Agaric that is employed for producing intoxicating effects. As to the "oak fungus, that, as it ages, turns to a fluid once used for printing Bank of England notes," I fancy the reporter has developed his notes in a way not intended by his informant. *Coprinus comatus* and *C. atramentarius* both yield a fluid that may be used as ink (of a sort), but it is extremely doubtful that they were ever used to make ink for printing Bank of England notes. The word "spaes" is probably an error for spores, but the fact that it appears helps to show that the writer does not quite understand his subject; but why the "barber's wig" (*C. comatus*) should be called the oak fungus is a puzzle, as it grows in pastures and gardens. I have seen it on the Victoria Embankment when the soil for the garden beds was brought there some years ago. What is meant by the "bracket-like form" is also a puzzle; but presumably it is the Oyster mushroom, *A. ostreatus*, which is generally found as an "imbricated" mass. That may be an error again, though "bracket" is scarcely like imbricated in the most careless manuscript. But the mention of the "beefsteak fungus" leads to the suspicion that the "bracket" is *Polyporus squamosus* or *P. betulinus*, which is found on trees. Perhaps some of your correspondents will explain what is meant by "candle-snuff" that marks the spot where "other trees" have fallen. I cannot trust the paragraph above quoted, for even the name of Dr. M. C. Cooke is incorrectly printed, and I thought everyone who understood anything about fungi knew how to spell his name. **S. R.**

The "Practical Engineer Pocket-book" for 1900 has been issued by the Technical Publishing Company, Ltd., Manchester, and has been increased in size as well as recast, so as to facilitate reference.

The main line of the Orleans Railway Company into Paris is being prolonged into the Quai d'Orsay, a distance of $2\frac{1}{4}$ miles, nearly two miles of which will be in tunnel. Steam locomotives will continue to haul the trains to the Austerlitz Station, whence electric locomotives will be used. The three-phase current of 5,500 volts will be generated at a station over three miles distant from the Quai d'Orsay.

Briar Pipes.—In the course of an article in the *Windsor Magazine* on "The Making of a 'Briar' Pipe," one of the greatest authorities on the subject is stated to have said:—"It is strange, and yet it is a fact, that the English workman is of no use in the manufacture of pipes. The most skilful artisans are either the Austrians or the French. The pipemakers are a very select, small body, and observe every precaution to prevent their trade being learned by outsiders. They will have no apprentices, and if I introduced any boys into my factory I should have to pay them the Union minimum wage, which is two pounds a week. On the other hand, the workmen are clever, and they earn high wages." Speaking of the cost of a pipe, Mr. Weingott remarks:—"When the blocks arrive over here they are at once sorted. Out of one gross of blocks I rarely ever get more than three or four pieces of wood good enough for the very finest class of pipes, about a dozen good briars for fine quality pipes, and perhaps as many as four dozen pieces of wood for the ordinary everyday pipe. The remaining seven dozen pieces of wood are thrown into the furnace, and, I might mention, help considerably to generate the necessary steam power for the machinery."

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[96511.]—**Brazing-Lamp (U.Q.)**—See sketch on p. 71, Vol. LXIV. of "Ours." GLATTON.

[96514.]—**Dry Cleaning (U.Q.)**—I have always understood that the articles are first soaked in benzoline in vessels specially constructed to prevent loss of vapour or risk of explosion, &c. This removes grease, oil, paint, and almost all the substances which usually cause the adherence of dirt. After this the clothes are dried, and the dirt, no longer cemented to the fabric, is easily beaten out as dust. I am not sure of the correctness of the above—perhaps someone will correct or supplement it? GLATTON.

[96516.]—**Heat Consumed in Mechanical Work (U.Q.)**—The temperature would fall on expanding into the atmosphere to a degree depending on its original pressure and temperature. The fall would be due to work done in displacing the atmosphere. Both in this and the first case every foot-pound of work done would use up 778 thermal units, causing a corresponding alteration of temperature depending on the pressure to which the air is expanded. GLATTON.

[96532.]—**Geometrical Solution (U.Q.)**—I suppose "J. S." has overlooked this query. His solution is, I think, very ingenious, and should not be difficult to understand. G O, G Q, G R are drawn in any convenient direction near where G X is expected to fall. They are merely used as a device for obtaining the short curve cutting E F at O, and their exact position is unimportant. E X F is a right-angled triangle, X O = B D by construction; and if it can be shown that the angle D B Z equals the angle E X O, no further proof is necessary. Being on the same base, and similar in the same circle, the angles E X G and E F G are necessarily equal; and as the latter is by construction equal D B Z, D B Z is also equal to it. GLATTON.

[96548.]—**Bent Timber (U.Q.)**—Surely this is a matter which can only be settled by trial with the particular timber you propose to use. GLATTON.

[96668.]—**Mirror-back Showcards.**—To "ESSAR."—Many thanks for reply; but there is something more wanted. There is no trouble to make bronze-powder stick to glass, but I cannot get the brilliant looking-glass appearance there is upon the mirror-back showcards to be seen in most tobacco shops. There must be some little trick about it—something after the hot-water trick to make gold leaf brilliant in sign painting. I hope someone of "Ours" will put me up to the method wanted. Does M. Cole know how to do it? SIGNWRITER.

[96689.]—**Cooling (U.Q.)**—Assuming adiabatic expansion, Peabody gives—

$$\frac{T_4}{T_3} = \left(\frac{p_4}{p_3}\right)^{\frac{K-K}{K}}$$

Where—

T_3 = absolute temperature at cut-off in the expanding cylinder (= 273·7 − 50 = 223·7° Centigrade)
T_4 = absolute temperature of exhaust
p_3 = pressure at cut-off (= 360 atm.)
p_4 = pressure of exhaust (= 36 atm.)
K = 1·405 with adiabatic expansion.

Hence— $\frac{K-1}{K} = \frac{\cdot 405}{1\cdot 405} = \cdot 288.$

$$\frac{T_4}{T_3} = \left(\frac{36}{360}\right)^{\cdot 288} = \left(\frac{1}{10}\right)^{\cdot 288} = \cdot 515$$

Hence— $T_4 = \cdot 515 \times 223\cdot 7$
= 115·25 absolute
273·7

= − 158·45 below zero Centigrade. GLATTON.

[96712.]—**Lantern Slides (U.Q.)**—Is there no one among your readers capable or willing to give advice *re* choice of a hand camera for this purpose? May I make another appeal for help? My query appeared on page 144. A. TESTER.

[96722.]—**Preservation of Indiarubber.**—This query refers to the preservation of vulcanised caoutchouc, and a definite answer would be valuable. As a matter of fact all vulcanised rubber goods soon go wrong, probably because the sulphur is worked out by the caoutchouc. Probably in the case given, smothering the "rubber" with flowers of sulphur is a good preventive of the rottenness that sets in, especially if the rubber is not used. Keeping under water is said to be useful, but much depends on the way in which the vulcanising has been done. Here is a remedy to prevent vulcanised rubber becoming hard or cracking, and it would do for cycle tires:—Dip in a bath of melted paraffin and dry in a temperature of about 212° Fahr. S. R.

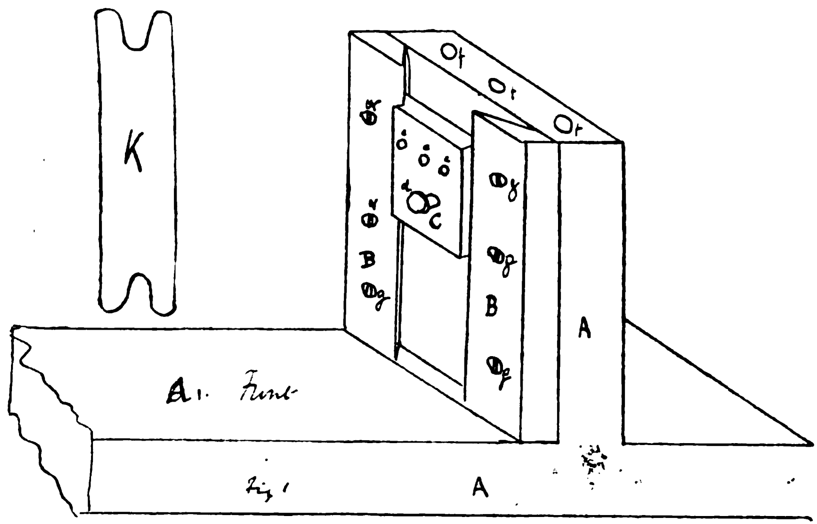


Fig. 1

[96737.]—**Chemical Balances.**—These appliances are amongst the most delicate of the scientific instruments. Directions for making can be found in back volumes; but I suspect that anyone capable of doing the requisite work would not need to ask for information. The idea of a "rough drawing showing dimensions and details of knife-edges and other important parts" is good. Surely the querist must see that a very exact drawing is necessary: otherwise the ordinary pictures of weighing scales in the cyclopædias would answer. M. T.

[96757.]—**French Polishing.**—If this powder is an advertised article, the querist probably knows where to find it; but I never heard of a "powder" to dispense with the process of spiriting-off. Where has "Rubber" heard of the "fine finish and the lasting properties of this powder," that he finds it necessary to ask for information? He surely must know more about it than those who have never heard of it, and I for one know nothing about a powder used instead of "finish." H. WALKER.

[96759.]—**Bikes and Prams.**—What "B. H." says on p. 278 is definite enough, but it does not answer the question. The query appears on p. 168, and was based on the fact that the chairman of a bench of magistrates, in the course of a case of wheeling a bike on the footpath, fined himself as well as the defendant, when he learnt from the clerk that "judgment" had been given that bikes must not be wheeled on the footpath. "R. R." said on p. 235 that it has been "decided in a court of law, &c.," and on p. 255 I said that what I wanted to know was "where and when it was decided." As "B. H." says that an Act "expressly enacts, &c.," there is "no necessity for a court of law to decide." I have heard something about even Acts of Parliament being indefinite until their provisions have been determined by the Courts. That is not the point, however. It has been asserted that the question has been decided—as "R. R." says, in a "court of law." I want to know where and when, because he reiterates the statement of the magistrates' clerk. The question about when is a carriage not a "carriage" is quite a side issue; but it is satisfactory to learn, as I gather, that the section referred to "repeals all previous powers exercised by local authorities." This happily is a free country, and while all good citizens obey the law (except some magistrates over the last Vaccination Act), we are at liberty to think what we like about the "law," and even to express an opinion about it. ROTA.

[96768.]—**Ironmould in Copper.**—If the querist has tried the recipe given on p. 191, it would be of interest if he gave his experience, and stated how the distemper of magnesite, or petrifite, answers. It seems to be useless to ask "Regent's Park" what he means; but as many people would like a remedy for ironmoulding through the zinc or tin becoming worn off so-called "coppers," perhaps some reader will try magnesite, or petrifite, and publish the result. It would be more useful than the rubbishy paragraphs from our friend, "R. P." LAUNDRY.

[96862.]—**Fret-Saw Machine.**—The beech upright, 14in. by 6in. by 2in., is strongly mortised into the sole-plate A_1. Two mahogany guide-pieces, B B, full length (14in.) of A, are screwed to it. C, of oak, thicker than B B, is fitted to slide freely, but without shake, between B B. An ordinary hand fret-saw is screwed to C by the wooden screws *e e e*. A 2½in. or 3in. lathe headstock is bolted to the front portion of A_1. This headstock should be fitted with a face-plate drilled with a series of holes varying from ½in. to 1½in. from centre, so as to allow of the stroke of saw being adjusted as necessary. These holes should be tapped and a pin fitted, together with a pitman rod. The pin *d* is fitted to C to take other end of rod. The platform H, of pine, 12in. by 12in. by ⅜in., is next temporarily screwed to A, the position of hole for saw found, and bored. It is then sawn down the centre, hinged at back, and the small

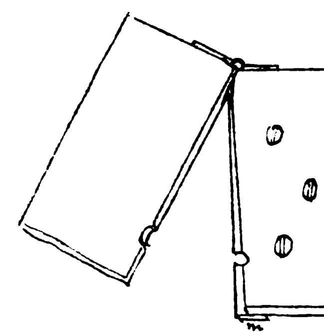

plate of brass, *m*, screwed on under the steady half, and a hook and eye fitted to front, and then firmly screwed to A_1, the screwheads being well countersunk. K is a piece of ½in. mahogany, cut to shape, and fitted between arms of saw-frame to decrease vibration when at high speeds. A good lubricant for the slide is a mixture of black-lead, olive-oil, and a few drops of petroleum, about as thick as very thin cream. This arrangement was originally adapted for a lathe, and is a really good and serviceable one. The split platform is an addition of my own to prevent much stooping when changing saws in dim light. GRAHAM.

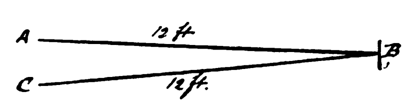
[96871.]—**Image in Mirror.**—Where is the image formed? Proposition: The focal distance of the image of an object as seen in a reflector is equal to the distance of the object A from the reflector B, plus the distance of the observer C from the reflector. The distance of the object and



observer being each 12ft. from the mirror, the focal distance will be 12 + 12 = 24ft. The focal distance of the reflection of the sun is equal to the sun's distance from the reflector plus the distance of the observer from the reflector; the latter is a *quantité négligible*. And everyone who uses a sextant for the purpose of taking a distance realises that the focal distance of the sun's limb is also sharp focus for the bright limbs of the moon reflecting the sun's rays. Place a mirror on the ground in the sun's rays, and put on it a scrap of paper, or anything that can be focussed sharp; take up a position to receive the sun's reflected rays in a telescope or binocular, and first focus the paper; then direct the telescope to the sun's reflection, and you will find a blurred image. Now correct the focus to a sharp image, and you will find it in focus for the sun 92 million miles away. Evidently there is no image on the glass, or the focus for the paper would be right for it; so also there is no image behind the mirror, through 8,000 miles of solid earth, and millions of miles beyond, which, of course, is an absurdity, or the visual angle of the said image would be 16′ instead of 32′. To show that this absurdity is taught, I will quote from "Optics and Light" (Lommel), p. 30. "It [*sic*] sees *in*—that is to say, behind the mirror," &c. "In the same way, an image-point behind the mirror corre-

sponds," &c. Such teaching misleads the student, and gives him no insight into the actual phenomenon of reflection. Where, then, is the image formed? The answer is a reply in brief to the question, What is light? The sun, great centre of disturbance to his system, sends forth his energy in waves of exceeding smallness; some of these waves, moving in right lines, strike the surface of a reflector without affecting it in any visual manner; but being stopped by the solid body, a portion of them—less or more, according to the angle of incidence—is deflected at a like angle, unchanged, except as regards planes of vibration flying off from the reflector in right lines, whose direction is governed by the plane of incidence. If an optical apparatus, eye and brain, receives these deflected vibrations, they are modified into those luxuries of intelligence, the sensations of light, colour, and form. Let the student take a slip of paper, fold it in half, open it at any angle, and place the angle against the mirror. The two sides will represent the incident and reflected—i.e., equal angles—beam; and if he can also assimilate the fact that there is no light outside an eye, he will be in possession of the phenomenon of reflection. Again, let the distance A C be 12ft., and from position C mark the place B on the mirror where reflection occurs, A B C being equilateral, the angle consequently 60°; but if the reflected rays came from a point "as far behind the reflecting surface as this (the luminous point) is in front of it," the angle would be 30°. There is a strange propensity in writers on optics for going behind the mirror. Is not this an inheritance from remote ancestry? Place a monkey, for the first time, in front of a mirror, and he will immediately dart behind it in search of that other monkey; and we may take it for granted that the "missing link" would have done the same had it been placed before a mirror. But the monkey, after two or three attempts to find that other behind the mirror, finds out his mistake, and resigns itself to the fact as something no monkey can understand. Moral: There still remains unanswered, or perhaps we should say unproved, the question, Where does the modification take place? Is it possible to find proof with the help of the proposition which heads this paper? I suggest an experiment. An observer with telescope, a bright light by him, a pair of eyes about 10ft. or 12ft. away looking at the light. Now, if the observer can see the reflection of the light in the eyes opposite to him, and succeeds in getting a sharp focus, he will then examine the features of the face, and if he finds the focus correct for both, it will be good proof that the image is formed on the retina, and that there is the place where the modification of motion into light and colour takes place, and I suppose we shall have to concede intelligence to the retina. If, on the contrary, he finds that the focus of the reflection from the retina differs from that of the face, it will be proof that the image is not formed there, but that the retina receives the vibrations, a portion of them being reflected, whilst the remainder are conveyed by the optic nerve to the seat of intelligence, where they are modified into visual sensations. With the assistance of a friend, I have tried this experiment, not very satisfactorily, using a binocular, power 10.

FRED. H. EWER.

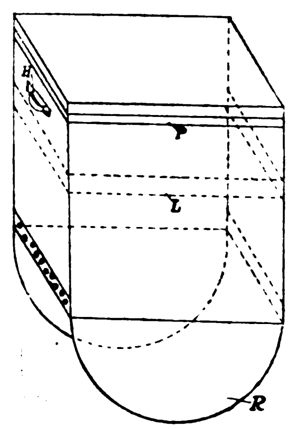
88, Victoria-road, St. Peter Port, Guernsey.

[96886.]—**French Verbs.**—If "W. B." is not actuated by mere passing curiosity, but has a genuine desire to understand the inner life of the French language, he cannot acquire this by a few lines in these columns, but must study such works as Raymonard's "Grammaire Comparée des Langues de l'Europe Latine," and Ampere's "Histoire de la Formation de la Langue Française." He will there find that during the transition from the "Langue Romane" into the "Langue Française" the termination *oie* of the two last conjugations came to replace exclusively the old termination *oue* of the first conjugation—see "Roman de la Rose" (12th century), "A la vie que tu menoies," &c. In the 16th century they suppressed the mute *e*, and wrote *oy* in place of *oi*, the *y* being substituted for no particular reason beyond that it was the fashion then, as witness such words as "roy," "loy," &c., in place of "roi," "loi." This remains still in such words as "envoyer," &c. Later on the useless *y* was dropped, and then the final *s*, adopted to distinguish the first person singular of the various tenses of the indicative, was similarly applied to the same persons of the imperfect and the conditional (which originally had the inflection *eie*, *oie*). We thus arrive at the termination *ois*, which naturally was pronounced as written (compare modern French "Danois"). This brings us to the end of the 18th and the beginning of the 19th century, when Voltaire, for apparently no end or reason, initiated the spelling *ais*, which is contrary to all etymology, the *a* not occurring at any period in the termination of the imperfect.

G.

[96904.]—**Ashes or Cinder Sifter.**—In reply to your correspondent "Hard Up," I have pleasure in giving you a rough sketch of a cinder sifter, which he can easily make himself at little cost, and which will be neat and tidy if painted, &c., and will do away with the cumbersome riddle and bag arrangement he speaks of, and I hope he will not now annoy the neighbours any longer. To make the same, first make an oblong box, any size according to the amount of cinders to be dealt with (see Fig. 1). On to this the rocker R is

FIG. 1.



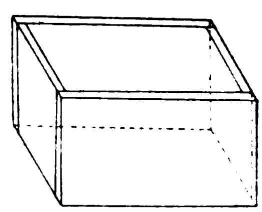


FIG. 2.

screwed, as shown (see R, Fig. 1), and the rocker can be made out of a piece of thin tough wood, bending it into position and screwing it against the bottom ends of the body. On to the box body, Fig. 1, put a plinth all round, to come within about 1in. of the top edge (see P, Fig. 1), and inside the box body, rather below the centre, screw ledges all round (see the dotted lines L, Fig. 1). Now make two boxes like Fig. 2, one rather less than the other, so that it will go into the box body to come up flush with the ledge pieces L, Fig. 1, and this box has a proper wooden bottom. Another box is now required which is made large enough to come up flush with the top edges of the box body, Fig. 1, and which, when in position, rests on the ledges L inside the box body, Fig. 1, and this box has some suitable wire gauze as the bottom, and a piece taken from an old riddle would answer the purpose well. Handles are screwed on each end of the cinder sifter, see H, Fig. 1, and a lid is made to fit over the whole and lie on the plinth P, Fig. 1, when the same is complete. The method of using same is simply as follows:—The box with the wooden bottom is first put into the body of Fig. 1, and rests on the bottom of same, then the box with the wire gauze on the bottom is put in, and filled with the cinders; the person then closes the lid, and then taking hold of one of the handles, rocks the apparatus to and fro until the cylinders are thoroughly sifted; then the cinders remaining in the top box are removed, and for this purpose the boxes should have some small handles attached, or the wood hollowed out for the fingers to grip hold of. The top box can then again be filled with cinders, and the ash sifted out, which goes into the bottom box, can be easily removed when full.

W. H. BLAND.

[96896.]—**Drawing an Eccentric Ellipse.**—With reference to the answer to "B. B. M.," on p. 274, by "F.R.A.S.," I beg to point out that the latest Moy's ellipsograph—of which I am maker—describes an ellipse whose major axis is 3¾in.

W. H. HARLING.

[96915.]—**Isle of Man Steamers.**—The mean speed of the *Mona's Queen* during her trial was 19 knots, the maximum being 19·4 knots. The ordinary seagoing speed of the *Peveril* was from about 13 to 14 knots. The *Duchess of Devonshire* was launched in January, '97 at Barrow. She is 300ft. long, 35ft. broad, and 15ft. deep to main deck; her gross register tonnage is 1,300 tons, and she is fitted with two sets of triple-expansion engines, and during her trials she made 19·47 knots under forced draught; being guaranteed for 19 knots. Now she has settled down, she makes 20 knots, performing the journey from Barrow to Douglas in 2½ hours, and from Barrow to Belfast in 6 hours. The distance from Peel to Belfast is 67 miles, from Douglas to Fleetwood 63, and Douglas to Ardrossan is 130 miles.

RED ADMIRAL.

[96918.]—**Scrap Arc-Lamp Carbon.**—I have never heard of these having been put to any practical use.

S. ELLIMAN.

[96923.]—**Heating Tank.**—The water in the tank should be able to be raised to the required temperature in about ten minutes, and maintained at that while in use.

HEAT.

[96938.]—**Question in Arithmetic.**—There are not sufficient data to answer this question. There would be four plots of land, each 55 yards square, divided by a path 13ft. wide; but we do not know how wide the gravel walk will be between them and the wall. Given that, it is easy to calculate the length of the wall.

NO SIRRAH.

[96955.]—**Stage Thunder.**—Stage thunder is usually produced by shaking a piece of sheet iron. To perform this, choose a piece about 3ft. square (that used for lining the inside of packing-cases suits admirably), hold it by the corner, and shake gently with a trembling kind of motion. A very good imitation of thunder is thus produced. Where greater realism is required, cannon-balls rolled backwards and forwards up in the flies produces a good effect, and is usually the method adopted in most large theatres. To imitate lightning, place some lycopodium powder in the bowl of a common clay-pipe. Blow through the stem, so as to force the powder through the flame of a spirit-lamp. If this be performed neatly, an instantaneous flash is the result. Of course, the stage should be darkened to produce a good effect.

VICTOR E. ARMSTRONG.

[96959.]—**Moulding Slag.**—I have to thank "F. I. S. E." for his answers to my queries, and will be pleased to have his further replies. I would also be glad to know what sort of a furnace is required for remelting slag.

CONSTANT READER.

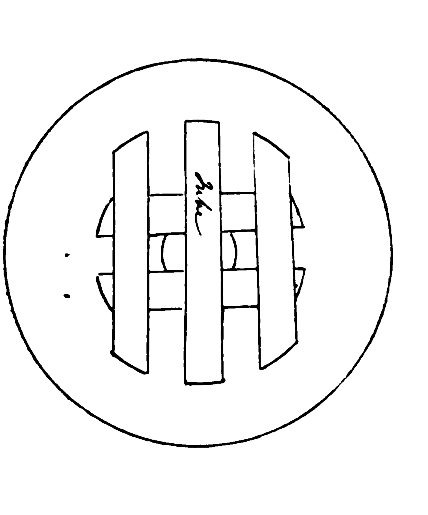
[96963.]—**Gassner Dry Cell.**—Its peculiarity consists in the zinc element forming the outside cell, in which the carbon is placed, separated from the zinc by a thick paste or jelly made of gypsum and oxide of zinc. The cell can be placed in any position, works as well on its side as upright, is not subject to creeping, has an E.M.F. up to about 1·5 volts with an internal resistance of only 0·25 ohm. in the round form, and 0·6 in the flat form. The Gassner dry battery polarises much less quickly than the ordinary Leclanché cell, the only defect at present noticeable is the fact that the outer cases, being metal, must be carefully guarded from touching one another. A very good composition for placing between the carbon and zinc of the Gassner dry cell is made as follows:—oxide of zinc ¼lb., plaster of Paris 1lb., chloride of zinc 2oz., glycerine 1oz., water 1½ pint. Mix the solids first, then add water and glycerine. One useful property of this battery is its capability of being renovated when it has lost power by having a current of electricity passed through it for a comparatively short space of time. This is effected precisely as an accumulator is charged—viz., by connecting up the + terminal of a battery or dynamo with the carbon of Gassner, while the − terminal is connected to the zinc. The charging current must have an E.M.F. of not less than two volts for each cell to be charged. A current of about two or three ampères for about three hours will be found to revivify a spent cell of one quart capacity.

SAB.

[96963.]—**Gassner Dry Cells.**—Gypsum is plaster of Paris. The recipe given by me in "Electric Bells" is reproduced from Gassner's original paper; and according to that the quantity of oxide of zinc and of plaster of Paris needed to make up a cell 3in. in diameter by 6in. high would be about 1oz. zinc oxide to 4oz. of plaster. But you will produce a much more satisfactory dry cell if you procure sufficient fine sawdust to half-fill your cell. Soak this for several days in a mixture made up of half a pint of water to which has been added 1oz. of chloride of zinc, 2oz. of salammoniac, and ½oz. of glycerine. Another paste must also be made up, consisting of about 1oz. coarsely-powdered gas carbon (graphite), ½oz. granular black oxide of manganese, 60 grains of rouge, with sufficient treacle added to make the whole into a very stiff paste. Take your carbon plate, and having put a slice of cork at the bottom of the cell to prevent the carbon touching the bottom, make a line along the top edge of the carbon about ⅜in. below the edge of the cell. Now coat the carbon plate up as far as this line with the treacle paste. Place the carbon plate in the centre of the cell, resting on the cork, and having squeezed out any excess of liquor from the prepared sawdust, ram it tightly round the inside of the cell between the zinc and the carbon, as far as the line on the carbon. Wipe the inside edge of zinc cell quite dry, and pour in sufficient melted pitch to fill up the cell flush with the rim. When the pitch is quite cold and set hard, make a hole with a hot knitting-needle right through the pitch to the sawdust. This will prevent the pitch bursting when gases are given off during work.

S. BOTTONE.

[96952.]—**Model Boiler.**—I send herewith sketch of one which will be suitable for "Amateur Engineer," and any tinsmith can make it; no rivets required; best made of sheet copper. The five cross-



tubes of ⅜in. copper add very greatly to the production of steam. Either Bunsen burner or spirit lamp can be used for heat, as may be found convenient. Total height 4in., diameter 3½in.

C. F. R.

[96963.]—**Gassner Dry Cell.** — If you can obtain "plaster of Paris" you can obtain gypsum—they are the same thing! You want a cylinder of zinc to contain your carbon plate about 6in. by 3in. high, with a bottom. Make a mixture, of the plaster 25 parts, ammonium chloride 10 parts, and water 55 parts. The interior of the cell is coated with this to the depth of about ¼in., the top being left uncovered to about the depth of 1in. When set almost hard, the carbon plate is put in the centre, and the space is filled rather tightly with the following mixture:—Powdered graphite 75 parts, black oxide of manganese 10 parts, chloride of zinc 5 parts, chloride of ammonium 10 parts, glycerine 2 parts. This is mixed with sufficient water to make a stiff paste, which is not to come higher than the top of the plaster. Fill up with pitch, and put terminals to zinc and carbon, as usual.

R. A. R. Bennett.

[96966.]—**Selenium.**—Selenium is an element, and can therefore not be produced. It is closely allied to sulphur in its general properties, and, like sulphur, is generally found in combination with metals, with which it forms "selenides." It occurs sparingly in combination with lead, cobalt, copper, and mercury in the Hartz, at Jilkerode; with copper and silver in Sweden, with tellurium and bismuth in Norway, &c., and along with sulphur in many iron and copper pyrites. It is procured from these ores by oxidising them with the aid of nitrate of potash, which converts the selenium into a soluble seleniate of potash; this is treated with hydrochloric acid, which liberates selenic acid, that in the presence of excess of hydrochloric acid is reduced to the state of selenious acid. Finally, the solution of this latter body is subjected to the action of a current of sulphurous anhydride, which abstracts its oxygen, and reduces to the state of pure selenium. I have never heard that a coil is necessary to overcome the resistance of the selenium cubes used in telephotography. The selenium must be in the condition it acquires after being melted at 217° C. Even then, in the dark it does not conduct electricity freely; but at the instant it is exposed to light, its resistance falls. Any good work on chemistry will give you information respecting selenium.

S. Bottone.

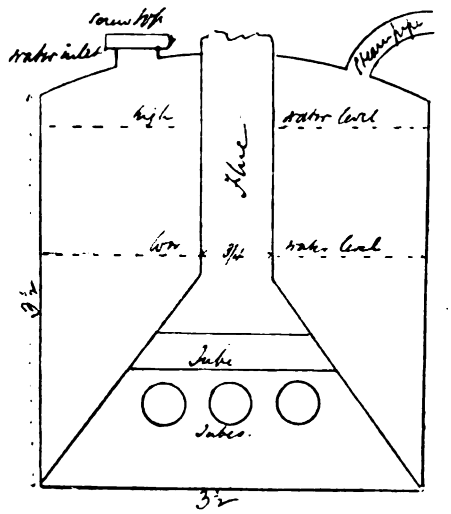
[96966.] — **Selenium.** — Rare element, closely allied to sulphur; found sparingly in free state, more commonly combined with metals or selenides. The Fahlun pyrites (Sweden) contains it, and was source when first obtained. The F.P. is used for making oil of vitriol, and in leaden chambers of apparatus a brownish (or reddish brown) deposit is found. Analysed by Berzelius in 1817, and found to contain new element. See Bloxam's "Chemistry," as to make, &c., and in "Electricity in Service of Man," for application of seleniun.

Regent's Park.

[96966.]—**Selenium.**—Selenium is an element allied to sulphur in its properties, and chiefly obtained from a double selenide of lead and copper found in the Hartz. Its resistance as a conductor of electricity is very sensitive to light, and this property has successfully been made use of in Graham Bell's "Photophone," where a beam of light takes the place of the usual line wire. "Seeing at a distance" had better be taken meantime *cum grano salis*.

W. J. G. Forman.

[96968.]—**Liquid in Toys.**—In good ones, the liquid is ether, coloured with alkanet or similar red colouring matter; the cheaper ones containing methylated spirits coloured. The boiling depends



on air having been thoroughly extracted from the tube, and with a good vacuum even water will boil at a comparatively low temperature.

S. Bottone.

[96968.]—**Liquid in Toys.**—Sulphuric ether, with a little colouring matter added.

W. J. G. Forman.

[96976.]—**Kieselguhr.**—I suppose "W. M." could "solidify or harden" kieselguhr by mixing it with lime, Portland or Roman cement, plaster of Paris, &c., or, if wanted, without too much foreign substance, with silicate of soda, alum-water, linseed oil, or varnish. If the querist had stated the object, a more definite reply would have been given; but he can find the information by searching through the back volumes. The substance named is used, I believe, for making dynamite, and also as a non-conducting composition to cover steam-pipes and boilers. For many purposes a thin mixture of plaster of Paris or a "cement wash" would answer.

S. R.

[96976.]—**Kieselguhr.**—Mix it with a sufficiency of soluble sodium silicate solution (water-glass) to make it into a stiff paste, and set it aside for some time to harden.

S. Bottone.

[96971.]—**Wind Motor.**—Some time ago I constructed a windmill for the purpose of driving a dynamo and pumping water; but I found considerable difficulty in the first place in getting sufficient data to work upon. America seems to have done most in this direction, and their type of wheel, as opposed to the old-fashioned English four-armed affair, is recognised as most efficient. It is very necessary to have speed as constant as possible, so the windmill must be governing to an extent. There are several methods by which this is effected, either by having the slats to open and shut, or by turning the whole wheel (which, in this case, has fixed slats) from the wind should it become too high. The simplest method, as far as I could ascertain, was by the latter method. In this a fixed vane stands out from the edge of wheel, and in the same plane. The rudder, which keeps the wheel facing the wind, is pivoted on an extension of the frame which carries the wheel, and is kept square by means of a weight. When the wind blows over a certain rate, the vane at side of wheel causes the wheel to turn slightly from the wind, and the rudder being pivoted allows this to be accomplished. In my design the wheel was 16ft. diam., with eight arms radiating from a cast-iron boss. Stays were fixed from arm to arm at a distance of 2ft. from centre; and, again, 6in. from the outer ends of arms, and on these stays the slats were screwed. The whole thing was designed with a view of easy manufacture; but a certain amount of metal-work is unavoidable. Should H. Brand think I could be of any service to him, if he will advertise his address, I shall be pleased to communicate with him, and give him full particulars.

Vent.

[96981.]—**Barometer.**—Mr. J. B. Jordan has written a pamphlet, published by Stanford, describing the methods and precautions he adopted when constructing his celebrated glycerine barometer, and anyone wishing to embark on the somewhat difficult enterprise of making a similar instrument may be recommended to obtain this little book.

A. H. B.

[96982.]—**Noisy Wimshurst.**—The machine will always "hiss" more or less. If very bad it is due to sharp points or edges on the conductors. It is caused by electrified air being driven off with some force from such points. Turn the machine in the dark, and you will soon see where the "hissing" comes from.

W. J. G. Forman.

[96982.]—**Noisy Wimshurst.**—Any Wimshurst, no matter how good the insulation, will, when the jars are fully charged, attempt to discharge these either through the air or along the nearest conductors, and in so doing produce a sizzling sound. Should, however, this sound be very loud, and especially if it is accompanied by poor working of the machine, it shows that there are some roughnesses or points at which the jars leak. Work the machine in the dark, and notice the spots which glow with brushes on or near the jars when the hissing is going on. On examining these spots with a strong light, you will be able to detect jagged edges or points. Smooth these and varnish over them.

S. Bottone.

[96982.]—**Noisy Wimshurst.** — The hissing noise is caused by the escape of electricity from the points on the conductor, not from the jars if they are properly made and have no points on them. Your query rather leads one to suppose that you think it is a fault in your machine. On the contrary, it proves that it is producing plenty of electricity.

R. A. R. Bennett.

[96983.]—**Steam Motor Waggon.**—The power required to propel 30cwt. up an incline of 1 in 6 on an ordinary road in fair condition, and at a speed of two miles per hour, would be 6·5H.P. Your engine would develop about 8I.H.P., so that you would have some power in hand for emergencies. You are compelled by the Locomotives on Highways Act to provide two independent brakes, and the vehicle must also be capable of travelling backwards as well as forward; therefore if your engine is not capable of being reversed, you will have to provide reversing gear as well as the two-speed gear. The best means of steering a vehicle of this weight is by the Ackerman system. It is simple, and obviates the use of a heavy fore-carriage. Differential gear will allow of the two rear driving wheels revolving at different speeds when turning a corner. If you drive each wheel separately by means of a chain, this will have to be placed on the intermediate shaft; but the proper place for the differential gear is on the driving axle or shaft, and it should be driven by a chain, or chains, from the intermediate shaft. I could provide working drawing of differential gear, steering gear, reversing gear, and speed gear, &c., if you care to advertise your address.

Auto-car Engineer.

[96986.]—**To Mr. Reginald A. R. Bennett.**—I do not quite understand this query. You talk about a "phonograph," but I have written no article in "Ours" on the subject of phonographs. I suppose you mean the grammaphone; if so, your needle must not have a "cutting edge," but simply a sharp point. In the phonograph an agate stylus is used. The latter part of your query I am still more at sea about, for you speak of "cylinders"; but the grammaphone uses no cylinders. You cannot use brass for making grammaphone records, as the acid would not act on it properly. If you are trying to make wax cylinders for a phonograph in the way that the protecting film is placed on the zinc grammaphone discs, I do not think you are likely to succeed, as the upper surface is sure to be too rough. I should recommend your greasing the cylinder or covering it with vaseline. Perhaps you can explain more clearly what it is you wish to do.

R. A. R. Bennett.

[96989.]—**Polish for Brown Shoes.**—Perhaps bookbinders' brown lacquer may apply. Paris brown lacquer:—Shellac 8¾oz., oil lavender ·525oz., gamboge 1·05oz., alcohol (98 per cent.) 2⅝lb. Dissolve, filter, and evaporate to a quarter of its bulk by distillation. Then add 1·4 bookbinders' brown lacquer, 1·4oz.; finally filter from sediment. B.B. lacquer made thus:—Brown shellac 4½oz., alcohol (84 per cent.) 3⅝lb.; dissolve shellac, filter, evaporate, as before, half the alcohol, add ¼oz. oil of lavender to remaining fluids. (H. C. Standage.)

Regent's Park.

[96991.]—**Cutting Mitre Wheels.**—As you have one of the Cincinnati universal-geared milling machines, is well shown in Paul Hasluck's "Milling Machines and Processes," of Crosby Lockwood and Co., and on the plate, Fig. 100, there seems to be dividing scales or index with graduated markings, and further on he gives, at page 337, he suggests for cutters from 4in. to 15in. in diameter

$$\sqrt{(\text{dia. in inches} \times 8)} \times \cdot 0625 = \text{pitch in inches},$$

or measure pitch in 30 seconds of an inch, and multiply it by the pitch in inches; products show required diameter of cutter. In Robert Grimshaw's "Shop Kinks," S. Low, Marston, and Co., speaking of gear teeth, they vary much both in make and material, and to a certain independent of the tooth outline. The pitch being 1, the depth to pitch-line may be 3-10, working depth 6-10, whole depth 7-10, thickness 5-11, breadth of space 6-11. One English proportion is pitch 100, depth 75, working depth 70, clearance 5, thickness 45, space 55, play 10, inside pitch-line 40, outside 35. Re gear-cutters (not gear-cutting machines), much is being done to unify practice as to outlines and dimensions of cut gears. Cutters of one or two large firms are alike, except a difference in bottom clearance; but of no consequence, being very trifling. The same proportions

best adhered to for teeth of circular as for diametral pitch. For the former working depth would be 0·64 the pitch (correctly 0·43662), and the bottom clearance 0·5p. In the matter of width of face of cut gearing, probably no standard would be possible or necessary; it so depends on circumstances. Three times the pitch, however, is by many considered a very satisfactory width. Small teeth require proportionately more clearance at the roof than large ones. In order to reduce to a minimum the cutting of a shoulder in flanks of epicycloid teeth, if flanks have excessive taper, thinning teeth for a distance of half the height of flank, measured from roof, &c. REGENT'S PARK.

[96993.]—Coil.—To Mr. Bottone.—1. A 2in. coil, with suitable relay and coherer, will work easily up to two or three miles. 2. The length of sky rod should be approximately 10ft. per mile over the surrounding objects. 3. A 6in. spark coil should work in similar circumstances to a distance of ten miles or more. 4. The only readable book on the subject at present is Kerr's "Wireless Telegraphy." I am at present engaged in writing a book on the subject, containing historical, theoretical, practical, and constructional details. S. BOTTONE.

[96997.]—Dynamo.—The trouble very evidently lies in the fact of the F.M. shunt coils being of too low a resistance. This can be avoided to a certain extent by inserting a variable resistance in series with the shunt coils and raising the speed of the dynamo to counteract the drop in volts resulting therefrom. There is no danger in the coils warming up as long as the insulation does not suffer, and the drop of potential may simply be due to undercompounding of the dynamo.

A. H. AVERY, A.Inst.E.E.
Fulmen Works, Tunbridge Wells.

[96997.]—Dynamo.—If you will kindly state (1) the type of machine, (2) the size of armature, (3) the gauge of wire on the armature and field-magnets, (4) whether armature is solid or laminated, and (5) what you mean by *casts*, I will try and help you. Has the machine ever run cool? Apparently there is a leak in the F.M. wires. S. BOTTONE.

[96997.]—Dynamo.—Must be a badly-designed machine, or is not wound for the output you are taking from it. Disconnecting from the mains would tend to aggravate the coil by sending all the more current through the shunt coils. The trouble might possibly be somewhat lessened by inserting a resistance in the shunt circuit. Fill a trough-shaped vessel with water, disconnect the shunt coils, and remake the connection through two sheet-iron plates in the water. Then try and get your output with the plates as far apart as possible, and see if it helps matters. If so, find out how much resistance you have in, and insert an equal resistance permanently. W. J. G. FORMAN.

[96997.]—Dynamo.—By casts getting hot we suppose you mean cast-iron pole-pieces. If these get hot without the copper wire coils it shows they are of too small a section for the magnetism induced, or that eddy currents are circulating in the iron. Running dynamo, with heads, &c., disconnected, makes no difference as to the heating. If the coils get hot there is not sufficient wire in them to prevent an excess of current flowing through them: hence they are carrying a greater current than they should do. Increase the quantity of wire, thereby increasing the resistance to the passage of current. This will stop heating of coils.

WEBSTER MICHELSON AND Co.,
Dudley. Electrical Engineers.

[96998.]—Accumulator.—The resistance is unsuitable. The back E.M.F. of the cell, when fully charged, would be about 8 volts, whereas you are cutting down 100 volts on your 105-volt mains, thus leaving only 5 volts charging pressure, which is not sufficient to effect anything like a full charge. A 97-volt lamp would be the correct thing, or even a 95-volt lamp, and a small extra resistance in series with it. A. H. AVERY, A.Inst.E.E.
Fulmen Works, Tunbridge Wells.

[96998.]—Accumulator.—Probably not enough current goes through, so that the accumulator is not fully charged. Put two, or even three, lamps in parallel, so as to let two or three ampères go through. S. BOTTONE.

[96999.]—Nitrate of Soda in Bunsen Cell.—To Mr. BOTTONE.—In porous cell, along with carbon, use: Nitrate of soda, 3oz.; water, 1 pint; oil of vitriol, 4oz. S. BOTTONE.

[97000.]—Armature.—A full reply would take too much space, covering, as it does, one of the most important parts of dynamo designing. If the querist can refer to Thomson's "Dynamo-Electric Machinery," or even to the "A B C of Dynamo Design," by myself in the pages of the *Model Engineer*, he will gain the desired information. An armature to the dimensions given should be capable of generating 100 watts. The gauge of wire depends on the voltage required, on the speed, and also on the magnetic flux.

A. H. AVERY, A.Inst.E.E.
Fulmen Works, Tunbridge Wells.

[97000.]—Armature.—By reading carefully my book, "The Dynamo: How Made and How Used." S. BOTTONE.

[97001.]—Collodion Cotton.—Make a mixture of 1 part of alcohol (sp.gr. ·825) and 7 parts of ether. This will dissolve it readily. Or, dissolve it directly in amyl acetate. S. BOTTONE.

[97001.]—Collodion Cotton.—Soluble in a mixture of ether, with $\frac{1}{7}$th of alcohol, yielding a viscous solution, which leaves the transparent collodion film when evaporated. It is much less combustible than pyroxilin. REGENT'S PARK.

[97001.]—Collodion Cotton.—Try gun cotton. Use sulphuric ether only.

WEBSTER MICHELSON AND Co.

[97002.]—Nasmyth's Locomotives.—The first locomotive engine built by Nasmyth and Co., at the Bridgewater Foundry, near Manchester, was named "Hawk," and was delivered to the London and Southampton Railway Company in 1839. It was a six-wheeled passenger engine, having cylinders 12in. diameter, 18in. stroke, and "single" driving-wheels of 5ft. 6in. diameter. The locomotive business is still carried on by Messrs. Nasmyth, Wilson, and Co. I have the complete list of the locomotives built by the firm, but to give this would take far too much space. CLEMENT E. STRETTON.

[97003.]—Rothwell's Engines.—Messrs. Rothwell, Hick, and Rothwell built the Union Foundry, Bolton, and completed their first locomotive engine in 1831. It was a four-wheeled passenger engine, named "Union," for the Bolton and Leigh Railway. After the year 1860 the business began to be unsuccessful financially, and ultimately the works were closed, and so they remained until about seventeen years ago, when the Bolton Iron and Steel Company purchased the Union Foundry, and added it to its own large establishment. A list of the engines built by Rothwell will be found in the railway collection at the free library at Liverpool.

CLEMENT E. STRETTON.

[97003.]—Rothwell's Engines.—I think at Bristol, but no doubt extinct. Have you looked at back volumes of the *Transactions* of Civil and Mechanical Engineers, locomotive magazines or journals, &c., at Patent Office?

REGENT'S PARK.

[97004.]—Wireless Telegraphy.—To Mr. BOTTONE.—1. About four or five miles. 2. If no air has got in the coherer, yes. 2. Core, a bundle of soft-iron wire $1\frac{1}{4}$in. long, $\frac{3}{8}$in. diam.; wire, 1oz. No. 36 silk-covered copper. 3. Two quart cells should be ample. 4. The wing to earth may be any wire, say No. 16 copper; the sky rods should be stout iron rods, surmounted by a pretty large roll of galvanised wire netting, and insulated from all except the coherer. A similar rod should be placed on the + side of transmitter balls. Allow 10ft. per mile. In reply 96940, for "a *wall* of wire netting," read "a *roll* of wire netting." S. BOTTONE.

[97006.]—Metallurgy.—The late C. Tomlinson, in his "Cyclopædia," has several pages on iron and manufacture. Wood or charcoal chiefly used before coal. Dud Dudley used coal; this was 1619, or so on. The making of coal into coke was known in England in the same century, and described by Dr. Plot in his "History of Staffordshire," &c.

REGENT'S PARK.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered, are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

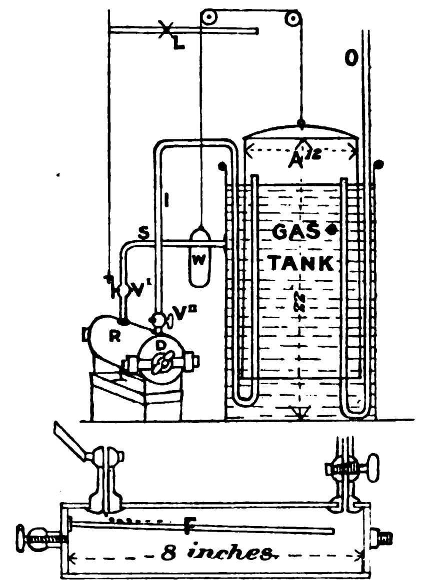
[97007.]—Boat.—Would any reader kindly inform me as to the kind and section of wood which would most suitably do for a small boat 12ft. long, 3ft. beam, 1ft. 6in. deep?—NOVICE.

[97008.]—Motor Cycle.—Will any reader kindly oblige with particulars of induction-coil, sizes, and quantities of wire, &c.; also explain why the valve-spindle in carburettor is made of German silver?—SENLAC.

[97009.]—Cleaning Paper.—Could any kind reader give me a recipe for cleaning paper without damage. I have some valuable music which has got rather dirty by use?—MUSICIAN.

[97010.]—Spectroscope.—Will some reader kindly give me information on the following? I have a table spectroscope by Browning, a few parts of which are missing, and which I could replace if I knew what was required. The collimator tube has at one end an adjustable slit, at about 3in. from this a lens, next follows a series of two sets of five prisms; then, at the end of the tube, a thread is cut, but the filling is missing. If a lens is required, of what kind and focus should this be? The diameter of collimator tube is $1\frac{5}{8}$in bare, while the mounting on stand has an aperture of $1\frac{5}{8}$in. Particulars of the adapter to use would oblige. In the collimator tube at farther end from slit there is a slot $\frac{5}{16}$in. by $\frac{13}{16}$in. What is this for?—E. S.

[97011.]—Acetylene.—The diagram is the plan of an acetylene apparatus that I have made; but before starting I would like all defects pointed out. A is the usual gas-holder, O outlet, I inlet from generator, W



weight for holder, L lever for automatically controlling water supply by shutting valve V'; valve V'' is for shutting off gas when charging R. Generator is a piece of 3in. steam-pipe 8in. in length with rubber-faced ends. F is a piece of flat iron for distributing water in generator. Will I need a purifier between generator and holder?—FRASER.

[97012.]—Accumulators.—In the cells there are three positive plates of about 10in. to 10in. What current ought each cell to discharge, and how long, after being charged to milkiness? What specific gravity of dilute acid should be put into cells that have been cleaned out, and some of the acid thrown away? If the acid is of wrong specific gravity will the cells work?—ATTENDANT.

[97013.]—Ice Storage.—What is the best form of an icehouse (that is, a house to store ice frozen in winter to keep till summer), and the method of packing the ice?—J. R. F.

[97014.]—Sledge.—Would some reader kindly give design of a well-built strong sledge to carry, say, four people, and materials used?—J. R. F.

[97015.]—Sidereal Time Indicator.—Has anything been devised to simplify the process of converting Sidereal to Mean Time when taking transits, something more accurate than the device figured in "Chambers' Astronomy"? Also say if the Transit Tables formerly issued by Latimer Clark are still published, and by whom?—J. BENTLEY.

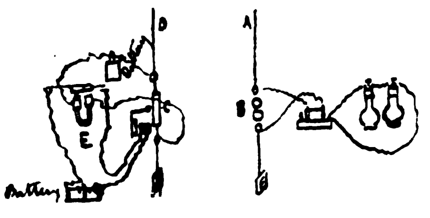
[97016.]—Electro-Gilding Solution.—Having a very good electro-gilding solution which has accidentally had added to it an excess of cyanide, can anyone who knows give an efficient way of getting rid of this excess without adding fresh gold?—ELECTRO.

[97017.]—Gas v. Steam.—Which would be the cheapest to work, all things considered—a steam-engine of 8H.P. (coal 18s. per ton, including cartage) or gas-engine of same power with gas at 4s. 2d. per 1,000ft.? Would be worked about eight hours per day, sometimes less.—OPTICAL L.

[97018.]—Electric Bath.—I have a very fine medical battery, with primary and induced currents, very strong or very weak if necessary. Can you kindly tell me the proper way to connect the current to water for an electric bath, and also what material should bath be made of? I only have an ordinary painted metal bath. Is there any handbook by a medical electrician that I could get? I wonder if any of your readers have benefited in health by taking a course of electric baths? I have hay fever in its most violent form for six or eight weeks every year—have had all my life; have tried about every known

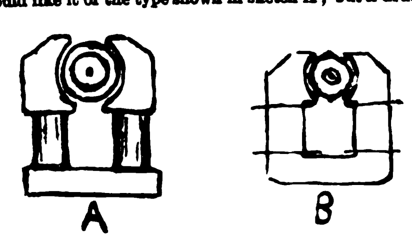
remedy, and could write a volume about it; have to give up work for several weeks. I am thinking about persevering with electric baths next year, and want to get all the information I can about them.—Perseverance.

[97019.]—**Wireless Telegraphy.**—To Mr. Bottone.—Please tell me what size induction coil I must



use to work a wireless telegraph for about half a mile? There are about eight houses in the way. Also how can I make a coherer out of a piece of glass tube, and must the air be exhausted, and is a battery placed in the same circuit between the coherer and relay? Please say if sketch is correct, and give the dimensions for the lettering?—Chase.

[97020.]—**Dynamo.**—To Mr. Bottone.—Please tell me what size to make a dynamo to give 6 or 8 volts at 2 ampères of current, with either a ring or drum armature. H armature will not suit. If a ring armature is best, I would like it of the type shown in sketch A; but if drum,



as sketch B. I want to keep the shaft low, and to use as little wire as possible. Also, how much wire must I use?—Chase.

[97021.]—**Bromide Printing.**—Attempting to produce prints by this process, have been troubled by a thick fog all over the print, including that part of paper protected by rebate of printing frame. Use ferrous-oxalate developer with subsequent clearing bath according to maker's formula, and have tried hydroquinone, with same result. Image is a long time appearing, and is very "hard" when complete. Safe ruby light used. Fog appears during development. Am suspicious that paper has been stocked a long time by dealer. Would stale paper show fog like this?—Faineant.

[97022.]—**Metric System.**—Would any of your correspondents inform me how to calculate the area of a triangle in mètres, &c.? The sides of the triangle are 1,660, 1,454, and 1,372 links respectively.—Enquirer.

[97023.]—**Engraving Tools.**—Can I get some information as to the sharpening and tempering of engraving tools? I want them for inscription and monogram work on gold and silver.—Jeweller.

[97024.]—**Horse-power.**—Will some reader let me know what indicated horse-power I should expect out of two cylinders, 2¼in. diam., 5in. stroke; cut-off, ¾ stroke; boiler pressure, 30lb.; revolutions 300 per minute? And what may I expect with 60lb. in boiler; also 120lb.?—Nottingham.

[97025.]—**Punts.**—Will any reader kindly give me the dimensions for above, such as length, breadth, and depth, and also how to make the shapes?—A. B. C.

[97026.]—**To "F.R.A.S."**—Will you kindly name a few standard books—up to date, but not too expensive—on modern field and siege artillery, path of projectiles, and explosives? Young, in his "General Astronomy," refers to "Astronomisches Nachrichten," No. 1426, for a proof of a formula for orbital velocity. The proof is in German, and therefore beyond my reach; but I hope it would not be asking too much to ask for a translation?—Second Differential.

[97027.]—**To "M.I.C.E."**—Please name an easy book on the calculus of variations. What is the calculus of operations, and what is the curve of sines?—Second Differential.

[97028.]—**Honey.**—I should like to know the analysis of honey.—Merchant.

[97029.]—**Pumping Boiling Water.**—Will an ordinary lift-pump with leathers pump boiling water out of a farmyard boiler? How long would leathers stand?—M. S.

[97030.]—**Dry Cell.**—What is the best dry cell to use in connection with wireless telegraphy? What is the construction of the Obach dry cell?—No Sirrah.

[97031.]—**Enamelling Oven.**—1. What thickness of sheet iron would I require for making enamelling oven to hold two or three cycle frames? 2. Where to fix burners, and how many would I require? 3. What kind of burners are best for gas? 4. At what heat would I have to keep it? Any other particulars would greatly oblige.—J. Green.

[97032.]—**Ink for Recording Instruments.**—Can anyone give me a recipe for ink for recording instruments?—A Subscriber from the First Number.

[97033.]—**Acetylene Container.**—Would any of our kind contributors give advice in the following circumstances? I have got an "Incanto" generator capable of containing 1lb. of carbide. Could I connect this machine with a home-made container in such a way as to utilise several charges one after another, until the container is full, and then use the stored gas to light the house? Would the gas deteriorate, and is there any danger in this method? I thought of using an ordinary oil-cask as the outer vessel of the container, and a zinc vessel for the inner.—Thelma.

[97034.]—**Trellis.**—I bought recently a piece of ready-made trellis, which, when closed, becomes proximately a flat board, but expanded becomes an open trellis 12ft. by 6ft. Suppose this set up vertically in an open space exposed to the wind. Is the wind pressure against it the same whether it is closed or open—the actual surface exposed being the same?—O. J. L.

[97035.]—**Paint for Baths.**—Can anyone give me a recipe for a paint absolutely unaffected by hot water? There is such a paint in which copperas plays an important part, and it will resist even hot water and soda. A workman was going to give me the details but I have left the place, and forgot to obtain them.—O. J. L.

[97036.]—**The Planets.**—Will some reader of the "E M." please inform me how I can find the position of the planets at any given time within the last 40 years?—Neptune.

[97037.]—**Copying Drawings.**—Can any reader give me a method of copying drawings or diagrams when placed in the horizontal position?—Optical L.

[97038.]—**Colouring Oil.**—Can any reader inform me how to colour paraffin oil, either red, black, blue, or green? I have made one or two attempts, but failed to get them to mingle, the colouring either remaining at the bottom and the oil above, or vice versa? What I wish is some harmless ingredient or non-poisonous chemical that will assimilate without elaboration.—Keemo.

[97039.]—**Clark Cell Method of Measuring Volts.**—Will any reader kindly give me a clear explanation of this method, using a bridge and known resistance? 1. Volts higher than Clark cell. 2. Volts lower than Clark cell.—Van Wang.

[97040.]—**Solio Paper.**—I have a quantity of solio paper prints, printed much too dark. What is the best thing I can do with them? Is there any process I can put them through to make them all right?—Watty.

[97041.]—**Motor Bicycle.**—To "Monty" and "The Writer of the Articles."—I am desirous of fitting a small motor to an ordinary safety bicycle, something after the fashion of the Armand-Garreau machine, capable of travelling at about 17 or 18 miles per hour along the level road (illustrated some time ago in these pages), the motor being fitted to the bottom bracket. So far as I can see, no definite information has yet been given with regard to making such a motor, although asked for several times; neither have I seen the necessary castings advertised. Will not the above gentlemen or others help us out of our difficulty, and give us the required information? I am sure drawings would be greatly welcomed by most of our cycling readers, including—Motor.

[97042.]—**Shoe Jobbing.**—Will any kind reader who is in the habit of doing this sort of work kindly give me a little information, more particularly on the tapping of shoes? Please name tools and materials required. Is there a handbook published on the subject?—Cobbler.

[97043.]—**Flue-tubes of Steam Boilers.**—Will someone tell me the cause and how to prevent steel flue-tubes from eating into little holes, and blistering same as little cinders stuck on? The water I use is rain-water. I always filter it through a rag before using. The boiler stands cold and idle more than used. It is only twelve months since I got it retubed. The old tubes were very rough, and full of little holes, and these are starting the same trick. Size of boiler (vertical) is 4ft. high, 1ft. 8in. wide, with six vertical 2in. steel flue-tubes.—H. N.

[97044.]—**Accumulators.**—I should like to know through "Ours" how to make accumulators for storage? Having a small engine and dynamo for lighting twelve lights, what metals and chemicals, and sizes, should I require to prevent always running engine when lighting up?—H. Cooper.

[97045.]—**Imitation Watered Silk Paper.**—Can any reader tell me the ingredients of the black colour that is put on paper called imitation watered silk paper?—S. J. B.

[97046.]—**Steam Exhaust.**—As I cannot run exhaust-pipe into chimney, is there any other way of condensing steam from exhaust of 3H.P. engine by any kind of fitting or arrangement I can fix on pipe so that no steam will be seen?—N. N.

[97047.]—**X-Ray.**—To Mr. Bottone or Others.—I have made a Wimshurst machine, which gives intermittent sparks of 5in. with jars, and continuous sparks of 2in. without jars. What kind of tube should I get for same? Would a tube for 3in. spark be suitable? Also cost of tubes for 3in. to 6in. spark? Would a 3in. tube be suitable for the thicker part of man's leg?—Novice.

[97048.]—**Fluorescent Screen.**—Will some kind reader of "Ours" please instruct me how to make a fluorescent screen?—Novice.

[97049.]—**Ohm's Law and the Decrease of Voltage.**—I was reading a book on electricity the other day, and it mentioned that the drop of potential in mains was considerable in some instances. Now, according to Ohm's law the potential always remains the same, and the ampères suffer diminution.

$$\text{Ohm's Law, } C = \frac{E}{R}.$$

Now, if Ohm's law is correct, how is it possible for the voltage to decrease? The voltage would remain the same if the current was transmitted one thousand miles or only transmitted one mile. I certainly think there should be a thorough investigation on this point, and have it settled. It is rather annoying for a student to grasp the principles of Ohm's law, and then to read that the voltage decreases according to the distance the current is transmitted. If some competent reader would give his opinion on this subject, I should consider it a great favour?—J. Brown.

[97050.]—**Electric Lighting.**—Has the old-fashioned atmospheric gas-engine advertised in these pages many years ago ever been used to drive dynamos? If so, with what results?—A.I.E.E.

[97051.]—**Metalised Bearings for Dynamos.**—Have these bearings, once advertised so much for dynamos by A. H. Bateman, of Greenwich, ever been used for this purpose? If not, why?—A.I.E.E.

[97052.]—**Atmospheric Engine.**—Can any of "ours" give a section of Lownes' atmospheric engine?—A.I.E.E.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, *332, Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries, put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Nov. 8, and unacknowledged elsewhere:—

Induction.—Young Engineer.—Meteor.—Rook Rifle.—J. M. de Havilland.—J. F. Sefton.—W. J. Shaw.—A Fellow of the Royal Astronomical Society.—Arithmos.—R. D. Hall.

W. H. B.—Yes, we pay for articles; not, of course, for replies or letters. We are open to suggestions as regards subjects.

T. R. Clapham.—This is really a matter Fellows must discuss with the Royal Astronomical Society itself. That Society apparently does not desire publicity for its meetings; besides, the point you discuss is of no interest at all to the great majority of our readers.

X. P. L. T.—Thanks; we have often thought of it, but are pretty full now. You probably have little idea how slowly such books sell!

No Sirrah.—We always adopt your gardener's plan ourselves.

W. G. Shaw.—You must kindly excuse us from offering an opinion. That is entirely a question for a lawyer. Our only obligation to readers and advertisers is to try and prevent frauds, or help them to redress where fraud has been consummated. In all cases where dispute is simply about quality of goods, or breach of agreement to supply, readers must seek the ordinary remedy and ordinary advice from their lawyers.

Alan.—1. Any of the large booksellers could supply you with works on hypnotism, mesmerism, &c. See also the back volumes for many notes on the subject. 2. Do not know the work mentioned. 3. All particulars can be obtained from the secretary of the society. The address is, we think, Dean's-yard, Westminster, S.W.

Sorrowing Annie.—The cause of the eyelashes falling must be ascertained. Perhaps there is some inflammation of the eyelids. A medical man should be consulted.

Redbun.—It is scarcely likely that the book can be restored if it has been saturated with oil. It could be done by treating each leaf separately; but that would be rather costly in time, if not for the detergent.

Anxious.—No one can give any useful information without examining the patient. Possibly bathing the part with hot water would be sufficient to give relief.

Institute.—When information is required as to the "rules and regulations" of institutes and societies the best plan is to apply to the secretary. Your particular question has been answered many times. You must enter as a Stud. Inst. C.E., and to do that you must be articled to a member of the Institute. But apply to the secretary for the rules.

T. M. C.—If you can tell us what the subject was, probably the article can be found. Nothing of the name mentioned in the Vols. for '95 and '96. Have you given the correct name?

W. G. H.—See Hints to Correspondents above, No. 4. Any of our advertisers who deal in electrical or physical apparatus can supply selenium. One firm in your city, for example.

Constant Reader, W.B.—See the back volumes for many articles on the subject, and refer to the works mentioned in the answer to A. Adams, last week.

Desirable.—First question beyond our purpose; as for the second, better see some of the kilns used in the district.

W. E. C.—Presumably you mean talc. It is not manufactured, but is a natural product, and is split into thin sheets. Mica is also used, and, like talc, is a silicate of magnesia.

W. Collinge.—Probably of the secretary of the Sanitary Institute. The query is inadmissible.

N. D. P.—1. Various remedies have been suggested, but the cause must be discovered before a satisfactory remedy can be found. 2. The "cement" generally used is a solution of caoutchouc in mineral naphtha, sold at most shops where they supply leather, &c., for shoemakers.

Anxious (Hammersmith).—That is a question that only

a medical man can answer, after a personal interview. We believe ourselves that the effects of mercury as a medicine are much more permanent than the majority of doctors think; and often more pernicious than the maladies it is supposed to cure.

ANXIOUS (Redditch).—We should be inclined to try massage. Write Dr. Allinson, 4, Spanish-place, Manchester Square, W., and ask his advice.

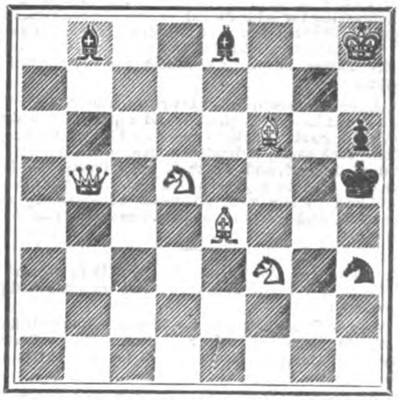
ARBOR.—Not exactly common, but by no means unfrequent in mild autumns. We have a laburnum tree that often flowers on the second growth late in the year.

CHESS.

All communications for this column to be addressed to The CHESS EDITOR, at the Office, 332, Strand.

PROBLEM No. 1700.—By H. V. GOTTSCHALL.

Black. [5 pieces.



White. [6 pieces.

White to play and mate in two moves.

(*Solutions should reach us not later than Nov. 20.*)

Solution of PROBLEM No. 1698.—By F. SCHINDLER.

Key-move, Q-Q 3.

NOTICES TO CORRESPONDENTS.

PROBLEM No. 1698.—Correct solution has been received from Richard Inwards, F. B. (Oldham), Quizco, J. Mason, W. Peters, Rev. Dr. Quilter, J. E. Gore ("Pretty").

M., J. W. HOOD.—The solution should not have proved too difficult. (See above.)

A. T.—You give Q-K 3. Above is correct.

ADVERTISEMENT CHARGES.

The Charge for Advertisements in the Columns headed:—

For Exchange.
For Sale.
Wanted.
Addresses.
Situations.

is Sixpence for the first Sixteen Words, and Sixpence for every succeeding Eight or part of Eight, which must be prepaid. *No* reduction on repeated insertions. Advertisers should state under which heading they wish their announcements to appear.

The address is included as part of the Advertisement and charged for. No displayed Advertisements can appear in above columns. Rates for Displayed Advertisements are as follows:—

For advertisements on inside pages, except page facing leader, for ess than a quarter-page; per inch single column—

1	6	13	26	52 insertions.
7s. 0d. ..	6s. 6d. ..	6s. 0d. ..	5s. 6d. ..	5s. 0d. each.

Per Column.—

1	6	13	26	52 insertions
£3 0s. ..	£2 15s. ..	£2 10s. ..	£2 5s. ..	£2 0s. each.

	1	6	13	26	52 insertions.	
	£ s.	£ s.	£ s.	£ s.	£ s.	
Per Page....	8 8 ..	7 0 ..	6 0 ..	5 5 ..	5 0	each.
Half-page ..	4 10 ..	3 15 ..	3 10 ..	3 0 ..	2 10	"
Quarter-page	2 10 ..	2 5 ..	2 0 ..	1 15 ..	1 10	"

Back Page, £10 10s. A few dates open during 1899.

ORDINARY ADVERTISEMENTS.

	£ s.
Thirty Words	2 6
Every Additional Eight Words	0 6

Front Page, Five Shillings for the first 40 words, afterwards 9d. per line. Displayed Advertisements, 10s. 6d. per inch. Paragraph Advertisements, One Shilling per line. No Front Page or Paragraph Advertisement inserted for less than Five Shillings.

All Advertisements must be prepaid, and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.'s.

Advertisements *must* reach the Office by 1 p.m. on Wednesday to insure insertion in the following Friday's number.

For the convenience of advertisers, replies to advertisements (except those in the Exchange and Sale Columns) may be addressed to "———," care of the ENGLISH MECHANIC Office, and will be forwarded by post to the advertiser, for an extra fee of Sixpence per insertion over and above the cost of the advertisement.

All Cheques and Post-Office Orders to be made payable to THE STRAND NEWSPAPER COMPANY, LIMITED, and all communications respecting Advertisements should be distinctly addressed to:—

THE PUBLISHER,
THE "ENGLISH MECHANIC,"
332, STRAND, LONDON, W.C.

This is necessary, as there are several papers published at the same address, and unless letters are fully directed, it is impossible to tell for which paper they are intended.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, post free to any part of the United Kingdom. For the United States, 13s., or 3dol. 25c. gold; to France or Belgium, 13s. or 16f. 50c.; to India, New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-Office Order. Back numbers can also be sent out by the ordinary newspaper post at the rate of 3d. each.

Vols. XXIV., XXX., XXXII., XXXVI., XXXIX., XL., XLII., XLIII., XLIV., XLV., XLVI., XLVIII., L., LI., LII., LIII., LIV., LV., LVI., LVII., LVIII., LIX., LX., LXI., LXII., LXIII., LXIV., LXV., LXVI., LXVII., and LXVIII., bound in cloth, 7s. each. Post free, 7s. 7d.

Indexes to Vol. LI., and to subsequent Vols., except Vols. LIII., LV., LVI., LVII., LIX., LXI., 3d. each, or post free 3½d. Cases for binding 1s. 6d. each.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each post free from the office (except index numbers, which are 3d. each, or post free 3½d.)

NOTICE TO SUBSCRIBERS.

Home Subscribers receiving their copies direct from the Office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK WRAPPER, as an intimation that a fresh remittance is necessary if it is desired to continue their subscription.

Foreign Subscribers will have the Pink Wrapper sent ONE MONTH before expiration, in order to give them time to forward fresh remittance before subscription expires.

For Exchange.

The charge for Advertisements in this column is 6d. for the first 16 words, and 6d. every succeeding Eight, which must be prepaid.

SPECIAL NOTICE. — *Correspondents are strongly recommended not to send money or goods to strangers. The safest way when dealing with unknown advertisers is to send a Post Office Order made payable —— days after date, when in case of non-arrival of goods, or dissatisfaction, payment can be stopped.*

Wanted, **Motor Tricycle**, condition no object; exchange Gas-Engine, 3in. Screw-cutting Lathe.—G. GOUDE, Whittlesea.

"**English Mechanic**," 10 years, exchange for Gas Stocks and Dies, Drilling Machine, or offers in Tools or Bicycle. —PALMER, General Smith, High-street, Fareham.

Dynamo, about 2-horse, partly finished; exchange anything useful.—SKINNER, Engineer, Whittlesea.

"**Sirius**" **Equatorial Head**, nearly new, 16s., or exchange.—A., 33, Fernhead-road, Paddington.

Printing Press and Type, outfit complete, value 50s. Offers, cash or exchange.—Apply ADAMS BROS., Daventry.

High-speed ½H.P. **Steam-Engine**, castings nearly finished, 35s.—GEO. MORGAN, Merthyr. See "Wanted" column.

"**Imperial Journal Arts and Sciences**," two volumes, 1,600 pages, cost 52s., sell 15s., or exchange below.

Wanted, **Flywheel and Crank**, suitable for bench lathe.—SMITH, 66, Woodland-terrace, Old Charlton, Kent.

Lady's Pneumatic, splendid machine, honestly worth £10, take £6. Also Smith's Oil Brazing Blowpipe, take 14s.

Will Exchange Above for Gas or Oil-Engine, Boiler, or anything useful.—HIND Thorne, Yorkshire.

Lathe, treadle motion, for 3½ centres, complete. What offers, exchange?—WILLIS, 50, Glenparke-road, Forest Gate.

Smith **Paraffin Brazing Lamps** for cycle work, 12s., or exchange.—ROBERTS, 4, Manette-street, Soho.

For Sale.

The charge for Advertisements in this column is 6d. for the first 16 words, and 6d. every succeeding Eight, which must be prepaid.

New Illustrated Price List of **Screws, Bolts, and** NUTS for model work, drawn to actual size, sent on receipt of stamp. —MORRIS COHEN, 132, Kirkgate, Leeds.

Watch and Clock Tools and Materials. Catalogue, over 1,000 Illustrations, post free, 6d.—MORRIS COHEN, 132, Kirkgate, Leeds.

Wheel-cutting and Dividing in Brass or Iron to 12in. diameter.—CLEGG, Belinda-street, Hunslet, Leeds.

Lathes and Machined Parts, Wheels, Chucks, Fans, Angle-plates. Illustrated list, 2d.—JARRATT, Queen-street, Leicester.

Books.—All out-of-print books speedily procured, any subject. State wants.—BAKER'S GREAT BOOKSHOP, Birmingham.

Rubber Outer Covers, 8s. 6d. Prepared Canvas, 90 by 9, 1s. 3d.; rubber solution, best quality, 1lb. tins, 1s. 6d.—PEMBERTON.

Air Tubes, all sizes, best quality, 2s. 9d. each. Air tubes with Dunlop valves fixed, 3s. 9d.—PEMBERTON.

Cushion Tires, 3s., 4s., 5s. Solid Tires, 3s. All sizes stocked.—PEMBERTON.

Detachable Outer Covers (Licensed), 12s. 6d. each; all cycle accessories and cycle rubber goods stocked.—PEMBERTON and Co., 1, Cardwell-place, Blackburn.

50,000 Choicest Microscopical Objects.—Bargains. Catalogues free. Microscopes, cabinets. Collections purchased.—SUTER, 10, Highweek-road, Tottenham.

Nuts and Bolts for Model Work. Illustrated List, 2,800 varieties, 3d.—BUTLER BROS., Haggerston, London.

Screws, Screw-plates, Taps, round and hexagon special steel brass and iron rods. See list.—BUTLER.

"**Simplex**" **Gas and Oil-Engines**, new series, "Otto" principle, ½B.H.P. to 2B.H.P., from £9. Guaranteed.—Below.

"**Demon**" **Gas-Engines**, awarded prize medal, ½B.H.P. to 12B.H.P., low price, high efficiency, economical. Guaranteed.—Below.

"**Demon**" **Gas and Oil-Engines** are thoroughly reliable. First-class workmanship.—PASLEY and Co, Sherborne, Dorset.

New **Engine Castings**, ¼-horse, 5s. 6d.; half-horse, 11s. per set. Catalogue two stamps.—TOMLIN, Ironfounder, Oldham.

Rubber Outer Covers, average 16oz., Para rubber 5s. each.—FRANKLANDS.

Rubber Outer Covers, 3s. 6d. each, 36s. per dozen. —FRANKLANDS.

Cushion Tires, 3s., 4s., 5s. Solid Tires, 2s. 6d., 3s. All sizes stocked.—FRANKLANDS.

Air Tubes, best quality rubber, 2s. 9d. each. Fitted with Dunlop valve, 3s. 9d.—FRANKLANDS.

Air Tube, Para rubber. Marvellous value. Large stock to clear. Perfectly air-tight., 2s. each.; 21s. per dozen.—FRANKLANDS.

Cycle Capes, 3s. 6d., 4s. 6d., 5s. 6d. Also a few cycle Capes, guaranteed waterproof, 2s. 6d. each.—FRANKLANDS.

Detachable Outer Covers, licensed, 12s. 6d. each. —FRANKLANDS.

Saddles.—A clearing line in ladies' and gents' saddles, 2s. 6d. each, 24s. per dozen.—FRANKLANDS.

Inflators, 18in., 1s. 6d. each, 15s. dozen.—FRANKLANDS.

Bells.—Special line, double gong, usual price, 12s. dozen, will clear 5s. per dozen.—FRANKLANDS.

Prepared Canvas, 90 by 9, 1s. 3d. each, 12s. per dozen.—FRANKLANDS.

Pedal Rubbers, 6d. per set of four, 4s. 6d. per dozen sets; no rubbish.—FRANKLANDS.

Spanners, nickel, usual price, 13s. per dozen. Will clear a few dozen at 7s. 6d. per dozen.—FRANKLANDS.

Cycle Accessories and Cycle Rubber Goods. We hold the largest stock in the North.—FRANKLANDS, Astley Gate Blackburn.

Brass and Gunmetal Castings of finest quality. Prices on application.—DANIEL YOUNG, Witney, Oxfordshire.

W. Probert and Son, Brassfounders, Whateley-road, Handsworth, Birmingham,

Manufacture Brass Fittings in quantity to sample or drawing.

Brass Tubes, Sheet, Rods, Wire or Strip.

Brass Castings to Pattern.

W. Probert and Son, Whateley-road, Handsworth, Birmingham. Works: Tower-road, Aston.

Calver's **Complete Equatorial**, best ever designed, revolving eye-end, set any latitude by screw and vernier at once. Second-hand Telescopes, perfect order. "Hints on Reflectors," 13 stamps.—G. CALVER, F.R.A.S., Chelmsford.

Mail Cart Wheels and Perambulator **Furniture.**—WALKER BROS., Primo Wheel Works, Sheepscar, Leeds.

"**Gem**" **Gas-Engines.**—Still simplest and best for small powers.—MOTOGEAR Co., below.

"**Gem**" **Gas-Engine Castings.** — Easiest to make up.—MOTOGEAR ENGINEERING Co., 78, Queen Victoria-street, London.

Wheel-Cutting.—Spur, bevel, mitre, or spiral gear, in all metals, to any pitch.—MOTOGEAR, below.

Differential and Spur Gearing as illustrated in "E. M." for motor tricycles. Special prices.—MOTOGEAR, below.

The Motogear Engineering Co. have duplicated their machines and plant to cope with orders received.

They regret **Past Delays** and **Orders Declined**, unavoidable through limited capacity to deal with the quantity of work placed in their hands.

Orders can now be dealt with more promptly.—Address, 78, Queen Victoria-street, London, E.C.

Denning's "Great Meteoric Shower of NOVEMBER," illustrated, one shilling.—TAYLOR and FRANCIS, Red Lion-court, Fleet-street.

"**Spesco**" **Belting Syrup** prevents slipping, and keeps belts in good condition; 1lb. sample tin, post free, one shilling. —SPESCO Ltd., Suffolk-place, Bermondsey, London.

Small Engineering Business, with (patent) speciality, for sale as going concern. Inspection invited.—BEECHING, Mareham, Boston

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, NOVEMBER 17, 1899.

INLAYING.—VI.

THE process of veneering may seem simple enough, and it is so to the practical workman; but with the amateur it is often a difficult task. If an uneven pressure has been given to the work where contact is not perfect, a series of ridges will show. Assuming half this work is perfect, the caul must be heated again and placed, not upon the part that is sound, but upon that portion that is imperfect. Pressure should commence from the centre to drive the excess glue outwards, using the felt carpet as explained in the last chapter.

Assuming the work has every appearance of perfect adhesion, it can be laid aside until thoroughly dry. The outer paper that has adhered to the cutting should be very carefully removed, but must be damped to facilitate matters. The tool that has been used for the shell will be of service to remove the paper by scraping, and this will soon bring up any imperfection. If any portion of either shell or brass seems to appear unsound, small cauls and felt must be applied with pressure until perfect.

We may next give the means employed to bring the surface up to the polishing point. After the paper is removed, a coarse file is worked in all directions to level the excess, using second cut and smooth files for finishing; after which a piece of flattened pumicestone is used, lubricated with linseed-oil, until all file-marks are entirely obliterated. The final polishing of shell and brass is gained by means of charcoal and oil. It is of vital importance that the charcoal is of the proper kind, and cut in such a manner that it will cut and polish, but not scratch. Choose a piece of box, if possible, that has been charred properly in a muffled furnace. It should be about 1½in. diameter, and should be cut on the angle, so that when separated four or five slightly star-shaped crevices are discernible. It should not be too dense or heavy, nor should it be light and spongy. The desired quality will show itself very quickly in working. In passing the coal over the work, a certain adhesion or biting should be distinctly present, and with the working, a film of oil, fully impregnated with the brass in the shape of minute particles, should be discernible to the eye. The brighter the brass shows up in the oil, the nearer will our work approach perfection. The proof will be plain if all file and pumicestone marks are polished out. The crust or bark of the coal must be removed. It is in the crude hard casing that is the enemy. If all has been well, the work, when forced from all oil, &c., should present an even polish, free from scratches. The final touches we can well leave until the polishing paper is discussed. Fig. 108 indicates the manner of blending part and counterpart. A portion has the ornament cut in brass, the other has it in the shell. The same holds good with brass or German silver and wood. The design is for a panel which is got by assembling the four cut corners and jointing up at the dotted lines, thus forming one large panel. Although we say jointing up, we imply that the small centre ornaments are added when the four corners are together; otherwise an unsightly joint would show in the brass, which should be closely fitted. As far as the shell goes, it does not matter. The centre portion (when jointed up) is for the purpose of showing the brass ornament cut in the shell, which when engraved shows up well. The outer corners are the reverse: hence we call them the counterpart, and if the reverse was the case as regards the outer corner, we should not gain that variety now obtained. Yet it must not be forgotten that the panel would be pleasing if the shell ornament was central and the brass formed the four corners. Therefore in cutting buhlwork have as fine a saw as will carry well and save all after gluing-up (assembling).

We now come to one of the most pleasing portions of our task—the inlaying of leather, one of the most simple processes imaginable, because the tools are few, the material cheap and easy to work, and the job will last long if varnished after all gluing is done, and always bear revarnishing.

Russia leather can be got in all colours, andof fairly even substance. We will take, for instance, the simple ornament (Fig. 109), which can be greatly enlarged. If we glue a piece of salmon-coloured leather on a piece of deal or any kind of wood, and cut the outline of the ornament from a design already prepared, we shall be able to lift the ornament before the glue sets. It then remains to let in the dot or ball in, say, red, the centre in blue, the other pieces in whatever colour may be chosen. If by chance the joints should show open, a little stretching will soon rectify matters. Even as it is, it will not look out of the way; but if we "crease" the joints the value is highly enhanced. Creasing-irons can be made or purchased. If made, they should be as sketched in Fig. 110, and from ⅜in. to ⅞in. wide. The

FIG. 108.

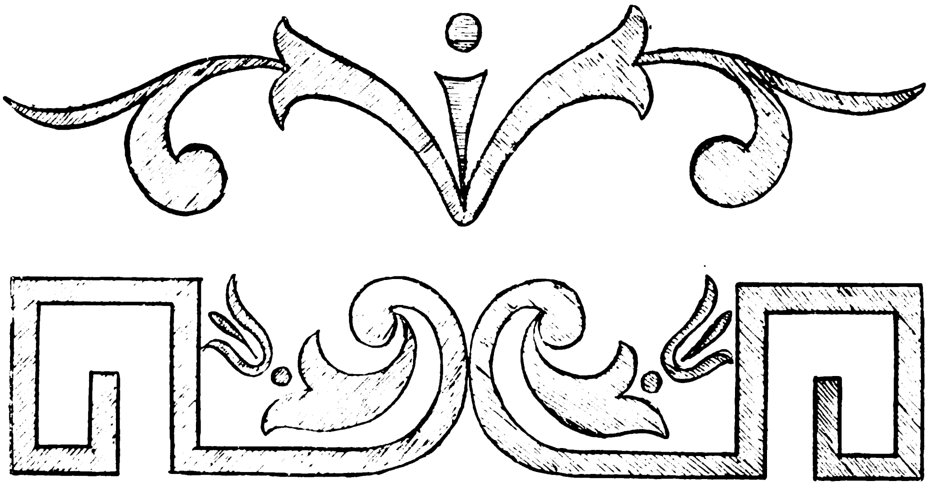


Fig. 109.

brighter or more highly burnished they are the better will be the crease line. A side tool is also shown. It is for the purpose of running a border line close to the edge of the work. Different thicknesses of creasing tools produce lines of corresponding widths,

Fig. 111.

so it will be readily seen the scope of ornamentation is unlimited.

We have given another example (Fig. 111) which requires a different method of working. The leather that forms the groundwork

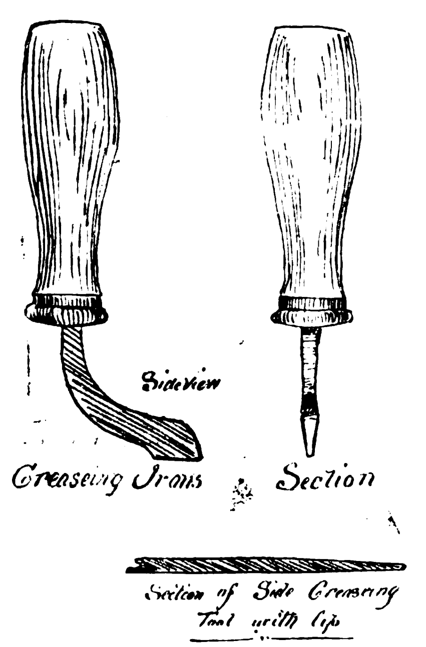

Fig. 110.

should be rolled with a round piece of wood to stiffen or toughen the skin. It should be laid on a board, and not glued at present. Four drawing-pins stuck in each corner will suffice. The chosen design is now laid on the leather, and with a sharp knife cut cleanly through to the back. The leather should be turned over, and the edge of the ornamental portion pared clean to about half its thickness, and extending about ¼in., which consequently forms a *feather* edge, inclining inwards. As each ornamental leaf or flower is cut, so must they be pared to correspond in substance. To give an appearance of roundness to the leaf or flower, a portion of the leather is carved out, so to speak, exactly coincident to the veins, on the under side, of course. When glued down and creased, the veins will consequently be lower than the outer surface, simply because all paring has been done on the under side. When all paring is done, the ground can be glued down, without stretching, adding the other portions afterwards. The parts that are thinnest should be well seated down to the glue, and that may be helped with the bone folder. When dry, or nearly so, the creasing-irons are warmed just up to the degree of heat that will burnish without burning. If the white of an egg, well diluted, is washed over the work, it will help the after-varnishing process. A special leather varnish is employed. Other designs can readily be elaborated with this simple caution—do not have any scrolls that cannot well be creased. Practise on larger work until efficiency is gained, and bear in mind the face side of the leather is *never* pared.

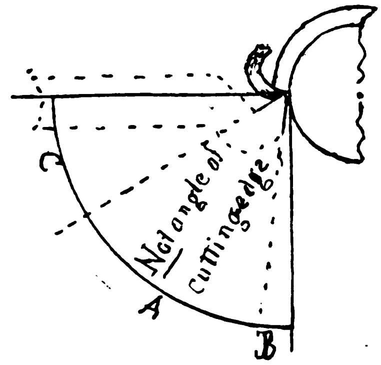
ON THE ANGLES OF THE EDGES OF SLIDE-REST TOOLS.—I.

By "D. H. G."

When referring to some back numbers of the English Mechanic a short time ago, I chanced upon a diagram given to describe the angles of the slide-rest tool, and was reminded thereby that I had intended to offer some observations suggested by the illustration; but, being unable to do so at the time, the matter escaped my memory. The diagram occurs in the series of articles entiled "Engineers' Machinists' Work," by "J. H." (*vide* "E.M." of May 1, 1896, No. XVIII.), and having re-read the two papers devoted to the subject, I venture to think that, although my remarks appear so long after date, the subject may still be of interest to amateurs who deal with metals in the lathe, and who hold that practice may be improved by the knowledge of the principles by which it should be guided.

There is no novelty about the diagram referred to above, which, though slightly changed in position on paper, is virtually a reproduction of that of Mr. Babbage to be found in the appendix of "Holtzapffel," Vol. II. p. 934. Although the diagram is useful as illustrating (in a very exaggerated form) certain points which ought to be borne in mind in the shape of the slide-rest tool regarded as a *whole*, it is probably responsible for much misapprehension on a still more important point of detail—viz., the angles of the edges which do the work. For some writers on the subject have taken the diagram as sufficient definition of the angle of the *cutting-edge* proper to be used on different metals, under the name of the "cutting-angle." "J. H." uses the diagram in this way; and the deductions which the writer founds upon this basis, coupled with the examples adduced in their support, afford unusually good material for the practical demonstration of the misleading character of the term "cutting-angle" when used in this sense. I think, therefore, it may, in the interests of the junior members of the amateur fraternity, be well to take this opportunity of drawing attention to the question. For the amateur will find that a sound acquaintance with the principles on which the cutting-edges of slide-rest tools are formed and should be applied may go far to compensate for the want of apprenticeship, and the lack of the practised eye which enables the trained artisan to form and select his tools by their general shape alone. Mr. Babbage has said that the excellency of all slide-rest work must, in the first place, depend on the angular relation of the facets which compose the edge to *each other* (and conjointly) to the *work*. But then these angles must be correctly measured, or they will become snares instead of aids.

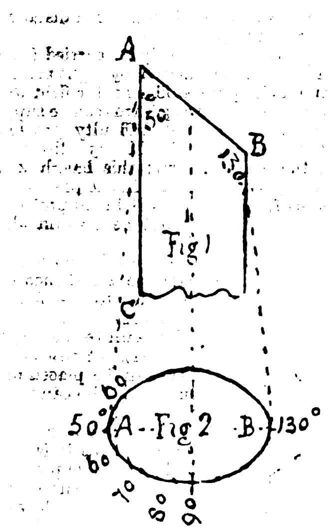
The following observations will be better understood by referring to so much of Mr. Babbage's diagram as relates to the particular question, though this must be familiar to most amateurs,



either in whole or part, from its frequent occurrence in manuals and essays on the subject.

Mr. Babbage divided the *quadrant* into three angles, which will here be called respectively the angles of "relief" (B), of the "tool" (A), and of "escape" (C). The definitions are Mr. Babbage's, but the distinguishing letters are those used by "J. H." It is difficult to believe that Mr. Babbage should have intended the angle assigned to the "tool" to define also that of the edges formed upon it. For it is obvious that no *plane* drawing, such as that of the quadrant illustration, can represent in the same view both the vertical elevation of the tool from point to stem, and also show the angle which the edge presents to its work when moving laterally in the horizontal direction. Yet "J. H.," in the text explaining the diagram, writes:—"In Fig. 110, A is the tool-angle or cutting-angle," adding only, "this is varied to suit different metals and alloys." If there were any fixed proportion between the angle of the cutting-edge and that of the so-called "cutting-angle," it would not be a matter of so much practical importance what the angle of the latter might be called. But Prof. Willis has demonstrated that in tools of this class the angle shown in a side-view of the tool (as shown in the "quadrant" diagram) must always be *more* acute than that of the cutting-edges; and also that this difference may be very wide indeed, as it will depend on the form given to the flat upper face of the edge. The so-called "cutting-angle" can, therefore, be no certain indication of the acuteness of the edge employed, for edges varying widely in their acuteness may be formed on one and the same

"cutting angle" simply by varying the shape of the upper face. Moreover, in a side view of the tool it is impossible to tell whether the edge may be pointed or rounded, and though the *principle* involved in the flat upper face is the same in both cases, its *action* is very different in degree (*vide* Treatise by Prof. Willis, in the Appendix of Holtzapffel, Vol. II. p. 991). The "cutting angle" can only show the angle which the *bevel*, or "top-rake," makes with the highest point in the front line of the edge. And Mr. Smith observes: "It is not only the front edge of the tool that *cuts*. A most important part of the cutting is done at the *side* of the edge" (*vide* "Cutting-Tools," by R. H. Smith, M.I.M.E., &c., Chapter V. pp. 82-3). The same authority also insists on the "mathematical impossibility" of describing the angle of any edge having a flat upper face by giving one angle alone. "J. H." admits that, "The subject of cutting angles is one of very great importance, as malformations cause waste of power and indifferent workmanship"; but the writer also says that "angles may exist in books, but do not survive in practice" (vide "E.M." No. 1624, p. 251). It is rather hard to harmonise these two quotations. Doubtless such books as describe the angle of the edge by the one so-called "cutting-angle," are open to this indictment; and as the writer adopts the same system of measurement, it is probable that this is the key to this sweeping censure of the value of "book-learning." But it is somewhat remarkable "J. H." should have adduced the two tool-holders of Messrs. Smith and Coventry in



support of the conclusions based on the theory of the one "cutting-angle"; for no two better examples could be found to demonstrate the misleading character of this system of measurement. The writer says that "the tool-holder for round bars maintains a constant cutting-angle of 50°, while those for *wedge-shaped* (*sic*) cutters embody a cutting-angle of 68°." With regard to the tool-holder for *round* cutters, their circular cross-section admits of the simplest form of mathematical demonstration that, so far from the angle of the edge being "*constant*," no two adjacent points can possibly be of exactly the same angle.

Let Fig. 1 represent the side view of a round cutter bevelled to contain an angle of 50°, and Fig. 2 be the *flat* view of the elliptical upper face so produced. If the angle at A be 50°, the angle at B must be 130°, or the supplement of 180°. Thus the edge must gradually pass (on either side) through every angle from 50° at the highest point at A to 130° at B. The gradual decrease of acuteness is approximately indicated by the degrees marked on either side of the highest point at A in Fig. 2, and continued on the lower side up to 90°, after which point the edge becomes obtuse. That Mr. Smith fully recognised this mathematical fact is apparent from his description of the tool-holder in question—to be found in his work on "Cutting Tools" (Chap. VII. p. 163-4), where the writer gives a very candid account of the merits and limitations of his holder. Mr. Smith writes thus: "The elliptical section forms the cutting-face, and the *cutting-edge is the highest sharp corner of the ellipse.*" It will be seen by reference to Fig. 2 that the decrease of acuteness in this section of the edge is confined to limits which are of no practical moment in a *light* cut. But the writer goes on to say that, "With a deep, heavy feed, the steel is apt to slip downwards a little, thereby causing inaccuracy in the work." As this holder places the cutter in a position very slightly relieved from the vertical, it can readily be supposed that this would be the case when the metal engages the edge at points where its decrease of acuteness may amount to 70° or 80°, or even more.

To describe these edges as "maintaining a *constant* cutting angle of 50°" gives no idea that the edge contains only *one single point* of this angle, and that it varies gradually up to 90°; nor of the limitation in its use as described by Mr. Smith; nor of what would be the case if the cross-section of the edge were other than truly circular—viz., that the variations of acuteness at the several points of the edge would all be different in degrees. "J. H." quotes the "cutting-angle" of the "wedge" (or V)-"shaped" cutters as being 68°. But this is equally misleading with respect to the true angle of the cutting-edges, which cannot be far short of 80°. This, however, will be more clearly understood when the way to estimate the value of solid angles has been considered.

(*To be continued.*)

MILLWRIGHT'S WORK.—XVII.

THE Lagrelle fasteners are shown in Fig. 102. The belt, butt-jointed, is laid face to face at the ends; the links or loops, *a*, are inserted in punched holes, punched slightly smaller than the loops, and bars, *b*, are passed through them.

Walker's plate jump-joint is illustrated in Figs. 103-105. There are several modifications.

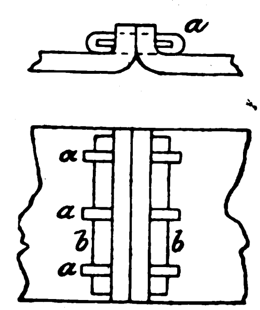


FIG. 102.

The older form consisted of links and pins only; in the later ones, the joint is stiffened with plates, Fig. 103 being the completed joint, Fig. 104 a link, Fig. 105 a plate. This is a good joint in cases when the projections are not objectionable.

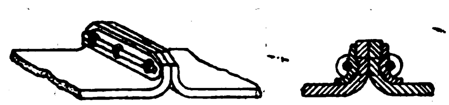

FIG. 103.

The advantage of the plates is that they prevent the pins from being pulled into the material of which the belting is composed.

The "camel" fastening of Reddaway and Co. is shown in Fig. 106. Like all those which grip firmly, the strain on the holes tending to tear out the belting is practically *nil*, resembling in this

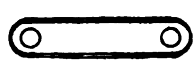

FIG. 104.

the frictional hold of rivets when first closed. The fastening consists of bolts dished upwards to bend the belt inwards in cup-shaped depressions. The nuts are screwed on the top of links which bridge across the joint. The Reddaway camel-hair belts are used largely in the Lancashire cotton mills for heavy driving. They possess several advantages for this class of work over leather. Their tensile strength is greater, and they are less liable to slip, having a higher coefficient of friction than leather. The combination of these two characteristics permits of the use of thinner belts in camel hair than leather. They lie closely to the pulleys, and slip but slightly. A $\frac{5}{16}$in. camel belt is as efficient as a $\frac{1}{2}$in. one of leather.

There is a leather belting in the market which is woven of narrow thongs, and which appears to fulfil the functions of link belting in regard to extreme flexibility, and in allowing the air to escape through the interstices. The joints are

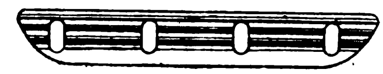

FIG. 105.

woven also. The price is the same as that of first-class leather belting. The leather link belting does good work, and is a distinct boon to engineers. That it has many advantages over the solid flat leather belting is clear from a consideration of some of the practical points already touched on. The frictional grip is better. In an ordinary belt there is always some air entangled between the belt and the pulley face, preventing intimate contact. Many pulley rims are pierced with holes, in order to permit of the escape of the air in cases where wide belts are used. The link belting allows the escape of air in a more complete way. It is very flexible, and will lap easily round the smallest pulleys, against which a double belt would be strained excessively. It is suited for short drives. Jointing-up can be done more easily than with any other kind, because the only fastening required is a pin which is inserted through the holes in the links, after adjustment for length. The joint so made is as flexible as any other part, which is not the case with laced belts united with a scarfed joint. But this is not the only advantage. For pulleys with convex rims, link belting is made with a convex driving

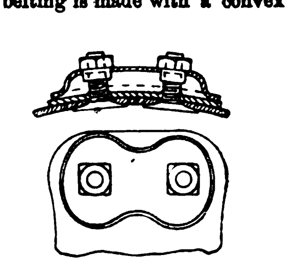

FIG. 106.

face to lap round the rim, and give frictional grip over the whole width of the belt. But its principal value is seen in twist drives. The difficulty of driving twisted belts of only a fair width is great, especially when, as is usually the case, the drive is a short one. A narrow portion of the belt only is in contact with the pulleys, and while that presses very hardly, the remainder is thrown off. In the hands of Messrs. Tullis and Son, the link belting has been made exactly adaptable to conditions such as these, so that it lies in contact with the pulley across its entire width, no matter how wide the face. The belting is made of a bevel or wedge section. The links are selected of different widths to suit a given twist, and the result is a thick-sided belt, which may vary in some cases from 1in. deep on

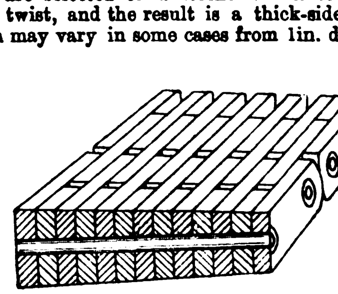

FIG. 107.

one edge, to $\frac{3}{8}$in. on the other. Fig. 107 shows a section through one of this class.

Tullis and Son adopt the plan for ordinary wide driving, of curving the link belting to suit the rounding of the pulleys. This is effected without straining the rivets, by a patent flexible centre. That is, there is a row of double links down the centre, which are not fastened closely like the others, but loosely, so that the belt will lie to the pulley on each side to right and left. Fig. 108 shows one of these belts, as

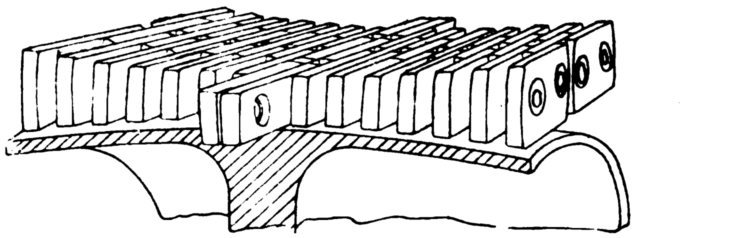

Fig. 108.

made for working at various angles, and Fig. 111. one for straight driving. Another advantage of the link belting is that it can be united more readily and rapidly than any other, since the links are coupled immediately by the insertion of their pins. Lastly, its great flexibility renders it especially adapted for

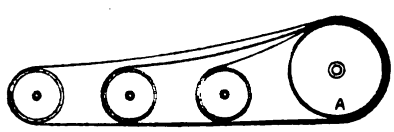

Fig. 109.

short drives, and it is probably less injured by binder pulleys than the rigid belting.

One of the most interesting developments of driving in recent years is that of compound belts—that is, super-imposed belts. The addition of a second belt adds immensely to the efficiency of the drive. Tullis and Son, of Glasgow, have fitted many of these, under varying conditions, and with entire success. There is more than one advantage in the adoption of this method:—

When a double belt is used, the outer layers

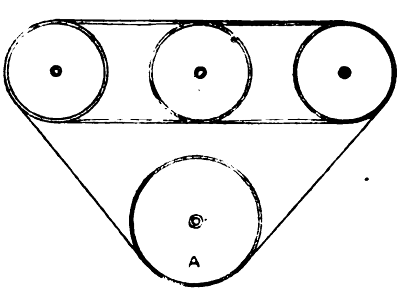

Fig. 110.

are under a greater strain than the inner ones. The belt moves stiffly round small pulleys. It is not always practicable to use pulleys of sufficient size for a thick belt to work with advantage; and it may not always be convenient to widen the pulleys and use wider belts, when an increase in power is desirable. Then the advantage of using two belts of moderate thickness comes in. Without experience, one would say that this method of driving would be impractical and unsuitable.

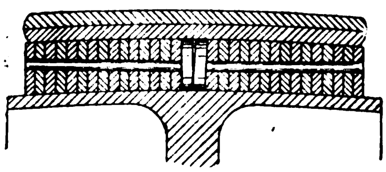

Fig. 111.

Actually, it is employed in a large number of instances, and under varying modifications.

Belts used thus increase the power transmitted; two, and in some cases three or four being used. When so employed, they run at slightly different speeds, the second travelling rather faster than the first, and the third than the second. They are also employed to drive from a single shaft to two or three or more shafts, situated at various distances apart, the advantage being that space is saved in the lateral direction. Fig. 109 is one of the Tullis' drives, in which power is transmitted from a main driving pulley A to two, three, or more driven pulleys in direct line. Fig. 110 is another, in which driving is from a main pulley A to three driven pulleys, the main belt driving outside the driven.

The compound system of belting is especially applicable to short drives, as well as small pulleys. Instead of using very tight belts, slack ones will perform the same purpose without straining the shafting. For compound driving, link belting forms a good basis for wide pulleys. Having a flexible centre-link belt, with top edge rounding, a shallow leather belt can be run upon this to gain in power, or to drive to a pulley other than that which the link belt drives to, Fig. 111.

In many of the mills in the North, the Reddaway camel-hair belts have been used compounded, and have given satisfaction. When more than one belt is to be run on a pulley, the latter should be strengthened to take the extra strain.

J. H.

ROYAL NAVY AND ARMY MEDICAL SERVICES.—THE ROENTGEN RAYS IN MILITARY SURGERY.

By John Hall-Edwards, L.R.C.P., F.R.P.S., Surgical Radiographer to the General Hospital, Birmingham.

FROM the report published in the *British Medical Journal* of November 4 of the arrangements made by the War Office for the transportation of Röntgen ray apparatus to the seat of war, it would appear that this adjunct to military surgery is not receiving the amount of attention which its importance warrants. Of the ten sets of apparatus provided, four only have reached South Africa, whilst two of these are located so far away from the field of operations that they must be of little service. The remaining six sets, we are told, are either on their way out, or are about to be despatched.

It is freely acknowledged that no medical equipment for active military service can be considered complete unless an X-ray apparatus is included; it must, therefore, follow that, in many instances, our wounded are not having the best possible done for them. Up to the present time some 750 men have been wounded, and as it is fair to assume that in at least 80 per cent. of the cases the X rays must have proved of service, the two apparatuses in Natal must have been kept exceedingly busy, or, as is much more probable, they cannot have been used in half the cases in which they were necessary.

It has been proved beyond the shadow of a doubt that the application of the X rays to military surgery constitutes one of the greatest advances of the century. Mr. Mansell Moullin, F.R.C.S., in his presidential address to the Röntgen Society, in July last, said:

"The benefit which surgery has derived from the improvements which have been effected in the use of the Röntgen rays during the past year is no less striking. Military surgery will have to be re-written. Thanks to the ease with which suitably planned apparatus can be carried on campaign, all the wearisome and intensely painful probings after bullets and foreign bodies, to which the wounded look forward with such dread, have been swept away."

As one of the first in this country to apply the Röntgen rays to practical surgery, and as a constant worker both in hospital and private practice since, I have no hesitation in echoing the statement above quoted. It may be argued that inasmuch as in modern warfare few bullets find their billets in the bodies of the wounded, the X rays must prove of little practical use. This is, however, incorrect, for in every case in which a bone has been injured the amount of injury can be ascertained, and the subsequent treatment arranged accordingly.

The great drawback to successful surgery in the field is the difficulty of carrying out the principles of absolute cleanliness, upon which modern surgery is founded. That at certain times and in certain places absolute cleanliness is impossible I freely admit, and, knowing this, it becomes all the more necessary that every possible step in the direction of securing the desired end should be seized upon. With the X rays at command, an injured limb can be examined and the injury diagnosed, the presence, shape, and exact location of a foreign body ascertained, and the amount of injury to a bone discovered, without giving the patient pain, and without removing the dressings. The probe is rendered unnecessary, and dangerous manipulation can be dispensed with. In many cases all can be done with a small apparatus at a field hospital, or even at a dressing station, whilst in others the larger apparatus at the base can be brought into requisition.

After the recent Nile campaign much dissatisfaction was expressed both in Parliament and elsewhere, because the ambulance arrangements were imperfect, and the X rays had not been fully utilised. The Under-Secretary for War said "that there had been no case of a wounded man at the Atbara to whom the absence of the Röntgen apparatus had made any difference." That this statement was not an explanation must be patent, as the results of the application of the X rays could in no case be foreseen. The excuse offered by the War Office was that the transport difficulties had not been overcome. Since this time the necessary apparatus has been much simplified and improved, whilst Major Beevor, myself, and others have demonstrated that the transport difficulties are more imaginary than real.

With an apparatus I have devised I have given two demonstrations in the field in conjunction with Surgeon-Major Freer and the ambulance section of the 1st Volunteer Battalion Royal Warwickshire Regiment. In each instance three negatives were produced, and developed under the conditions of actual war. The apparatus (including portable 8in. spark coil, accumulators, developing tent and stand, and box for tubes, plates, and chemicals sufficient for 100 exposures) was carried to the field in the ambulance waggon, and although it was freely jolted for a distance of six miles it worked to perfection.

Such an apparatus can easily be carried (should necessity arise) for a long march by eight men, and although small it is quite sufficient for field work; more elaborate and larger apparatus can be supplied to the hospitals. The chief difficulty previously experienced in applying the X rays lies in the changing of the accumulators; this has, however, been successfully overcome, and in the present war, where the line of operations will in all probability follow the railway, there should be no difficulty in this respect.

The fluorescent screen is of very little use in the field, owing, on the one hand, to a darkened room being necessary, and on the other to the fact that the surgeon in command of the X-ray apparatus is rarely the one who is intrusted with the subsequent operation. A negative or series of negatives is much more useful, as they can be placed in the hands of the operating surgeon, who can refer to them at any stage of the operation.

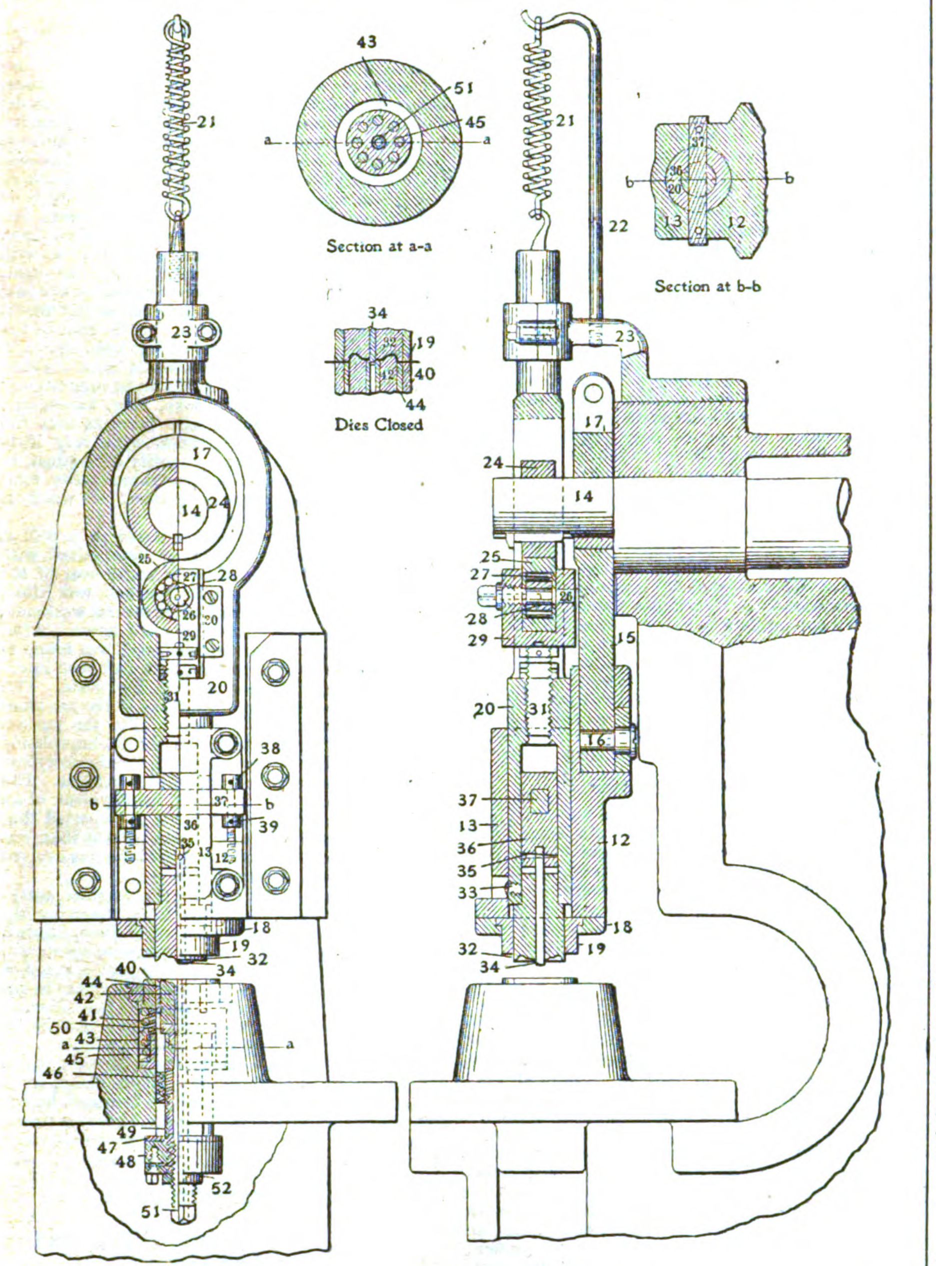
Even when the apparatus is working to perfection, the surgeon in whose hands it is placed must have a knowledge of photographic procedure, or his results will be useless, and in the event of anything going wrong the operator must have had considerable previous experience, in addition to a fair knowledge of electricity. I know not whether those sent out with the sets above mentioned have the requisite training to carry out their mission with success; but if they have not, I can confidently predict that their efforts will to a great extent fail. If military surgery is to be rewritten after the present campaign, no expense or trouble should be spared to render the Röntgen-ray arrangements as complete as possible.—*British Medical Journal.*

COMPOUND PUNCHING AND FORMING DIE.*

THE illustrations herewith show a novel arrangement of both press and the punch parts attached. Of the press, it may be said that it not being of the inclined variety, nor even having an open back, and it being desirable to remove the finished pieces by gravity, the plan of making the entire press sideways was adopted with perfect success in everything, except appearance, which was decidedly odd. New legs, giving a side inclination of 30° to the press, were provided in the place of the usual supports. The centre of gravity of the upper portion of the press being low, it was found to stand safely upon the new legs, and although the shorter one had on it by far the greater portion of the weight, no vibration or shakiness could be noticed while in action.

The special work for this press was the making of a small sheave pulley side, of mild bright sheet steel, about 2in. in diameter and ·04in. thick. These sheaves were produced in large quantities, about 40,000 sides per day being called for. They had previously been made by first blanking the side, then piercing the hole, and finally pressing into the desired shape in forming dies, the operations occupying three presses, each attended by an

* By W. E. Willis, in the *American Machinist*.



operator, as no automatic feeds had been employed on the work. After coming from the die the blanks were tumbled with sawdust as usual to remove any possible burr and the sharp edges, as well as to give a final semi-polish or brightening, and remove all trace of oil, which was plentifully used in the combined operation.

The design shown, while it was considered somewhat expensive in first cost, soon proved to be highly economical. Duplicate parts were made of those pieces which were likely to be broken or to wear out quickly, so that the press might run as uninterruptedly as possible, stopping only to make changes instead of repairs.

The alteration of the press, besides the inclined legs, consisted of a new special ram or slide, a new eccentric to move it, a special cam and cam yoke, operating through the slide, with a guide bracket on the top of the press, and a suitable heavy plate combining the functions of bolster, die-block, and support for the automatic roller feed, which was also added to it.

A detailed description of the drawing is given for those who may be interested. Fig. 12 represents the slide which is guided vertically in the press frame and carries a housing, 13, made in two parts for convenience of access, which form together a cylindrical bearing for the forming plunger. The slide 12 is connected with the crank 14 by a pitman or connecting-rod, 15, one end of the pitman being secured to the slide by a bolt, 16, while the other end encircles the eccentric 17, the eccentric being adjustably clamped by the upper end of the pitman, so that any desired adjustment relative to the crank may be had. To the lower end of the slide 12, by means of the ring 18, is secured the pressure-plate 19. This plate also serves as a blanking die.

Within the housing is guided the slide 20, which is held normally in an elevated position by the spring 21, which connects the upper portion of the slide with a standard arising from a fixed portion of the press frame, a portion of which, 23, forms a guide for the upper end of the slide. A cam, 24, is keyed to the crank 14, and operates the slide 20 against the pressure of the spring by bearing on a hardened steel wheel, 25, carried on the stud 26. Anti-frictional rollers, 27, are provided, travelling upon a hardened steel bushing, 28, fitted snugly on the stud. In order to obtain adjustment, this stud is carried in a yoke, 29, which is movable vertically in the slideway 30; an adjusting screw, 31, is provided for varying the elevation of the yoke.

The upper forming die 32 is fastened to the lower end of the slide 20 by a set-screw, 33, passing through an opening in the front of the housing. A piercer or punch, 34, is provided for punching the hole in the centre of the blank, which passes through a central opening in the former, 32, and has its upper end secured by a pin, 35, to the adjustable plunger 36, carried in a recess in the slide 12. An adjusting bar, 37, passes through the plunger 36, and has its ends secured adjustably to the housing 13 by means of the screws 38 and lock-nuts 39 in such manner that the punch 34 may be adjusted vertically with relation to the slide 12.

To hold the strip during the forming operation, a lower-pressure ring, 40, is provided in line with the upper ring 19, which is supported upon a strong steel spring, 41, serving to hold the ring 40 firmly up against the ring 19 when the latter begins to descend, thereby clamping the stock under a powerful tension. The lower former 42 rests solidly upon the ring 43, which is firmly supported by the cast-iron die-block, resting in turn on the bed of the press.

In order to blank out or sever the pulley section from the strip after it has been formed, a lower blanking ring or punch, 44, is provided, encircling the lower frame, said ring being supported on a series of laterally adjustable steel pins. Two of these, one of which is shown at 45, the other being diametrically opposite, are kept in contact with the punch by a coiled spring, 46, which causes the ring to act as a stripper, or means for forcing the blanked section out of the bottom former. The other pins rest on the steel washer 47, which is supported by the nut 48, the nut being split so that it can be securely clamped in any position.

The pins are of such length that there is a space between the bottom of the punch and the top of the pins, this space representing the amount of compression of the springs 46. As the blanking ring 44 is worn or ground away it may be adjusted vertically by the nut 48 on the screw 49. This pressure plate 19 also serves as a blanking die, the material being sheared between the edge of the plate or ring 19 and the edge of the plate or ring 44, as indicated in the sectional view of the punches and dies. It is to be noted that the severing of the blank from the strip of sheet metal does not take place until the blank has been fully formed.

On account of the reciprocating motion of the punch 44 there is a tendency of the former 42 to work up out of the holder, which is overcome by having a sleeve, 50, fastened to the bottom of the former 42 and threaded into the sleeve 43. In order that the hole in the centre may be punched by the piercer or punch 34 at the same time the blank is cut, a round die is provided, which is supported and adjusted by the hollow screw rod 51; this adjustable rod is threaded into the sleeve 43, and held in proper position by the lock-nut 52.

The operation is briefly described as follows:—The strip of metal is placed or fed between the formers, and the revolving of the crank forces the slides 12 and 20 down in unison. As soon as the rings or plates 19 and 40 come in contact with the work, the lower end is depressed and the formers 32 and 42 begin to draw the metal into shape, the surrounding stock being in the mean time securely held by the pressure-plates 19 and 40. When the former 32 has reached the limit of its downward stroke, and the blank is fully formed, the relative arrangement of the cams operating the slides is such that the slide 12, and with it the pressure plate 40 and punch 34, continues its downward movement. By this time, however, the springs 46 have been compressed until the ring 40 rests solidly on the pins, and the further downward movement of the pressure-plate 19, acting against the stationary edge of the ring 40, shears off the metal, while at the same time the punch 34 cuts out the centre hole. In the continued movement of the crank-shaft, as soon as the slide, with the ring 19, recedes, the pressure-ring 40 is forced upward by the springs 46 and 41 out of the former 42, when the cam 24 has revolved so that the former 32 will start downward, carrying with it the formed blank and strip, which, being moved along at the same time, should carry the formed blank out from under the tools, delivering it free from them and leaving the strip in readiness for the next operation.

PURIFICATION OF ACETYLENE.

IN common with all other writers on acetylene, we have repeatedly urged in past issues of the *Engineer* that under the existing conditions of calcium carbide manufacture, and the circumstance that this material is placed on the market in a "commercially pure" state, acetylene is not fitted to be used as an illuminant in dwelling-rooms unless it has been submitted to a rigorous and really chemical method of purification.

The gas can be evolved from carbide in two radically different ways; either by dropping the solid into a large excess of water—the so-called carbide-to-water principle, where the whole interior of the generator is full of water; or it can be prepared by bringing water into contact with carbide—the so-called water-to-carbide principle, where the whole interior of the generator is full of gas. We have already discussed the relative merits of the two processes; and in the present connection have nothing to do with the matter except in so far as the impurities of the resulting gas are concerned. The normal impurities of crude acetylene, which are of sufficient importance to require attention, are three in number—ammonia, sulphuretted hydrogen, and phosphoretted hydrogen. The two former are very soluble in water, the second is chemically absorbed by lime-water; and therefore it is not surprising that in carbide-to-water acetylene, phosphoretted hydrogen is practically the sole survivor. In another way, also, phosphoretted hydrogen is the impurity which gives most trouble to acetylene users; ammonia and sulphuretted hydrogen have for many years been well-known impurities in illuminating gas. Methods for their extraction have been thoroughly worked out by coal-gas makers, and all that "acetylenists" have to do is to borrow or steal existing processes. In the coal-gas trade, owing to its enormous size, these impurities become actual sources of revenue; and it is necessary to remove them from the gas in such fashion that the sulphur and the ammonia may be recovered in salable form. By the wildest flight

of imagination it cannot be conceived that the ammonia and sulphur in calcium carbide shall ever become pecuniarily valuable, therefore the generator maker is free to employ any processes for their extraction which seem good in his eyes, quite irrespective of the manner in which those bodies suffer during the operation.

In the Purification of Acetylene,

then, there is essentially but one substance to be dealt with; and this merits considerable study—first, because it is very difficult to remove without attacking the acetylene; secondly, because, left in the gas, it is far more objectionable and unhygienic than either or both of the others. On combustion, phosphoretted hydrogen is converted into phosphoric anhydride, which immediately takes up water and becomes phosphoric acid. Phosphoric acid in a closed room produces a whitish haze, misleadingly called by some generator makers a smoke, and is very irritating to the mucus membrane of the nose and lungs. Traces of sulphuric acid are bad enough, both in this way and in their action on gold leaf; probably, phosphoric acid would destroy picture frames and bookbindings to an equal extent, but it stands far beyond its rival as a throat irritant. In passing, perhaps a word of warning may be offered to those persons who are disposed to experiment wildly on the extraction of phosphoretted hydrogen. There are plenty of chemical substances that will oxidise and remove this impurity; the difficulty is to find something that will remove it without simultaneously oxidising the acetylene. Potassium permanganate and barium peroxide extract the phosphorus almost entirely, and some of the sulphur also; but they attack the acetylene and cause much waste of gas. Potassium bichromate at first removes the phosphoretted hydrogen, leaving the sulphuretted hydrogen behind; but its activity soon falls off, and it is not of much value as a purifying material. Ferric chloride touches neither the phosphorus nor the sulphur.

From the aspect of purification acetylene has passed through three stages. Originally purification was utterly ignored; next the gas was filtered through glass wool, asbestos, and similar straining materials, which undoubtedly are of service in extracting coke and lime dust, but which cannot be honestly termed purifiers; then some method of real chemical purification was found essential, and more or less intelligently was adopted. Writing in England, we fear the above sentence is scarcely correct; acetylene has not yet passed through the first two stages—it is still passing through them. Several English manufacturers have recognised the necessity of purification, and manfully have struggled to cope with it; others calmly put it on one side, smiling faintly when they are questioned about it; others provide their generators with purifying vessels containing some secret chemical (?) substance, and feel aggrieved when cautious expert writers will not affirm in print that the process is satisfactory.

Practically speaking, there are on the market at the present time three distinct methods of chemically purifying acetylene with varying degrees of efficiency. These are Ullmann's chromic acid, Frank's acid cuprous chloride, and chloride of lime. The primary reagents in the two former processes are solutions; but since liquids are not by way of being conveniently employed in practice, owing to the greater attention required during their utilisation, and to the greater loss of pressure in the service when the gas has to pass through a column of reasonable height, they are now being used in the form of solids after absorption in kieselguhr. Ullmann's solidified chromic acid is called commercially "Heratol"; Frank's solidified cuprous chloride is known as "Frankolin."

During the Past Few Months

all these processes have been submitted to careful examination in Germany by a number of investigators, whose conclusions respecting the value of the Frank and Ullmann powders all agree substantially with the opinions expressed by Dr. Ahrens, to which we referred on page 141 of our issue for August 11 last. Dr. Ahrens, it will be remembered, stated that chromic acid and cuprous chloride removed all the phosphoretted hydrogen, but left some sulphur behind; while chloride of lime extracted the whole of the impurities, but introduced others. The new impurities consist of carbonic oxide and certain compounds of chlorine, both sufficiently objectionable in their way; but, on the other hand, bleaching powder is so much cheaper and so much easier to manipulate that it is very desirable to be able to employ it. Moreover, on several occasions lately trouble has arisen with spent chloride of lime; every now and then it heats considerably, and in one case—at Budapest last spring—when the lid of an old purifier was lifted, the mass caught fire, injuring, we do not know how seriously, the man who was going to empty and recharge the vessel. Not altogether without cause, a small scare has sprung up, and chloride of lime has been proclaimed too dangerous a material to be adopted for removing the phosphoretted hydrogen from crude acetylene.

The earliest suggestion for using bleaching powder for this purpose was made by a couple of English, or Scotch, inventors—English patent 24,414, 1896; the real credit of working out the idea undoubtedly belongs to Lunge and Cedercreutz. The latter chemists carried out many experiments about two years ago, and said not a word about heating. The same reagent, too, we understand, has successfully been employed, either alone or mixed with some other substances, for quite a long time, by one of the chief Engish firms engaged in the acetylene business, who, with perfect justice, claim that their material vastly improves the atmosphere of an unventilated room where the gas is to be burnt, and who assert that they have "hundreds of purifiers" in use "giving great satisfaction." Yet a short while ago Prof. Vertess published an account of the acetylene installation at the Hungarian tower of Veszprim, in which he said that the burners smoked badly, and the gas exhibited all those defects which are recognised as characteristic of acetylene generated from calcium carbide of inferior quality, and burnt without purification. In a later communication to one of the German technical journals, Dr. Ahrens referred to the Veszprim difficulty, and explained—without noticing Vertess's observations—the whole matter. He said that the acetylene of that town was regularly purified with chloride of lime, but that the gas smelt so strongly of chlorine—by this expression we presume he meant that the products of combustion smelt so strongly of chlorine—that the consumers grumbled and threatened to go "on strike," and therefore the purifying apparatus was either temporarily or permanently put on one side. In the absence of the purifying system, Prof. Vertess no doubt examined the condition of affairs, and very naturally he heard complaints about the choking of the burners. The question thus arises, What is the practical value of chloride of lime as an acetylene purifier, and can it be employed with perfect safety or not?

The Whole Matter

seems to turn, like so many other industrial problems, on several small and apparently insignificant details. If chloride of lime is properly used it is satisfactory and safe; if it is improperly used it is a nuisance and a possible source of danger.

Although it is perfectly practicable to do so, it is not convenient in the small installations where acetylene is the illuminating agent to use liquid purifying materials. Chloride of lime could be bought into solution, but a slightly damp powder is preferable for various reasons. The acetylene, therefore, must not be too damp when it enters the purifier. Complete absence of moisture does not appear necessary; it is sufficient that the gas, either in the generator itself or in a separate condenser, shall be thoroughly cooled, and so freed from the greater proportion of its water vapour. Ammonia must be removed from the gas before it comes in contact with the bleaching powder, or the violently explosive chloride of nitrogen may be formed. In apparatus of such design, therefore, that the acetylene does not bubble through water—in which, of course, ammonia is enormously soluble—a washing vessel must be put before the purifier; or, if preferred, a vessel holding a little weak sulphuric acid. By remembering these two necessities—absence of excessive moisture and freedom from ammonia—acetylene can be quite safely brought into contact with chloride of lime, and by that material all the impurities will be removed.* Now it is said that chloride adds carbonic oxide and chlorine compounds. We cannot imagine that a method of withdrawing the carbonic oxide can be worked out, but we do consider that such a process is really wanted; for the proportion of this highly poisonous gas thus introduced must be extremely minute, and the acetylene after treatment cannot be regarded as in any way comparable to modern coal-gas enriched with carburetted water-gas, or to carburetted or non-carburetted water-gas itself, as regards toxicity. Probably if this introduction of carbonic oxide had not been noticed by very careful chemists the presence of the fresh impurity would have remained unrecognised for all time. The chloride compounds are more important, and, fortunately, are more amenable to treatment. By placing a second vessel charged with slaked lime only, after the bleaching powder purifier almost all the chlorine added by the chloride can be removed without injuring the acetylene; and as the percentage of chlorine compounds that need extraction must also be small, the second vessel should remain operative for a long while and require very little attention. In a recent investigation of chloride of lime for the present purpose, Dr. G. Benz has asserted that this lime vessel must always be added; and his prescription is endorsed by many other authorities. It most certainly appears a reasonable precaution, and should be followed until some means for preventing the formation of these chlorine compounds—if that be ever practicable—is discovered.

* This statement is distinctly admitted by Ullmann and Goldberg in a recent article; and Ullmann is the advocate of chromic acid.

The Occasional Heating

and the possibility of a fire when the spent chloride is brought into contact with air and light in the operation of recharging the purifier, is an unpleasant phenomenon, but it is equally under complete control, if we may trust, as we entirely do, the latest information on the subject. Ahrens has found that chloride of lime when used alone does not exhibit this liability to become hot. It has been the custom with some firms to dilute the bleaching powder with sawdust in order to render it more porous and, by increasing its surface, make it a more energetic absorber of phosphoretted hydrogen. And it is precisely this mixture of chloride with sawdust which is principally liable to heat. Manifestly, there is no peculiar virtue in sawdust as a diluent; a host of other harmless indifferent substances are to be thought of on the spur of the moment. Inasmuch as sawdust has been shown to be harmful, some of these materials must be substituted. Ahrens and Benz both make suggestions; coarsely powdered brick, coke, slag, kieselguhr, &c., will serve. Ahrens also remarks that the chloride must be mixed either with very little water, or with a very large quantity of sawdust, to make it quite safe; but, we submit, the total avoidance of the organic matter of wood is distinctly more advantageous.

Quite recently an accident occurred in a mill at Würtemberg, where chloride of lime mixed with kieselguhr was being used; the water-seal of the purifier was blown out, the holder bell was lifted, the gas caught fire, and suffocated several workmen, who remained unconscious for some hours. After the explosion, the purifying material was found to be pasty with water, although it had been introduced into the vessel in the dry state. This catastrophe seems to have been due to the gas passing directly from the generator into the purifier very hot and loaded with moisture; not improbably also the carbide was unusually bad, and the acetylene contained a notable proportion of ammonia. The trouble was aggravated by the employment of an abnormally large purifier; for it is reported that some 90 times more chloride was present than was necessary to deal with the whole of the gas evolved by the generating apparatus.

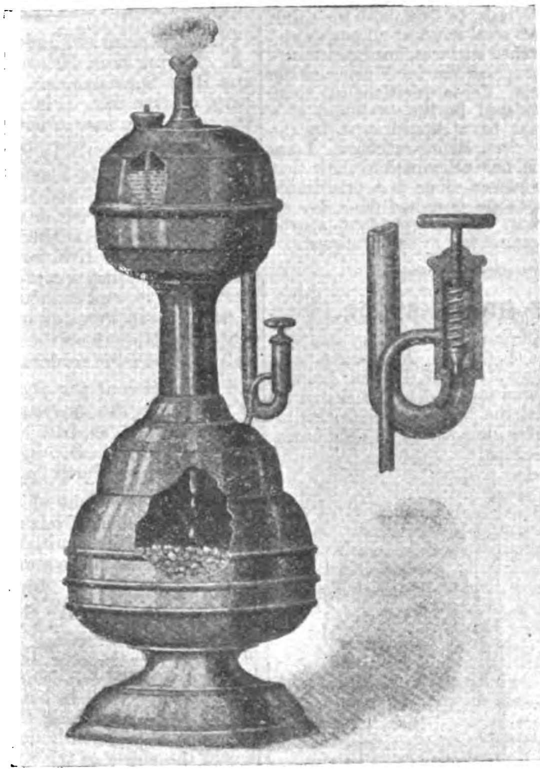
Thus we see that by keeping the original acetylene free from too much moisture, removing the ammonia, treating it with chloride of lime, diluted, if necessary, with some inert inorganic substance, and making it afterwards pass through a vessel of slaked lime, more of the impurities in the crude gas are extracted than if the Frank or the Ullmann process be adopted. The operation is said to be simpler for a non-chemical attendant; it is obviously far cheaper. The one disadvantage of the purified gas, its minute percentage of carbonic oxide, is far too trivial to be considered, and no fear need be felt that the half-spent material may become a source of anxiety by overheating, or the spent material a source of danger by actually catching fire.—*The Engineer.*

PREPARATION OF OIL COPAL VARNISH.

THIS is prepared by melting coarsely-crushed copal 240grm., purified oil of turpentine 260grm., readily-drying linseed-oil varnish 360grm. The copal is placed in a glazed earthen pot of sufficient size, and well moistened with oil of turpentine; the pot is then closed with a lid, placed on glowing coal, and left there about a quarter of an hour, until the copal is melted. When melting commences, stir with an iron rod until the copal has dissolved completely. Now add boiling hot linseed-oil varnish, slowly and with constant stirring, the coal fire being increased, so as to cause the mixture to bubble up a few more times, whereupon the pot is removed from the fire to cool off, and the warmed oil of turpentine kept in readiness is added.

The varnish produced in this manner is sifted through oakum into a dry, previously-warmed vessel. Before applying the varnish, the wooden articles are coated with weak glue-water (size) or with linseed-oil varnish, and when the ground has dried perfectly the varnish is put on uniformly with a good brush. As a rule, one coat of this varnish suffices; but if a second one becomes necessary, it should only be applied when the first one is completely dry. Later on the dry varnish is smoothed and rubbed down. The fusing of the copal may also be carried out in a glass flask surrounded with wirework. Hang the flask over a gas-flame, and keep it in constant motion until the copal has melted.—V. H. SOXHLET, in *Neueste Erfindungen und Erfahrungen.*

The Empire State Express was delayed one day recently, and in the successful endeavour to "get there" on time, the engineer made the splendid run of the 150 miles between Syracuse and Buffalo in 140 minutes. What this really means is best realised by engineers who handle fast trains daily.—*Locomotive Engineering*, N.Y.



PORTABLE ACETYLENE-GAS LAMP.

A NEW acetylene-gas lamp has been invented by Peter Josserand, of Josserand, Tex., which is particularly adapted for use as a table-lamp, and which is arranged to insure a uniform, perfect, and brilliant light, says the *Scientific American.*

The lamp comprises a base supporting a bowl forming a generator in which the calcium carbide is contained, and in which the gas is generated. A cap screws on the generator, and terminates in a pipe by which a water-reservoir is supported. A tube, provided at its upper end with a burner, extends through the reservoir, and serves to conduct the gas. Water is supplied from the reservoir to the generator below by means of a pipe provided with an automatic valve. As shown in our enlarged detail view, this valve has a downwardly extending stem fitting loosely in the end of the waterpipe, and an upwardly extending stem receiving the end of a rod screwed in a cap closing the valve-chamber. The screw-rod is provided with a collar engaged at its lower end by a spring coiled around the stem. A tube opening into the lower valve-chamber above the valve conducts the water to the generator.

When the screw-rod is screwed down, the valve is seated to cut off the water supply; but when the rod is screwed out until the collar abuts against the under side of the cap so as to allow the spring to hold the valve loosely to its seat, then the water rises in the valve-chamber, and flows drop by drop to the generator. When the gas pressure overbalances the water pressure, the valve is seated, thus preventing the further generation of gas. When the gas pressure has diminished, the valve is opened by the water, and generation is resumed.

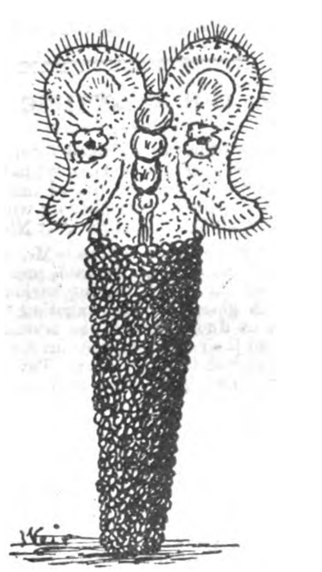
The supply of carbide can be replenished by unscrewing the generator cap, and placing the required quantity of the material within the bowl. The water reservoir can be filled by means of a filling cap.

HABIT OF AMUSEMENT IN ROTIFERS.*

WHEN a feeling of pleasure is experienced by an animal which is not aroused and incited by the gratification of an appetite, that feeling must be, necessarily, æsthetic in the abstract; yet many animals low in the scale of life experience such pleasure. This fact is plainly demonstrated by the habit of amusement which obtains in almost all genera and species, from the lowest to the highest throughout the entire animal kingdom. I have on several occasions seen ants when they were engaged in sports and pastimes. I once saw a spider which spun a broad silken ribbon which she used only as a pleasure resort; her hunting or trap web was some distance away. She would promenade up and down her shining roadway of glittering silk, for all the world like some ultra-fashionable dame, who, decked in a Parisian gown with which she hoped to dazzle the eyes of her less fortunate and envious sisters, "strutted her little hour" as only a well-dressed and complacent woman can. But not until I began to study the rotiferæ, did I discover the fact that animals of exceedingly low organisation likewise indulged in sports and pastimes.

This phase of animal intellection has been but little studied by observers; in fact, it seems to have been almost, if not wholly, neglected by students who have made the psychology of the lower animals the main object of their investigations.

There is a beautiful rotifer living in Tennessee river, which was listed by myself, and which I



named Melicerta Copeii, in the honour of my friend the late Prof. Cope, which shows plainly that it has moments of relaxation, during which it engages in sports and pastimes.

This almost microscopic animalcule builds little conical tubes in which it lies in wait for its prey, or into which it retreats when molested by an enemy. This melicerta lives close inshore in still and sheltered inlets or bays; therefore, its habits can easily be studied. It is so large that it can be seen as a small white object, the size of a pinpoint, with the naked eye, when it is swimming about in the water. It is a creature of much intelligence, comparatively speaking, inasmuch as it is able to find its way back to its home (the conical tube mentioned above) after an excursion abroad. This can be readily ascertained by watching one of these with a lens (x 15) when it leaves its tube on pleasure bent, for I am convinced that it never leaves home unless in search of pleasure.

Several of these little animals will meet in a still pool and immediately begin a game of "tag" or "hide-and-go-seek." One will playfully assault another, then presto! it is off in the twinkling of an eye, with the assaulted one in swift pursuit. Around and around the little pool they will circle so swiftly that the eye can scarcely follow them. Finally, the pursuer will overtake the pursued, which at once becomes the pursuer in turn and chases the other, which flies from it with all the speed it is capable of. This game of tag will be kept up from ten or fifteen minutes, then each little sportsman will seek its individual and particular home, which it enters tail first, and after protruding its cephalic or head extremity, will set its cilia in motion, thereby causing a current of water which sweeps food-particles (still smaller animalcules, microbes, bacteria, starch grains, &c., &c.), into its wide-open gullet. The sports of these rotifers are not incited by sexual promptings, for obvious reasons, neither have they anything to do with the satisfying of hunger; therefore, they must be play pure and simple.

The eyes of Melicerta, and it has two, are remarkably well developed for a creature of such low organisation. In point of fact, there is no other animal as low as this rotifer that can see as well. The eyes have both corneæ and retinæ, thus enabling them to form visual pictures of objects; they have vision. All other rotifers, as far as I know, as well as all kindred creatures, have primitive eyes—eyes which can only discriminate between light and darkness; they have sight, but not vision.

I have been able, in the case of the rotifer under discussion, to make out with a $\frac{1}{12}$in. objective, oil immersion, an arrangement of cells in the retina analogous to the "rods and cones" of the human retina! There is another creature, belonging, however, to an entirely different family, that is but little higher in the scale of animal life than Melicerta, which has eyes even more highly developed. I refer to Alciope, a marine worm.

This annelid's eyes have corneæ, lenses, and retinæ—the retinæ being composed of four layers—the rods and cones, the pigment layer, the granular layer, and the fibrous layer. In the case of Melicerta, however, the eyes may be safely considered unique and very wonderful. When playing "tag," this minute animal is directed in the pursuit of its fleeing playmate by sight, and not by another and analogous sense.

Again, while at play, one of these little creatures will hide behind a small pebble or bit of alga; when one of its playmates approaches, it will suddenly dart out upon the unsuspecting passer-by and greatly startle it. Their actions are so evidently innocent sport that the most casual and obtuse observer cannot mistake them for anything else. When we take into consideration the fact that this animalcule is almost microscopic in size, and that it is of very low organisation, this habit of amusement seems very wonderful indeed.

* By James Weir, jun., M.D., in *Popular Science*, N.Y.

SAILING BIRDS ARE DEPENDENT ON WAVE-POWER.

By L. Hargrave.*

THERE are many birds frequenting the southern oceans beyond the limits of the S.E. trade winds that are not adapted for soaring, and yet they circle, glide, and swoop around without flapping their wings. These have been well called sailing birds; and it is one of their oft-repeated evolutions that shows me, and I hope you, that sailing flight is not at all incomprehensible.

I will first point out that the Tropics are the home of heavy short-winged birds, such as gannets, boobies, divers, and small gulls. These seldom make any attempt to glide, much less sail or soar. The only exceptions I know are the frigate bird, and the boatswain bird; these two soar at high altitudes for long distances on motionless wings

It is worthy of remark that large flocks of sailing birds accompany vessels running down their easting, and this gives no opportunity for observing whether sailing birds really can work to windward. This point can only be determined from on board a steamer going westward, and south of what, I believe, is the usual track from Australia to the Cape.

My own opinion is that sailing birds cannot make anything to windward except during the limited time that the sea is running in an opposite direction to the wind; and, as an argument, I call attention to the absence of sailing birds in the S.E. trades, and attribute the scarcity to their inability to get out of the trades by standing to the S.W. if they get too far to leeward.

The most ordinary conditions for observing sailing birds are when the wind and sea are both aft. The waves are probably overtaking the ship, and passing at about six knots. Large numbers of birds follow the vessel and make wide circuits on either side of the wake; their interest is centred on

* Read before the Royal Society of N.S. Wales, Sept. 6, 1899.

garbage, and their efforts are directed to keeping astern, their weight and area are such that they must keep moving through the air at a nearly uniform speed in order that they may be supported; this velocity I estimate at 40 miles per hour.

If you direct your attention to the position of a bird *with regard to the wave surface*, it will speedily be noticed to be nearly always on the rising side or face of the wave and moving *apparently* at right angles to the wave's course, but really diagonal to it.

The bird is going to leeward as fast as the wave is; and, if that speed is too great for its requirements it turns towards the crest, points one wing to the sky, and uses its velocity to shoot upwards high above the back of the wave, and then descends to the trough of the following wave, along the face of which it glides; the back of the wave is its peculiar aversion. Now, there has been no flapping, and the performance takes place with or without wind; all the bird requires is the wave.

As to the effect of the wave on the air, we will suppose the water to be quite flat and the air motionless, a heavy undulation comes on the scene, it has to pass, so it pushes the air up with its face, letting it fall again as its back glides onwards. The air on the face is slightly compressed, that on the back lowered in pressure, both operations taking power out of the wave, and eventually largely contributing to its extinction.

The closer the bird is to the surface of the water, the firmer and more inelastic is the uplift of the rising air. The bird appears to almost feel the surface with the tip of its weather wing.

The case I wish you to consider is that of a sea-wave, for example, 180ft. long and 10ft. high, travelling at 18 knots, or, say, 30ft. per second, under calm air. This wave will raise all the air as it passes 10ft., at the mean rate of 3¼ft. per second.

The rate will vary from zero in the trough, attaining its maximum velocity at half the wave height, or where the wave is steepest, and falling to zero at the crest. Let us suppose the maximum velocity of uplift of the air to be about 4ft. per second and the steepest part to be 10° slope.

Now, according to Prof. S. P. Langley, a plane surface 30in. by 4·8in., weighing 1·1lb. will glide on air, without losing its elevation, at a speed of 49·8ft. per second, if sloped 5°. That is, the plane pushes 4·33ft. of air vertically downwards whilst it is translated 49·8ft. in 1 sec.

The same effect with regard to the position of the plane at the end of its journey of one second's duration is produced if the plane be sloped 5° downwards, and the air through which it passes be pushed bodily upwards 4·33ft. in one second.

Now the air over our wave is being lifted about 4ft. per second; so if the 1·1lb. plane were launched with 5° downward slope in the same direction the wave is travelling, from 1ft. above the steepest part of the wave, it would overrun the wave, which has only a velocity of 30ft. per second. It would thus get out of the air that is being lifted, and shoot into the water in the trough. But if the aspect of the plane be changed so that it face 53° either to the right or left of the track of the wave, its position above the mean sea level, and situation on the wave slope, will be unaltered; and if the wave was of unlimited width, the plane would continue on its course till dashed ashore.

The plane is simply abstracting the power stored in the wave by a distant gale, and using it to counteract gravity. And if the work be continued long enough, or a multitude of planes be continually drawing on the reservoir of power, the wave must inevitably be flattened.

The velocity of 49·8ft. per second is sufficient to raise the plane to an elevation of 38ft. in 1½ seconds; if its course be changed from horizontal to vertical, it there comes to rest. And from a poise at this station the plane may swoop down, at great disadvantage if close to the back of the wave, at various slopes and directions till it cuts into the air that is being raised by the face of the following wave, which again enables it to resume its velocity.

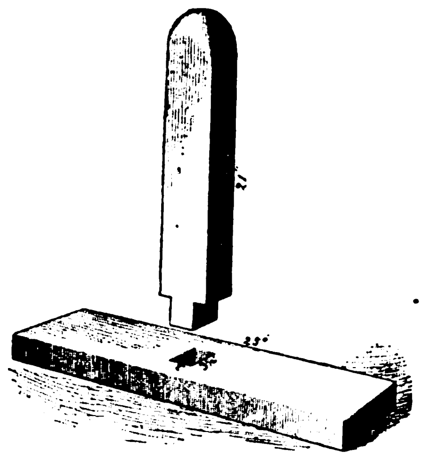
Observe that the wave I instance in this example, is one of the low round-topped sort that prevail in calm weather. If we were to base our calculations on a wave with a sharp crest approaching to the breaking dimensions, our plane would be travelling on its course through air having a velocity of uplift of 30 instead of 4·3 per second, if the wave slope were 45°, and would need loading approximately to $\frac{30}{4 \cdot 3} \times 1 \cdot 1 = 7$ 6lb. per square foot to keep it down to its original mean height, and could be made of seven gauge wrought iron.

If we figure out the result with 2° angle of incidence, and a horizontal velocity of 65·6ft. per second, we find that the 1·1lb. plane will be supported where the wave face is only 4½° slope, giving a velocity of uplift of 2·289ft. per second, and will make a course 62° 40′ to the right or left of that of the wave. Couple this with the fact that the head resistance of a sailing bird's form and the delicate arch of its wings are the survivals of untold numbers of cruder types, and no surprise should be felt at any intricate tactics pursued when further aided by the power derived from the wind and roughened sea.

This is the solution of the problem of a sailing bird's progression totally denuded of complications. It becomes a giant's task to compute the result when the effect of cross seas, wind at all angles and ever-varying force, arched surfaces, head resistance, ratio of weight to area, and the intelligence of the guiding power crop up. These questions all combined have been considered in the evolution of a sailing bird, and must be reckoned with by the designer of a wave-driven flying-machine. I am not aware that anyone has attempted to show that sailing flight by wave power alone is a practicable art; but even if someone else has done so, an observation free from an independent source confirming old work cannot fail to be of interest.

A HANDY HORSE STOOL.

THE foot-rest for a horse shown in the annexed engraving is sent to the *Blacksmith and Wheelwright* (N.Y.), by Mr. A. M. Talsma, Jamestown, Pennsylvania, who says:—I send a sketch of a horse stool that I rest the horse's front feet on to finish them up. It saves hard work, and the horse



likes to rest on it. It is made as follows:—Take a piece of plank 25in. long, 7in. or 8in. wide, 2in. thick. Mortise hole in the centre 3½in. by 2in. Then take a stick of 3½in. by 4in., 21in. long, make a tenon on one end 3½in. by 2in. rounding the other end for the horse's foot to stand on, and the stool is done.

USEFUL AND SCIENTIFIC NOTES.

THE first use of power obtained from the falls of Niagara was as long ago as 1725, when the French erected a sawmill near the site of the Pittsburgh Reduction Company's upper Niagara works, for the purpose of supplying lumber for Fort Niagara.

Crystals Etched on Glass.—Mr. C. E. Benham, of Colchester, has, it is said, produced some interesting effects by crystallising various salts in a thin layer on glass, and then exposing the glass to the vapour of fluoric acid. The crystals act as a "resist," and their microscopic forms are beautifully reproduced etched into the glass. The exposure to the vapour varies from three to five minutes, the glass being first well warmed to prevent the crystals from dissolving.

AN attempt made some time ago in Germany to convert coke-dust into briquettes, with a cement consisting of cellulose residue, did not succeed, because a prolonged drying in the open air was necessary for the briquettes to stand carriage; but in that case they crumbled in the fire, while they also burned so slowly that the furnace could not be kept at the desired temperature. For counteracting these disadvantages it was proposed to mix nitrate of soda with the cementing substance; but the only method which has hitherto been found to give good results is to use the dust itself as fuel, with one of the devices for feeding powdered fuel which have recently been introduced.

Copper Smelting.—In a paper read before the American Institute of Mining Engineers, the President, Mr. James Douglas, referred to the remarkable changes which have been effected within a few years in the methods of copper smelting. In place of small furnaces in which it was thought a feat to smelt 10 tons a day, some of the furnaces now in use will smelt as much as 400 to 500 tons of ore daily, and their contents being discharged into Bessemer converters, are converted into pure copper within as few minutes as formerly it occupied days to roast and re-roast, to fuse and re-fuse the ores and mattes when the cupola process of reduction was used.

SCIENTIFIC NEWS.

THREE more small planets are announced as having been discovered by Dr. Max Wolf and Herr Schwassmann, of Königstuhl, Heidelberg, on Oct. 27. It is not determined whether they are really new or not.

In the *Bulletin* de la Société Astronomique de France M. Camille Flammarion has an article in which he describes and illustrates the eclipses of the 20th century, which will be visible in Paris. Let us hope that the distinguished French astronomer will live to verify his drawings. There is the usual report of the meeting (séance) of the society, and then an article by M. Flammarion on the Perseids in 1899. A note by the Abbé Th. Moreux on the ninth satellite of Saturn will interest some readers.

The position of the Perth Observatory, W.A., is given by the government astronomer, Mr. W. E. Cooke, as Lat. 31° 57′ 09·63″ S., Long. 7h. 43m. 21·74s. E. Other observations gave the longitude of Perth 7h. 43m. 21·78s.

The first president of the newly-established Astronomical and Physical Society of America is Prof. Simon Newcomb, Assoc.R.A.S., and Prof. G. C. Comstock is the secretary.

The election of the officers and council of the Royal Society will take place at the anniversary meeting, St. Andrew's Day, Nov. 30. It is understood that Lord Rayleigh, F.R.S., Professor of Natural Philosophy in the Royal Institution, has been selected for the award of the Copley Gold Medal of the Royal Society—the highest scientific distinction, it may be said, that it is in the power of the Society to bestow. The medal is given in recognition of Lord Rayleigh's brilliant and, in many respects, unequalled investigations in mathematical and physical science.

The Christmas lectures at the Royal Institution will be delivered by Prof. Vernon Boys, F.R.S., on "Fluids in Motion and at Rest."

The "juvenile lectures" at the Society of Arts will be delivered on Jan. 3 and 10 by Mr. Herbert Jackson, on "The Phenomena of Phosphorescence."

A course of Cantor Lectures before the Society of Arts will be delivered by Mr. H. H. Cunynghame on "Art Enamelling upon Metals," commencing Nov. 20 at 8 p.m., and continuing on three following Monday evenings.

In his address as president of the Royal Geographical Society, Sir Clements Markham said that the Fellows would be glad to hear that the School of Geography at Oxford had been established, and was now in working order. It was regulated by a Joint Committee, consisting of four members of the University and three members of their council. A lecture-room and laboratory had been fitted up for it in the old Ashmolean Museum; there was an efficient staff under the direction of Mr. Mackinder, and the course of instruction had commenced this term. The subject catalogue was in an advanced state, and the work of the Nomenclature Committee was progressing. Dr. Mill's investigation of the geography of Southern Sussex, in connection with the Ordnance map, was practically completed, and they hoped to publish it soon as a sample of what might be done with the aid of the Ordnance maps in working out the detailed geography of our native land, and indicating the influence which it had exerted on the country's history, on distribution of population, on agricultural, industrial, and commercial development. The president has invited M. Gerlache, commander of the Belgian Antarctic Expedition, to visit this country and give an account of his voyage.

Prof. O. J. Lodge suggests a method of establishing telegraphic communication over short distances by laying a wire east and west, and "earthing" the two ends thoroughly, so as to get as long a base as possible. Insert in the wire a powerful battery or dynamo and a signalling key, and an alternative switch, a pair of low resistance telephones, and a condenser to keep out earth currents. Another party is to lay a wire of greater length than the other, and with similar arrangements, and then unless the soil is hopelessly dry slow signalling by earth-tapping can be certainly achieved provided sufficiently strong currents are used.

It is stated that a "severe shock of earth-

quake" was experienced at Leghorn on Friday last; but unfortunately these "earthquakes" are not recorded with sufficient accuracy to make them of any use in the study of seismology. If these "earth shakes" were properly recorded as to time and extent, they might be useful in formulating a theory as to the cause.

In a memoir presented to the Paris Academy of Sciences, M. Ed. Branly refers to the transmission of Hertzian waves through liquids. He placed a "receiver" in the centre of a large glass vessel containing the special liquid, and then made measurements of the distance to which the exciter could be removed before the effects upon the receiver were reduced to nothing. It appears that distilled water possesses much greater absorptive power than oil or air, and sea-water practically prevents the passage of the radiations through a thickness of 8in.

The University of Vermont has been presented with £10,000 by Mr. J. A. Converse, of the Baldwin Locomotive Works, for the endowment of a professorship of commerce and economics.

Vienna, somehow, seems to be the city from which the most extraordinary "inventions" come, whether they are scientific or political. Here is one:—"The Austrian War Office has ordered a series of experiments to be made on a flying-machine invented by an engineer named Joseph Manniger. Herr Manniger states that the machine can carry one man, and travel at a height of 1,000ft., in any weather, at a speed of 60 miles per hour. It can remain in the air for six hours, and can be steered in any direction, even against the wind. The apparatus is simple, and only costs £10. Herr Manniger points out how useful the invention would be to General White at Ladysmith."

The report of Col. A. Ford, Chief Inspector of Explosives, on the disastrous explosion of potassium chlorate at the Kurtz Chemical Works of the United Alkali Company (Limited), at St. Helens, when five persons lost their lives and a number of persons sustained injuries, was issued last week. Col. Ford states that so far as he had been able to ascertain, an "explosion" of potassium chlorate had hitherto been unknown in the United Kingdom or in any other country. Accordingly, experiments were carried out to further test the matter, with the result that it was found that potassium chlorate is, after all, liable to explode under certain conditions. In view of this result, adds Col. Ford, it cannot be doubted that an explosion of a small portion of chlorate actually took place at St. Helens. Having regard to the fact that potassium chlorate had hitherto been held to be not liable to explode under any conditions, Col. Ford does not think that any blame could be justly attached to the United Alkali Company or anyone connected with the works. He, however, has no doubt that they will now take the necessary precautions to prevent a recurrence of the disaster by adopting the use of non-inflammable materials.

Whether chlorate of potash can be exploded by itself is a question for experiment. It is well known that it is used in the heads of lucifer matches, and, mixed with sulphur, is a very old "exploding" experiment in the elementary text-books of chemistry. It is used for preparing friction fuses in firing cannon, and as "white gunpowder," in which it forms the principal ingredient, has been the cause of many accidents.

It is stated that the new naval gun known as the "12in. steel and wire gun," is "far superior to any gun possessed by a foreign navy," and if mounted on the heights of Dover, can drop a shell on the shores of France. It weighs 50 tons, is 41ft. long, and has a muzzle velocity of 2,367ft. per second. The projectile weighs 850lb., the bursting charge being 83lb., and the firing charge 167½lb. of cordite. The Admiralty has ordered 450, at a cost of £10,000 each. Of these 150 have been completed, and 300 are still in the hands of the contractors. Each man-of-war will carry four of these formidable weapons, and when the navy is supplied, they will be issued to forts on the sea-front.

The fourth annual motor-car trip to Brighton took place on Monday, and it is stated that 95 cars completed the journey, the time occupied varying from three hours to five. It is reported that a large percentage of breakdowns occurred on the road. According to the Motor-Car Club, any of the machines used could run to Brighton and back easily in a day.

The French submarine boat *Goubet* has, according to reports from Toulon, remained under water for five hours, and, although the boat was hermetically sealed, and was frequently covered by waves, the crew suffered "no ill effects." It would be interesting to have "reports" from the crew.

A new lighthouse has been erected on Eilean Mor, an island off the west coast of Lewis, about 18 miles from Gallon Head. Two flashes of white light will be shown in quick succession every half-minute, and the power will be equal to 140,000 standard candles. The light will be visible all round, and, being elevated about 330ft., will be visible about 24 nautical miles in clear weather.

The following will be of interest:—"Naturalists will hear with regret that the two climbing perch, or Indian climbing fish, at the Zoological Gardens, have both succumbed to the English climate. This loss will be deplored by the public, who watched their movements with wonderment, especially as they were the first examples of these curious creatures exhibited here for the past 20 years. The history of their tree-climbing propensities dates back (according to the *Telegraph*) for a thousand years or more; but up to now the only testimony upon which the story rests is that of Lieut. Daldorf, who, in a communication to the Linnean Society, towards the end of last century, declared that he had seen one of them ascend a palm-tree for the purpose, unquestionably, of obtaining moisture."

As to the poisonous effects produced when cattle eat yew-tree shoots, Dr. A. Rawlings, of Herne-street, near Canterbury, says that "There are numerous cases on record of death resulting not only in cattle, but in human beings, from eating the leaves and berries of this tree (*Taxus baccata*). It acts as a cerebro-spinal poison rather than an irritant poison. The most prominent symptoms are convulsions and coma. There are only two coniferous trees that grow in England that are poisonous, the yew and the savin (*Juniperus Sabina*). I believe, as a rule, animals carefully avoid eating from them, having a mysterious intuition of their deadly nature. In Herne Churchyard there are some very ancient yew trees, and here sheep and cattle are often turned out to graze, but I have never heard of any resulting evil effect. I have also noticed that in some of these trees birds frequently nest and rear their progeny; but the yew may not be poisonous to birds, as there is a peculiar natural fact that what may be poisonous to one species of animal may be innocuous to another. Thus parsley is a deadly poison to parrots; the rabbit, again, can live and flourish when fed wholly on the deadly nightshade (*Atropa belladonna*); the horse can be given arsenic and nitre far out of all proportion as to what one would think the dose should be when comparing his size with that of man."

A patent has been obtained in America for the manufacture of artificial marble, by means of which the expensive method of "polishing and graining the marble is entirely dispensed with." The method consists in mixing lime-water and silicate of soda, and then adding cement. The mixture is allowed to harden on a highly polished surface. As a patent has been granted in the United States, it must be presumed that nothing of the kind has been heard of before.

There are five coal-producing centres in the Transvaal—namely, Boksburg, Heidelberg, Middelburg, Lydenburg, and Klerksdorp. The three former are by far the most important, and contain between them twenty-four mines. The total production in tons last year was 1,907,808.

It is significant of the success of the Manchester Ship Canal that the company is about to promote a Bill in Parliament sanctioning the purchase of the Manchester racecourse at New Barnes, which immediately adjoins the Manchester docks. The racecourse covers an area of about 100 acres, and is needed principally for railway sidings, and warehouse and storage accommodation.

The leading dimensions of a type of heavy two-cylinder compound Consolidation engine in use on the Southern Pacific Railroad are: Cylinders, 23in. and 35in. diameter by 34in. stroke; weight in working order, 86 tons—77 tons on the drivers. Boiler, 72in. diameter; working pressure, 220lb.; tubes, 332 in number, and 2¼in. diameter, affording a heating surface of 2,817·30sq.ft.; fire-box heating surface, 210·50 sq.ft., and the grate area 35·3sq ft.; driving-wheels, 57in. diameter.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

**_* In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks; a vice from whence great inconveniences derive their original." —*Montaigne's Essays.*

PHOTOGRAPHING A "SPIRIT": THE TRUSTWORTHINESS OF SECOND-HAND TESTIMONY—A STAR CATALOGUE BY PROF. SAFFORD — A NEW NEBULA IN MONOCEROS: THE INFINITY OF SPACE — THE CONSTANT OF ABERRATION AND THE PARALLAX OF POLARIS — IS A PERAMBULATOR A CARRIAGE?—PHYSIOLOGY OF THE BRAIN—THE MOON AND THE WEATHER—A SIXTIETH LONDON SUMMER — SIDEREAL TIME INDICATOR — METRES AND LINKS—WORKS ON ARTILLERY —ORBITAL VELOCITY—PLACES OF THE PLANETS—DO HOMING PIGEONS FIND THEIR WAY BY THE SUN?—STONEHENGE.

[43015.]—"NEVER," says a trite adage, "believe anything you hear, and not more than half what you see"—an adage of the truth and common sense of which I have just had a very remarkable and impressive illustration. In a letter which I wrote (41461) on p. 92 of your LXVIIIth Volume, I told a very curious story of the apparition of the seated figure of a deceased peer in a photograph taken of his empty library after his death—a story which I subsequently supplemented by details given on pp. 138, 186, 233, &c. This narrative I reproduced, practically verbatim, as it was told me by a common friend of mine and of the family—himself a man of rank and title, whose veracity and bona fides are beyond all question or dispute, and who lent me the photographs on which I commented. Now, however, I have learned, within the last 24 hours, that the account I gave (as it was given to me) was erroneous in many very material respects, and that the evidence that there was anything supernatural, or "spiritual," about the affair, is nearly as shadowy as the figure itself. Let me correct some of my—or my informant's—mis-statements seriatim. *Imprimis*, I have it now that Lord *x* did not die at (what I will call) *x* Hall at all, but in London, *x* hall being let at the time to the sister, Lady *z*, of the actual photographer (whose name has since been made public, so that I have no reason for concealing it), Miss Corbet. Secondly, neither Mrs. *y* nor Lady *z* were at *x* Hall at the time. Thirdly, it was by accident, and not by design, that the photograph was taken on the day of the funeral. Fourthly, neither of Lord *x*'s daughters either took or developed the photograph. Fifthly—and most important this is—I was utterly misinformed as to the room having been closed during the exposure of the plate in the camera, for Miss Corbet states that "the door was left open all the time the photograph was being taken, the camera being placed in the open doorway, while she and her sister went out for a walk, apparently leaving the house empty, except for the servants." Now, this being so, I revert to what I said in letter 41667, on p. 233 of your LXVIIIth volume: "I am driven to the conclusion that someone *must* have sat in the chair for a very short time during the exposure of the plate." I gather from an independent source that my friend Mr. Espin's very interesting experiments on the production of a similar "ghost" by light reflected from a vase on a tall brass pole are to be the subject of further investigation. I need hardly reiterate here that I have not the very slightest faith in "spiritual" apparitions, and (as I have often said), broadly divide spiritualists into two categories — knaves (the so-called "media") and fools (their dupes); but, like all men of science, I hold my opinions more or less loosely, and regard "Audi alteram partem" as essentially *the* motto of everyone who wishes to arrive at the truth. Hence, when I received the story, just as I told it, from what I regarded as an absolutely unimpeachable source, I did not think that my own belief or disbelief ought to stand in the way of my making it public, however much it might conflict with my own utterances public and

private. But this only furnishes yet another instance of the fallibility of testimony, or perhaps of the inability of the average man or woman to repeat a story with anything approaching to verbal —or even material—accuracy. I have been struck with this in one way, amongst others, which might have acted as a caution to me. I sometimes do a little conjuring, and have been at once amazed and amused to hear certain of the spectators subsequently tell people what they had *seen* me do; so wildly wide of the truth have their perfectly ingenuous narratives been. However, I have, I hope, learned my lesson this time, and will trouble my brother-readers with no more stories of apparitions, be they of peers or potboys, because I could only really give such a story first-hand if I were myself qualifying for a lunatic asylum.

The United States Government has recently circulated a catalogue of 621 stars, prepared by Prof. Safford, as an excerpt from the Report of the United States and Mexican Boundary Commission, 1892-1895, which is noteworthy for the pains which appear to have been taken to determine the proper motions of its component stars with the greatest attainable accuracy. This should be valuable to all those engaged in geodesical operations.

The number of your contemporary *Knowledge* for the current month contains one of Dr. Isaac Roberts's astonishing photographs of what appears to be a hitherto unknown nebula in Monoceros; and well worthy of study it is. The extraordinary black gap or rift, which appears in this great gaseous mass irresistibly suggests that we are looking through a hole or tunnel in it into the blackness of darkness of illimitable space beyond it. Some of those who argue that space is finite contend that were it infinite the infinitely distant stars in their aggregation would cover the face of the sky with light, quietly ignoring the fact that they are postulating something like an equable distribution of stars in space, which is utterly contrary to all observable phenomena. That infinite space involves the assumption of its occupation by an infinite number of suns symmetrically arranged throughout it, is the wholly unwarranted and unwarrantable assumption on which such an hypothesis can alone be founded. A glance at Dr. Roberts's beautiful picture will show that in looking through the opening in the nebula which it reproduces we are, at any rate, gazing into vacuity.

I think that it may be said of the determinations of the constant of aberration what the author of "Ecclesiastes" asserted of the making of books—that "there is no end." The latest one I have come across is in the pages of the *Observatory* for November, whence I learn that a certain Herr Johannes Kuiesche, of the University of Göttingen, has, from a discussion of the Greenwich observations of the Right Ascension of Polaris from 1851 to 1888, determined the nutation constant to be $= 9{\cdot}236'' \pm 0{\cdot}003''$, and the constant of aberration to be $= 20{\cdot}537'' \pm 0{\cdot}003''$. This would make the earth's mean distance from the sun upwards of 97,000,000 miles, which it most certainly is *not*. Incidentally, Dr. Kuiesche finds the parallax of Polaris to be $0{\cdot}1518'' \pm {\cdot}0041''$, as against Peters's $0{\cdot}073''$ and Pritchard's (photographic) $0{\cdot}052''$. Kuiesche's parallax give the distance in light years as only 21·49. I wonder what Mr. Holmes would say to the *fourth* decimal place, by the bye.

Will "B. H." (reply 96759, p. 278), mind telling me when and where it was decided in the High Court of Justice that a perambulator is not a "carriage" within the meaning of 5 and 6 William IV. c. 50, s. 72? Moreover, can he refer me to any decision in the case of a Bath chair (which is only a glorified perambulator) either under that statute or the subsequently interpreting one 51 and 52 Vict. c. 41, s. 85?

The paragraph quoted in query 97005 on p. 282 is the veriest penny-a-lining. There can be no doubt that the function of the cerebellum is to coordinate voluntary movements. Disease of this portion of the brain causes a condition of giddiness, and a mode of movement strictly akin to that of a drunken man. I do not suppose that there is a physiologist, or physio-psychologist, in the empire of the smallest authority who doubts that the frontal lobes of the brain are those mainly concerned in the higher intellectual operations.

I freely make "A. B. M." (letter 42989, p. 291) a present of the somewhat enigmatic utterance of Prof. Hazen *re* the occurrence of thunderstorms near the time of new moon; and would once more refer him, as I have done others, to the Aphorism of Bacon, "Men are more apt to mark when they hit than when they miss." It would be worth while to note how often a *prophecy* of a thunderstorm about the time of that particular lunar phase was fulfilled in any selected place.

Has not the summer of 1899, during a *minimum* of sunspots, been hot and protracted enough for Mr. MacDowall (letter 42999, p. 295)?

I do not know for what purpose Mr. Bentley (query 97015, p. 303) requires a sidereal time indicator. If it be merely to know when to begin to look out for a star-transit, Chambers's device illustrated on p. 261 of the volume of which your correspondent speaks will be found quite sufficiently accurate. A more elaborate and accurate apparatus, the invention of the late Major Skelton, is sold by Horne and Thornthwaite, the opticians. Unless, though, he is afraid of a little trouble, I cannot see why Mr. Bentley cannot get all he wants from the *Nautical Almanac* by the aid of the tables on pp. 586 to 589 inclusive. As my own observatory is at some little distance from the house, I always myself have one of Cooper's excellent sidereal watches on my library table, at which I can glance to see the Right Ascension of the stars on the meridian at any given instant. The transit tables, which were brought out by Mr. Latimer Clark, have long ceased to be published. Mr. Clark took the idea from the table with which your own "Astronomical Notes" have concluded for very many years past.

I know of no cheap book on modern siege and field artillery such as "Second Differential" asks for in query 97026 on p. 303. My own copy of Owen's standard book is somewhat out of date. If he can see the "Encyclopædia Britannica" in any public—or private—library, he will find a quantity of information of the kind he desires. With reference to the second portion of the query, two things would be needed to answer it—old back numbers of the *Astronomische Nachrichten*, and a competent knowledge of technical German—neither of which I possess.

I may tell "Enquirer" (query 97022, p. 303) that there are 4·97106 links in a mètre, and hence there must be 24·71143 square links in one square mètre. Now to find the area of a triangle of which the three sides are given, we employ the formula probably familiar to your correspondent. Find the sum of the three sides, and halve this sum, which is called s. Next find the difference between this half-sum and each of the sides, and call their differences a, b, and c respectively. Then the area of our triangle will be—

$$= \sqrt{s\,(s-a)\,(s-b)\,(s-c)}.$$

In his case we had better first compute the area in links. Here we have—

$a = 1660$
$b = 1454$
$c = 1372$
2)4486
$s = 2243$

$s = 2243$ log. 3·3508293
$s - a = 583$ log. 2·7656686
$s - b = 789$ log. 2·8970770
$s - c = 871$ log. 2·9400812
Divide by 2 to get the log. of sq. root 2)11·9536561

24·71143 sq. links in 1 sq. mètre — 5·9768281 log. of sq. links; log. 1·3928978

38364·6 sq. mètres log. 4·5839303

the area of his hypothetical triangle. I hope that this is not an examination question. I have looked at it with some hesitation, but will give "Enquirer" the benefit of the doubt. But are not feet and inches good enough for any Englishman?

"Neptune" (query 97036, p. 303) will find everything he requires by the study of the *Nautical Almanac* for the 40 years covered by his question.

I have had a letter signed "Jeune Homme" from a gentleman whose acquaintance I have hitherto been debarred from the privilege of making, discussing the question of the means by which the homer pigeon finds its way back after having been liberated at a considerable distance from its home; and asking whether I think that the sun can in any way assist the bird in determining the direction in which it should fly? To which question I should certainly return a negative answer. As viewed from the surface of the earth, in the latitude of Greenwich, the sun travels over an azimuth of upwards of 260°, on the longest day between its rising and its setting, and hence it seems to me almost idle to imagine that a bird can derive any notion whatever of direction from a body whose position, as referred to the cardinal points, varies so enormously in 24 hours. I am not a pigeon fancier, and hence speak under correction, but it appears to me that if, as I assume, homer pigeons are being trained by being taken gradually farther and farther away from their dovecot, sight and memory must come in as the leading factors in the identification of a route once flown over, and they must go on picking up identifiable terrestrial points. I fancy that a good many birds must be lost in training for long-distance flying. Instinct —in any legitimate sense—can have nothing to do with the bird's power of finding its way back again. Nor can I believe in its possession of anything in the shape of a sixth sense. At any rate, I utterly disbelieve in its making the slightest use of any celestial body, such as the sun or moon, in finding its way.

I learn from a reprint from the weekly supplement to the *Leeds Mercury* that the venerable ex-President of the Leeds Astronomical Society, Mr. Washington Teasdale, F.R.A.S., has been delivering an address before that body on the origin of Stonehenge, and has been discussing various astronomical, or quasi-astronomical, theories in connection with this. Unfortunately, I have never seen Stonehenge myself, and hence am in no condition to judge of the accuracy with which the azimuth of the so-called "pointer stone" has been determined; but if the orientation of this has been accurately ascertained, and it was originally so placed at the time of its erection as to mark the precise point of sunrise at the Summer Solstice, it would be by no means a difficult task to compute the amount of shift, and hence to fix the date at which the wonderful structure of which it forms an integral part was set up. Prof. Petrie, as I gather, fixes this as possibly as early as A.D. 400; that very able mathematician, Mr. Whitmell, more definitely as A.D. 476.

A Fellow of the Royal Astronomical Society.

γ^2 ANDROMEDÆ—TO "A MEMBER OF THE BRITISH ASTRONOMICAL ASSOCIATION."

[43016.]—The closing sentences of letter 42991 are altogether uncalled for. There is not the slightest proof that "where 12in. Newtonians have failed Gregorian reflectors have been (said to be) able to divide," at least from any data within the reach of readers of the "E. M." only on this subject.

Although the apertures of these despised Gregorians is unmentioned in 42991, by reason no doubt that no possible aperture of such telescopes could ever match a 12in. Newtonian, presumably the 6½in. so inaccurately referred to by the Master himself in this department of criticism is meant. We have record in "Ours" of comparatively recent date of *only one* set of observations on the above-named star by the use of *a* Gregorian reflector; that one was of 6½in. aperture, and the epoch which was fully and candidly explained, as well as revealed by the comparative results from refractors of moderate apertures, was at a time when a 12in. Newtonian could scarcely have failed, even if made in the way amateurs are usually supplied with the article. (See correspondence in "Ours" from Oct. 7 down).

H.

CRATER NEAR TIMOCHARIS.

[43017.]—The sketch given by "R. P." seems to dispose of the suggestion of error in orientation.

Referring again to-day to Elger's Notes in the *Astronomical Register*, I found that at 6h. Nov. 15, 1885, he "remarked a large round black spot near the summit of the western wall, and a conspicuous oval-shaped depression slightly to the south of it, and somewhat further from the edge." This may form a clue to the crater 2 on "R. P.'s" sketch. To-night I could see no detail except the break in the north wall. E. D.

TO COLONEL E. E. MARKWICK: CONCERNING AN "AMATEUR'S OBSERVATORY."—TO "H." AND "F R A S."—THE COMES TO ALDEBARAN.

[43018.] — Having read, with great interest, Colonel E. E. Markwick's very useful and instructive description of his observing house in letter 42996, I should like to avail myself of his kind permission, and ask two questions of him which might be of general interest.

Firstly, does an observing house, as a fixture, become the landlord's property, though erected by the tenant, and, if so, by what means may the tenant reserve to himself the right of removal?

Secondly, seeing an ordinary chair in Colonel Markwick's Observatory, I should be glad to learn if he uses any means for preventing neck-ache, without recourse to an expensive observing chair.

May I take this opportunity of thanking "H." for his very amiable reference to some of my letters, and "F.R.A.S." for his kind reply, in letter 42928, to my query (96860)? I thought new measurements would be of general interest, as the *comes* to Aldebaran is mentioned in some of the textbooks as a light-test for a 3in. achromatic, while my experience with 3½in. Gregorians, which showed it distinctly with Aldebaran in the field, led me to think that this test might be misleading at the present epoch. C. H. Stielow.

METEORS.

[43019.]—Two very fine fireballs were seen here last night, Nov. 10. Unfortunately at the time I was walking along a brilliantly-lighted street, and the glare of arc-lamps, together with the light of the moon in her first quarter, made it impossible to locate the paths of the meteors with any approach to accuracy. The first was seen at 7h. 41m. G.M.T. Its path, as well as I could make out, started from $+4°$ north of δ Ceti, and ran nearly parallel to the S. horizon, passing about 4° south of ζ Aquarii and 8° or 9° above the moon. The meteor was brighter than Jupiter, pale green in colour, leaving a train which would have been very conspicuous but for the moonlight. Just before disappearing, it separated into two unequal parts, travelling about 30° distant

from each other in the line of its motion. It disappeared when about 10° N.W. of the moon, having remained in sight about five seconds.

At 8h. 6m. 30s. I saw another fireball, equal to Sirius in brightness, but red in colour. It travelled downwards from near β Pegasi to close above ο Ceti; motion very slow, some train visible, but difficult to see owing to moonlight.

Meteors of a smaller size have been abundant here during the past week. On the night of Nov. 6, between 6.30 and 7.30, I saw three above second mag., besides smaller ones, all appearing to proceed from a radiant low down in the N.E.

Wm. F. A. Ellison.

THE LEONIDS, ETC., 1899.—I.

[43020.]—WATCHES that have been kept on favourable occasions for early Leonids have, thus far, only yielded two as the result here.

The watches in question were on the following dates:—

1899, Nov. 8	10h. 55m. to 13h. 10m.	=	2h.	15m.
10	11 25 14 0	=	2	35
			4	50

The numbers of meteors seen were 22 and 13 respectively. These, with one seen on Nov. 6, are recorded in the annexed table.

No.	1899.	G.M.T.	From.	To.	Mag.	Dur.	Description.
		h. m.	° °	° °		s.	
1	Nov. 6	6 44	57½ + 50	66 + 29	2	—	Rather swift.
2	„ 8	10 58	60½ + 19½	67 + 15½	4	—	——
3	„ 8	11 2	57 + 24	55 + 5	3	0.3	Very swift.
4	„ 8	11 6	92 + 30	81½ + 28½	4	0·2	Very swift.
5	„ 8	11 6	87½ + 45	90 + 47½	3	0·2	Swift.
6	„ 8	11 7	49 + 49	67½ + 48	3	—	Very swift.
7	„ 8	11 17	63 + 27½	87 + 36	2	—	Slow; faint train.
8	„ 8	11 19	56½ + 22½	55 + 10	4	—	Very swift.
9	„ 8	11 23½	80 + 27	81½ + 25	4	—	——
10	„ 8	11 26½	72 + 45	135 + 60	1	—	Slow; faint train; pale green.
11	„ 8	11 33	72½ + 12½	89 + 3	1	—	Slow; hardly perceptible train; pale green.
12	„ 8	11 39	81 + 33½	81 + 22½	2	—	Swift.
13	„ 8	12 1½	68½ + 44½	115 + 64	3	—	Slow.
14	„ 8	12 23½	130 + 27	111 + 28	1·5	—	Swift; streak.
15	„ 8	12 30½	91½ + 15½	91 + 11	4	—	——
16	„ 8	12 33	85 + 27	135 + 19	2	—	Slow.
17	„ 8	12 35	18 + 63	135 + 59	4	—	Very swift.
18	„ 8	12 46	70 + 27½	100 + 32	1·5	—	Rather slow.
19	„ 8	12 48	81 + 29	83½ + 30	4	—	——
20	„ 8	12 52	89 + 37½	23½ + 59	4	—	Extremely swift.
21	„ 8	12 55	102 — 13	93½ — 20	2	—	Extremely swift.
22	„ 8	12 58½	110 + 51½	110 + 80	2	0·3	Swift; streak.
23	„ 8	13 4	91½ + 15½	71 + 9	2	—	Swift; streak.
24	„ 10	11 28	95 + 5	80 + 3	3	—	Very swift.
25	„ 10	11 44	120 + 46½	112½ + 37½	4	0·2	Very swift.
26	„ 10	11 53	105 + 28½	87 + 50	3	0·4	Swift.
27	„ 10	12 0	81 + 16	90 + 12	3	0·3	Swift.
28	„ 10	12 7	42½ + 49	5 + 74	1	—	Slow.
29	„ 10	12 20	108 + 29	94 + 21½	3	—	Very swift; streak.
30	„ 10	12 31½	115 + 18	107½ + 7½	2	—	Very swift; streak.
31	„ 10	12 45	102½ + 22	111½ + 30	4	—	Very swift.
32	„ 10	12 50	160 + 73	112½ + 61	4	0·2	Very swift.
33	„ 10	12 55½	109 + 20	108½ + 25	3	0·3	Swift; streak.
34	„ 10	13 12½	126½ + 47½	90 + 41	3	0·2	Extremely swift.
35	„ 10	13 27½	109 + 19½	115 + 32	3	0·3	Swift; streak.
36	„ 10	13 58	116 + 29	141½ + 27	4	0·2	Extremely swift.

Several bright Taurids (Nos. 2, 7, 10, 11, 13, 16, 18, and 28) have been observed. They were from a radiant at 52° + 22½°.

The Leonids were Nos. 14 and 23.

There was a remarkable scarcity of meteors from 13h. to 14h. on Nov. 10. Walter E. Besley.

Clapham Common, Nov. 13.

THE METEORS.

[43021.]—WRITING these lines before the meteors have made their appearance, I am possibly "putting my foot in it," as the saying is; but I cannot help noting that, owing probably to the paucity of news from the seat of war, some of the papers have furnished amusing matter over the "shower." In one London morning paper I saw the heading thus (I cut it from the paper):—"The Astronomer Royal Points Out How Amateurs May Add to the Sum of Knowledge by Individual Work." When I came to look, I found that it had nothing to do with the "Astronomer Royal," but is apparently a circular letter issued from the "Solar Physics Observatory," which it appears is at South Kensington. For all I know the information given may be something better than the Astronomer Royal could give; but why he should be credited with it I fail to understand, for his quarters at Greenwich cannot be called the "Solar Physics Observatory," and I do not believe he has issued the letter; but the fact remains that in a London paper the letter is attributed to the Astronomer Royal. In a London evening paper I find "It may be observed that the comets such as 'Biela's,' which are known to be intimately connected with meteor swarms, are telescopic objects and rarely visible to the unaided eye, and it may happen that though in past ages they have been sufficiently large and brilliant to create a panic amongst the ancient inhabitants of the globe, as many and many have done, that they are now rapidly approaching a period of decay and death, and that a meteor swarm is a comet's legacy to the celestial hosts.'[2] I am without any knowledge of what the "ancient inhabitants" of the globe thought, but I have an idea that if they expressed some of the opinions I have read in the papers they must have been rather unwise—to put it mildly. I wonder, with Mr. Crummles, "how these things get into the papers." B. Am. A.

IS THE UNIVERSE FINITE?

[43022.]—THE question raised by Mr. Burns in your columns (No. 42994) is one on which I have written many notes, the latest being in my "Introduction to Stellar Astronomy," recently published. Of course, in speculations of the kind we are only dealing with luminous stars. Generally speaking, an examination of the heavens throws no light on the existence or non-existence of dark bodies in space. We occasionally learn their existence by means of an eclipse or of the perturbed motion of a luminous star, but we can form no rational estimate of their numbers.

If the stars were uniformly distributed in space (uniform in brightness, mass, and distance), the total light of the stars of the $n + 1$th magnitude would always exceed the total light of those of the nth magnitude. The number would, in fact (if we adopt Pogson's scale), increase for each magnitude in the proportion of $10^{0.6}$, while the intensity of the light would diminish in the proportion $10^{0.4}$, the total light thus increasing in the proportion of $10^{0.2}$ or 1·585 for each magnitude until so many stars got in the way of each other that a large proportion of the total light would be lost by means of eclipses.

But, of course, the amount actually lost by eclipses will depend on the number of dark bodies as well as of luminous bodies in space. If the total amount of star-light increased with each magnitude, the uniform brightness of the sky would follow as a matter of course. The stars of the tenth magnitude taken collectively would give ten times as much light as those of the fifth, and so on. But even if we supposed the total light of the stars of each magnitude to be the same, then the total light of the stars up to the millionth magnitude would be one million times the total light of those of the first magnitude. Will anyone place the total starlight as high as this? But, if so, let us go on to the stars whose magnitude is a million of millions. Plainly, we must stop before this.

Of course, if the sun is a member of a cluster, a thinning out of the stars as we move away from the sun, or the earth, is easily explained; but as soon as we have once got clear of the cluster the foregoing considerations again come into play. Even the stars in the Galactic Circle can hardly extend to infinity, or else that circle would be much more luminous than it is.

An infinite universe of bright stars (even if on the average less luminous than the sun) transmitting their light to us with but slight loss is thus inconsistent with the actual condition of the sky. This, I think, I have proved long ago, and probably others did so before me; but I hope Mr. Burns's letters and articles may help to attract the attention of astronomers to a problem which has been too much neglected. W. H. S. Monck.

THE FINITE NUMBER OF STARS.

[43023.]—WHILST not professing to be well versed in astronomy, I yet venture to disagree with Mr. Burns's postulate in letter 42994, that were the number of stars infinite, the brilliancy of the starry sky would be comparable with that of the sun.

Does every orb throughout the universe emit undulations capable of exciting vision? Surely not. And if dark worlds exist in comparative proximity to the earth, can one justly assume that beyond the uttermost shining star there is not a multitude of others unincandescent, or whose light has not yet reached the earth?

But apart from this, there seems another objection to an hypothesis that the number of stars is finite. It causes one profound astonishment to reflect on the extreme sensitiveness of the eye to light when one thinks of the minuteness of the retinal surface exposed to an illuminant so many millions of miles distant as the nearest star. The amount of light received depending on the distance of a surface from its illuminant, of course the farther off the star, *cæteris paribus*, the less light the earth receives from it. But at a certain, though indefinable, distance, the light reaching us is insufficient for the eye to distinguish the star. The light received, however, may still be sufficiently powerful to disturb the molecules of a sensitive photographic plate if the exposure be sufficiently prolonged. I believe, indeed, that it is practically necessary to limit the exposure, owing to the number of stars which register themselves increasing with the time their light is allowed to act. If this be so, we may fairly assume infinity of stars until plates register a finite number, no matter how long the exposure. The reason why the midnight sky does not appear as brilliant as the sun is clearly that a large proportion of the light we receive is too faint to have any sensible effect on the retina during the time it is possible to continue gazing steadily at a particular portion of the sky.

If we conceived an eye so sensitive to light that a star, even of the first magnitude, could only be regarded with the same precautions now taken when studying the sun, a starry night would obviously be much more brilliant than noonday now is. But such an eye would find the glare of our present noonday absolutely intolerable. Hence it seems to me we cannot argue the number of stars finite from the comparative dimness of the midnight sky, for our eyesight is suited to present terrestrial conditions, and, so far as we know, to those conditions alone. J. Dormer.

THE NUMBER OF STARS NOT INFINITE.

[43024.]—To start with, I should say it is quite illogical for anyone to assert as a dogma that the number of stars is infinite. The most that can be said is that we can find no proof of any limit to the universe, and the natural presumption is that there is no limit. The difficulty is to define infinite without degenerating into mere meaningless verbiage. Imagine the *apparent* surface of the heavens to be an elastic envelope, and placed at such a distance from the earth that the visible stars would completely cover its surface—say x stars. Now increase the diameter of the hollow sphere, and it will now require $x + y$ stars to cover the surface. Make the diameter infinite, and $x + y$ becomes infinite. Now it appears to me that two equally valid and yet apparently irreconcilable conclusions may be stated as the outcome of the problem: (1) No matter how great the surface, it will always be covered by stars if their number be infinite. (2) No matter how great the number of stars, they can never cover the surface if it be infinite. The former is the premisses on which Mr. Burns bases his argument; but has it any better claim to rank as a logical conclusion than the latter? Mr. Burns's method of reasoning is interesting and ingenious; but I doubt hardly covers all the ground. What about the probable existence in space of non-luminous bodies, such as exist in our Solar System? Again, on what line of reasoning does he base his assumption that "the superficial brightness . . . is independent of the distance"? The brightness of any given star (excluding any intercepting medium and also atmospheric effect) will depend (*a*) upon the intensity of the light-waves, (*b*) on the number in unit area. The former will be determined by the intensity of the origin of the light, the latter undoubtedly by the distance; for though for practical purposes we may take the rays of light from a star as not differing sensibly

from the parallel, in considering such a problem as this, it must be borne in mind that they are not parallel. There is a limit to the sensibility of the human eye. Direct the eye to a blank point in the sky, now apply a telescope, and a star appears, because the glass of the instrument increases the number of rays falling upon unit area in the eye. Although Mr. Burns, therefore, proves conclusively that any straight line drawn through space will intersect a heavenly body if their number be infinite, it does not necessarily follow that that body will be visibly luminous to the human eye, even when assisted by optical instruments.

W. J. G. Forman, C.E.

THE NUMBER OF STARS NOT INFINITE.

[43025.]—In Mr. G. J. Burns's interesting communication (42994, p. 292), he says that he believes "the number of *fixed* stars is finite." Is it usual now to speak of "fixed" stars, seeing that they have both rotary and orbital motions? The conclusion arrived at by Mr. Burns is, to my mind, unanswerable, although perhaps some difference of opinion as to the steps by which he has reached it may exist. Is not number itself necessarily finite? Should we not distinguish between indefinite or unlimited increase as a process to which finite quantity may be subjected, and the attainment of such a condition? In other words, can we not conceive of constant additions to the existing number of celestial bodies at any period, however remote, without assuming the impossible postulate of an existing infinite number?

If infinity be attained, we cannot add to it, hence any condition which permits of increase implies finiteness. Further, whatever be the number of stars scattered throughout space, that number cannot be other than finite, for if the process of stellar formation be continuous, the alleged "infinite number" is capable of augmentation, which is absurd; while if the universe of stars be already completed as to number, it is necessarily finite. In other words, the popular phrase "infinite number" is incorrect and nebulous, being confused with the *condition of unlimited increase*, a state necessarily never reached.

West Norwood. Henry T. Burgess.

MOCK-SUN.

[43026.]—This phenomenon was seen here on Sunday, the 12th inst., at 1h. 45m. p.m.

It was nearly due south, and same altitude as the sun, and lasted fully 15 minutes. It looked like a short vertical rainbow, with colours not quite so pronounced, with an ill-defined brighter patch or knot in the centre, and concave to the true sun. David Booth.

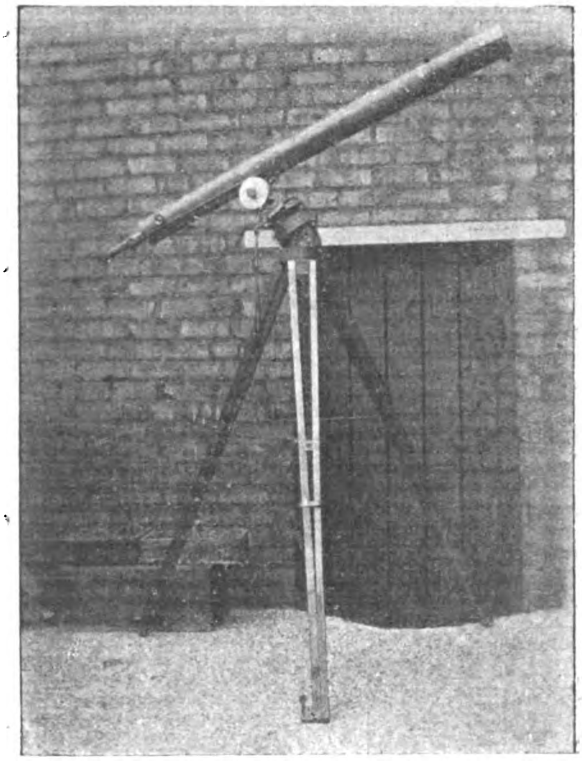
The Fall, Bramley, Leeds.

EQUATORIAL STAND FOR A FOUR-INCH OR FIVE-INCH REFRACTOR.

[43027.]—Having been asked by many correspondents to give a detailed account of the equatorial stand to which I have already referred in several letters to the "E. M.," I now proceed to do so to the best of my ability. Probably many readers who are better mechanics than I will be able to improve upon my plan. The problem, then, is:—Given an altazimuth mount (with or without slow motions) of the form usually adapted to a refractor of about 4in. to 5in. aperture, to convert the same into a steady and serviceable equatorial, to which divided circles can be fitted, if desired.

A glance through the catalogues of almost any of the leading opticians will show the kind of altazimuth referred to.

The legs of the tripod take the form of very long isosceles triangles, giving great rigidity. The sides of the triangle are bars of stout oak or mahogany, about 1in. by 1¼in. section. If I were making my stand over again, I should use thicker sides, say, 1¼in. by 1½in. section. If the legs of the original stand are of this form, it will save the trouble of making them, as they can be simply used again for the equatorial. However, my old stand, as I bought it, had legs made of each a single piece of hard wood, a very inferior plan, and sure to be unsteady. As this may be the case with other readers, and some may desire to buy the altazimuth head, and make the stand to mount it on, I give sketches of the legs of the tripod in Fig. 1, which should explain themselves. The block B is of oak, with 2in. square section. The mode of fitting it to the head will be given further on. The upper ends of the two sides of the leg are shod with sheet-brass to give strength and smooth working, and a bolt, *b b*, about 4½in. long by ¼in. thick is put through all, as shown, and can be tightened up as desired. It should have good wide washers to avoid crushing the wood. The little block *c* is useful as affording an attachment for the strut, as shown. It should be long enough to project about 1in. or 1½in. inside the leg. The manner of pivoting the strut to this projecting end is immaterial. In my case the strut



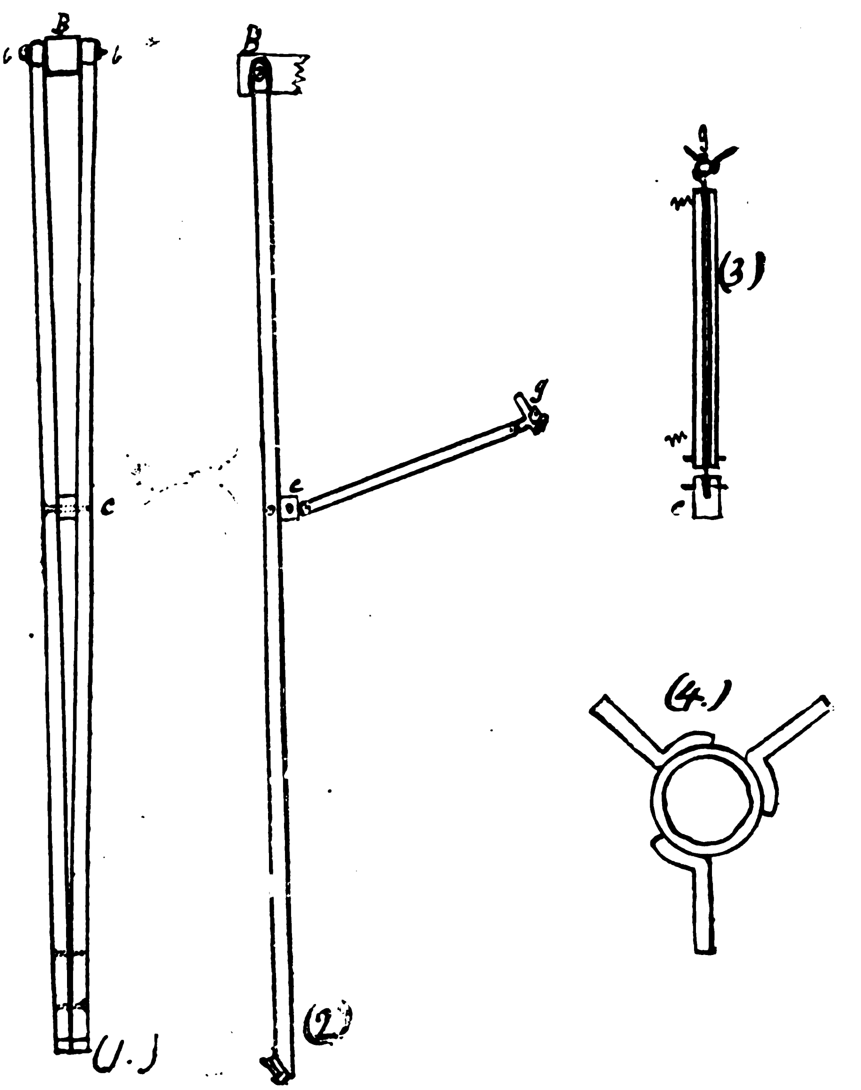


Fig. 1.

is made of two parallel pieces, with a piece of stout sheet-brass inserted between them at the end. This projects about 1in., and is inserted in a vertical saw-cut in the block *c*, and a stout screw put through from side to side.

Now comes the most important part—viz., the head of the stand. It is indispensable that this should be absolutely rigid. To this end we must have two thick discs of solid material. I got them made of oak 6½in. diam. and 2in. thick. One of these is to form the top of the stand to which the legs are rigidly bolted. Fig. 2 shows how this is

done. D D is the oak disc. B B B are three oak blocks, 2in. square section, and long enough to project about 1in. beyond the circumference of the disc when fitted, as shown. One end of each of these must be cut to an angle of exactly 120°. This can be done by plotting out the angle on stiff paper or card, either by the aid of a protractor, or by means of a geometrical construction. A little study of Euclid, Book I. Prop. 1, will show how it can be done. When the angle is

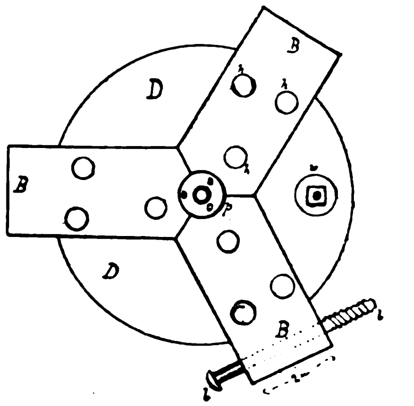

FIG. 2.

drawn, cut it out, and trace the outline on the wooden block to guide the saw. If correctly cut, the three blocks will fit each other exactly in the centre. They should be screwed to the disc with three very strong screws each. I used 2½in. screws, sinking the heads 1in. deep in the blocks by boring to that depth with a ⅝in. centre-bit. Thus 1½in. of each screw projects to grip in the disc. The holes for screws are shown at *h h h*, Fig. 2, which also shows one of the bolts to fasten the legs. The holes for this, both in the leg and in the block, should be bored with a shell-bit of the exact size of the bolt. This gives a very smooth hole, and a tight fit. At *p*, Fig. 2, is an important part of the apparatus. This is a small brass casting, known to gasfitters as a "ceiling-plate." It should be fastened exactly in the centre, attached to the blocks by three screws as shown. Into it screws the brass rod forming the "pillow," upon which the struts from the legs work; *w* is the nut and broad washer by which the adjustment for latitude is made, as will hereafter be described.

Having completed these fittings, and bolted the

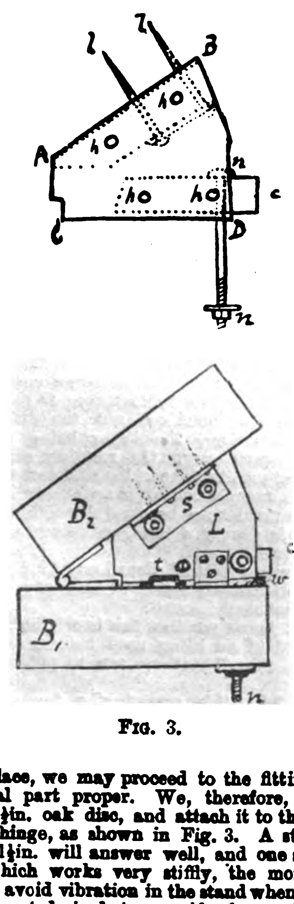

FIG. 3.

legs in place, we may proceed to the fitting of the equatorial part proper. We, therefore, take the second 6½in. oak disc, and attach it to the first by a strong hinge, as shown in Fig. 3. A steel hinge 3½in. by 1½in. will answer well, and one should be chosen which works very stiffly, the more so the better, to avoid vibration in the stand when finished. If it be not desired to provide for a change of latitude, all that is now necessary will be to get a strong wooden block, cut it to the necessary angle, and insert it between our two discs, bolting it securely to each. But to give a little variation in latitude we must complicate the arrangement somewhat.

The first step will be to cut out a pair of latitude blocks from a piece of 1in. oak plank (the harder and denser the better). Fig. 3 (*a*) shows the shape of one of these. The angle between the lines A B and C D should be a *little less* than the co-latitude of the place. The deficiency is made up by the wedges shown at *w*, Fig. 3 (*b*). We also require two connecting blocks of the shape shown by the dotted lines in Fig. 3 (*a*), and about 1½in. wide, cut from the same wood as the latitude blocks. These are placed as shown between the latitude blocks, and the holes *h h*, *h h*, bored through all while firmly held in the vice. To bore the holes use a ¾in. shell-bit, and see that they are bored accurately at right angles to the surface of the blocks. Have ready four 4in. bolts ¾in. thick, and two pieces of strong sheet brass (not less than 1/16in.) bent to a right angle, *s* Fig. 3 (*b*). These should measure about 3in. by 2½in. before bending, and holes should be drilled in the one flange of each to correspond to the holes *h h*, *h h*, and in the other five or six holes for 1in. screws to screw into the upper disc when all is in position (see *f f*, Fig. 4). Without removing the blocks from the vice, place the brass plates S in position, and drive the bolts through all and screw up tight. It is desirable that the upper connecting block have holes bored previously for the two 2½in. screws *l l*. These, with the screws through the

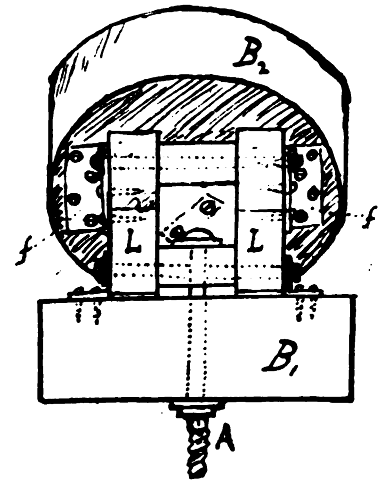

FIG. 4.

flange of the brass plate S, form its connection with the inclined disc B_2, and, of course, must be strong enough to be absolutely rigid. It will be well to place wide brass washers on the heads of the screws *l l*, or to pass them both through a little slip of stout sheet brass, as they then can be screwed home as hard as the brace can do it without damaging the wood.

The lower connecting block also must have a hole bored with the ⅝in. bit to receive the long bolt *n n*. This hole should be outside the hole *h*, as shown, but as near as possible to it without breaking into it. This bolt goes right through the disc B_1, and is provided with a strong nut and a very wide washer. (The nut and washer are seen at *w*, Fig. 2, and at *n*, Fig. 3, *b*, and A, Fig. 4.) The lower connecting block must project a little (*c*, Fig. 3, *a* and *b*) to give room for this bolt sufficiently near the edge of the disc B_1. To adjust for latitude, slacken the nut *n*, and insert or withdraw wedges at *w*, until the desired angle of inclination is obtained.

It only now remains to mount the altazimuth head upon the block B_2, and the arrangement is complete.

When describing the legs of the tripod, I omitted to give directions for the fitting of the struts (Fig. 1) upon the brass rod upon which they work. Into the "ceiling-plate" *p* (Fig. 2) we must screw a stout brass rod. A piece of ⅜in. or ½in. gaspipe will do. The lower end should be provided with a nut and a short piece of tube 2in. or 3in. long, just large enough to slide freely upon the rod. To this are attached three brass lugs, cut from stout sheet brass, bent to the shape shown, and soldered firmly to the tube. Fig. 1 (4). Each has a hole drilled in it, and, when in position, it is inserted between the two parallel pieces of the strut, and a screw put through from side to side. When the stand is folded up, the sliding tube carrying the inner ends of the three struts travels up the brass rod until the struts lie parallel to the rod.

It will materially add to the rigidity of the stand also to put a strong screw-eye into each side of each leg about half-way up, and connect these when the stand is open with three stout iron rods. Each rod is bent at one end into a ring, which hangs from the screw-eye, and at the other has about 1in. of its length turned down at right angles, to form a hook, which slips tightly over the opposite eye. When the stand is folded up, these rods hang down parallel to the legs; and it will conduce to neatness and portability to have a stout leather strap with buckle attached to one of the legs about 2ft. above its lower end, which can be buckled round the legs and iron rods when the stand is out of use. It is hardly necessary to describe the levelling screws. Any brass founder will make them for about 1s. each.

At *t*, Fig. 3 (*b*) is seen a small but most important article. It is one of Taylor, Taylor, and Hobson's circular spirit levels. One of those sold for use with a hand camera will do perfectly well. It only costs 1s., and occupies next to no space, being just 1in. in diameter.

To attach the metal parts to the block B_2, it may be necessary again to invoke the aid of the brass-founder, for three small castings; but as different makers differ in the design of this part of a stand, it is impossible to give directions which would be generally applicable. In the case of my stand, the brass attachments of the original legs a little modified, and with a few screw-holes drilled, answered the purpose.

The accompanying photograph shows the general effect of stand and telescope. The orientation of the legs of the tripod is a matter of some importance. If the hinge (Fig. 3 *b*) be mounted upon the disc B_1, immediately over one of the blocks B B B, Fig. 2, then the leg corresponding to this block will point due north when the stand is in the meridian. A small compass can then be mounted upon the strut corresponding to this leg, and will serve (with due correction for declination) to guide in placing the stand approximately in the meridian. A more accurate position can then be easily obtained by optical means, and when found rendered permanent by suitably marking the ground where the legs rest.

PROF. BONNEY ON THE AGE OF THE EARTH.

[43028.]—"E. L. G." (43001, p. 295) seems to forget that Prof. Bonney was not writing on comets, but the earth. No doubt the information he could give us on comets would be of a much more sound, reliable kind than that which "E. L. G." has treated us to lately. It is astounding to think that "comets, sun, and our satellite" are the only bodies that interest us at all. Where does the vast sidereal system come in, to say nothing of the rest of the Solar System.

If, by the statement "we have witnessed in the Andromeda nebula the birth of an earth," "E. L. G." is referring to the star which appeared in the said nebula in 1885, I think that has been satisfactorily disposed of by "F.R.A.S.," 42973, p. 274. I fail to see any connection between the Andromeda nebula, the birth of an earth, the destruction of Sodom, and Nov. 15. Why not make it Nov. 5? It is a much more suitable date!

Earlsfield, S.W. **Silverplume.**

REDUCING INTENSITY OF LIGHT—VEGA—"ASTRONOMY" (?) FOR AMATEURS.

[43029.]—LET me thank "H." for his letter (42997). Into the depths of mathematics, of course, I cannot follow him, nor can I touch the subject of curves for glasses when complicated by the conditions he introduces. It seems, however, as if my contention would be applicable enough in the case of a star, if not of the sun, or objects having a measurable disc; but this is hardly relevant, so we will let it alone. My plea was for a plane glass (if no better could be suggested) behind the eyepiece, and I still contend that for most purposes the disturbance of definition produced thereby would be immaterial.

"H." certainly did lead me to try a method which proved a thorough failure, for I should not have thought of trying a perforated stop (or "screen," if he likes it better) for stellar work, if he had not recommended it. But there is nothing like "try again," and I will try again at the next opportunity, using other kinds of screens than perforated zinc. That which I used in my former experiment was composed of a piece of ordinary perforated zinc, of about 80 holes per square inch, holes being 1/16in. in diameter.

Perhaps "H." would tell me what a poor fellow is to do who possesses no scientific equipment beyond his telescope and a love of the beauties of the heavens, and would like to do some useful work, however humble? Prebendary Webb had no better apparatus for the greater part of his life than I have, yet his work was more than mere "instrumentation."

As for my observation of Vega, either "H.'s"

copy of "Celestial Objects" is an old edition, or else he has not verified his references. Referring to the place, I find, a few lines after the words he quotes, the following:—"It" (the companion to Vega) "has been detected by Erck with $2\frac{1}{10}$in. of $7\frac{1}{2}$in. achr., glimpsed by Ward with $1\frac{6}{10}$in. of $4\frac{3}{10}$in. achr." After this, my seeing it with a $2\frac{3}{4}$in. is insignificant. Perhaps "H." could not see it with this aperture; but I have sight above the average. To me ε Lyræ has always been an easy naked-eye double, and I can count 16 or more stars in the Pleiades on a good clear night. The night of Oct. 11 last in Dublin was exceptionally clear, and the air steady. I was engaged in testing a $2\frac{3}{4}$in. Tulley, which a friend had recently bought, but he was dissatisfied with its performance. I soon found that it only needed adjusting, when its performance, both in light-grasp and definition was all that could be desired. Wm. F. A. Ellison.

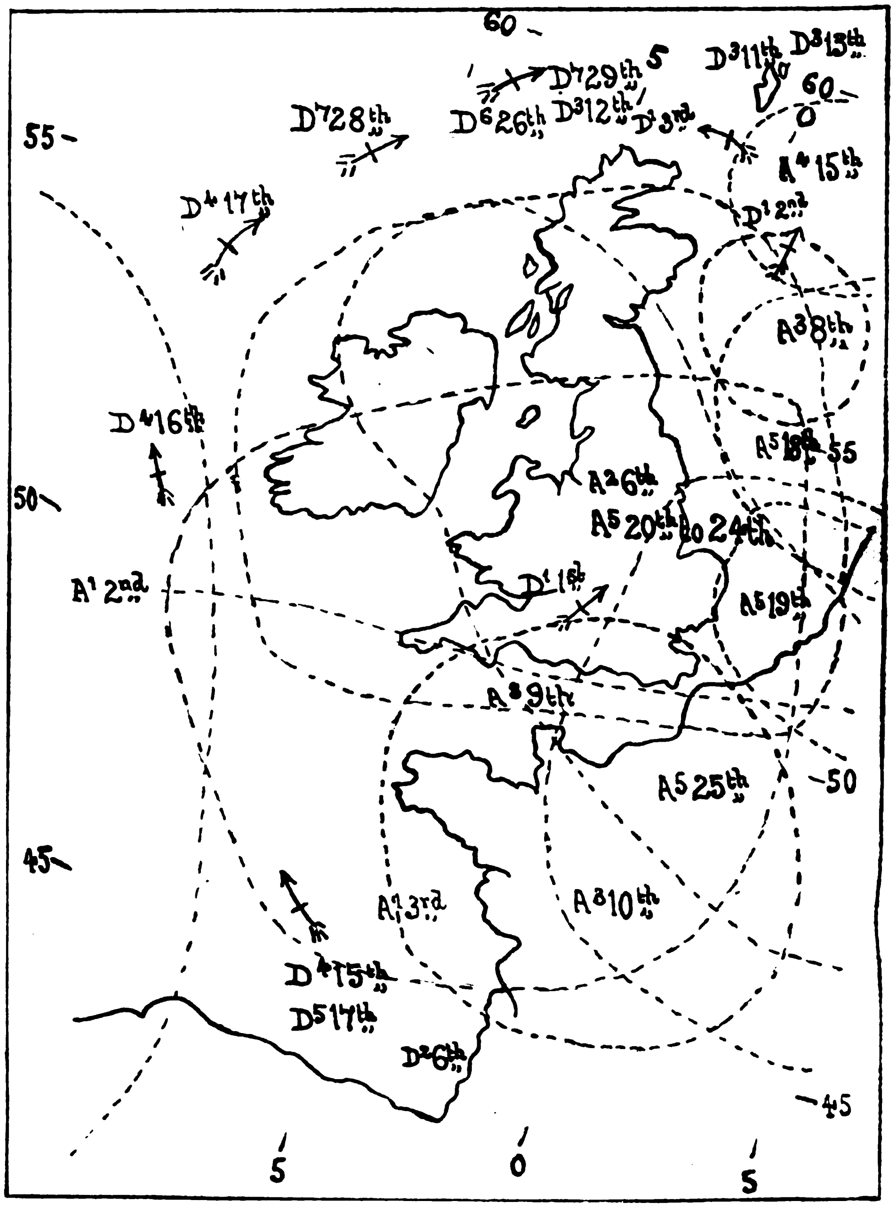
Monkwearmouth, Nov. 10.

THE WEATHER OF THE BRITISH ISLES IN OCTOBER.

[43030.]—

Date.	Cause.	Effect.
Oct. 1 to 3	Depression of considerable intensity passed directly across our islands, from S.W. to N.E.	Violent gale in the English Channel, accompanied by heavy thunderstorms. Much rain over the entire country.
2 to 5	Low-pressure system passing away to northward. Anticyclone moving in from the Atlantic.	Much quieter conditions generally. A fair amount of sunshine was recorded in the South of England.
6 to 12	Large well-marked anticyclone, almost stationary.	Very fine in the west, but foggy in the east; especially in the morning.
13, 14	Depression in the far North.	Rain in Scotland, but fair elsewhere.
15 to 18	Large high-pressure system lying over the Scandinavian Peninsula, Denmark, and the Baltic.	Very fine, clear, and warm in England, cloudy in Scotland, and also in Ireland.
19	Anticyclone reaches the eastern shores of the North Sea.	Weather fine everywhere, except in the extreme North of Scotland.
20 to 24	Anticyclone envelops our islands and remains stationary.	Fair; but much fog and mist generally throughout the country.
25 to 31	A series of depressions in the North. High pressure to the South-east.	Squally S.W. winds, heavy falls of rain, and very high temperatures for the time of year.

Meteor.



NATURAL HISTORY STORIES.

[43031.]—In spite of the space occupied by war news in the papers some extraordinary tales find their way into the journals. The sea-serpent is, I think by common consent, played out; but what about this robin redbreast? It appears that "last winter" a gentleman in Edinburgh had a somewhat remarkable experience with a robin, which during the cold weather "took refuge every evening in the lobby of his house after dark. The lobby contained a castor-oil plant, and upon this the robin perched himself as soon as it became dusk, getting access to the lobby by the open doorway. It mattered little to robin how many people were passing in or out. He remained all night on his perch in happy contentment, and as soon as the housemaid opened the door in the morning, he flew away with a chirp which might be interpreted as an expression of thanks for the night's entertainment. He returned on the following evening, again to rest on the plant, and kept up this programme during the whole winter, bidding farewell to his friends on the return of fine weather." It is not quite clear what is meant by "last winter," but presumably it is the winter of '98-99. The point is that robin has returned. It is announced that robin had almost been forgotten by his friends, "but he appears not to have forgotten them, for the other day he again put in an appearance, and commenced to roost as usual on the castor-oil plant, acting precisely in the same manner as he had done on previous occasions. Every evening he enters the open doorway and resumed his perch on the plant. When daylight arrives, and the door is opened, he flies away with his usual chirp, and returns again punctually in the evening. This will probably go on for the ensuing winter, as he appears to consider himself now a member of the household, with liberty to come and go at his own sweet pleasure." It is well known to naturalists that when robin wants "grub" he becomes a comparatively fearless bird, and will come even where the cheeky sparrow flies away when human beings appear; but the tale lacks the evidence of truth, because the horticulturist would want to know what sort of a plant is meant by "castor-oil." That a plant of Ricinus communis should survive the winter is almost as curious as the behaviour of the robin, for sceptics will want to know how a castor-oil plant managed to live through the winter. It is an annual, and dies off at the end of the year, never to come up again. Presumably some other plant is meant—possibly an Aralia. These little discrepancies throw doubt on these stories, which, well told, are nevertheless to be received with caution.

Here is another "natural-history story," which may be true, but which needs a little verification before it can be entered in the textbooks:—"The crew of the Stonehaven fishing-boat *Frigate Bird* are reported to have met with a curious marine monster while eight miles off the Kincardineshire coast last week. It was said to be black in colour, with a thin white stripe running to the tail. It came pretty close to the boat, and raised a long, slimy-looking arm out of the water till it towered 30ft. above the deck. The object remained in sight for five minutes." A fish, or "marine monster," with an arm 30ft. long must be a curiosity, and it is a pity it was not captured. Perhaps it was an undeveloped sea-serpent. Biela II.

AUTOMATIC BATTERY SWITCH.

[43032.]—I have recently been testing some high-speed steam and petrol engines, and as the location of the cause of a "knock" on small quick-revolving engines is always a matter of some difficulty and trouble, I devised a simple apparatus for rapidly ascertaining the loose brass, journal, or joint, and for allowing it to be very accurately adjusted. The success of the method was such as to save many hours of adjusting parts, and to produce almost total silence of running, even on a 5H.P. engine run up to 1,000 r.p.m. (explosive type).

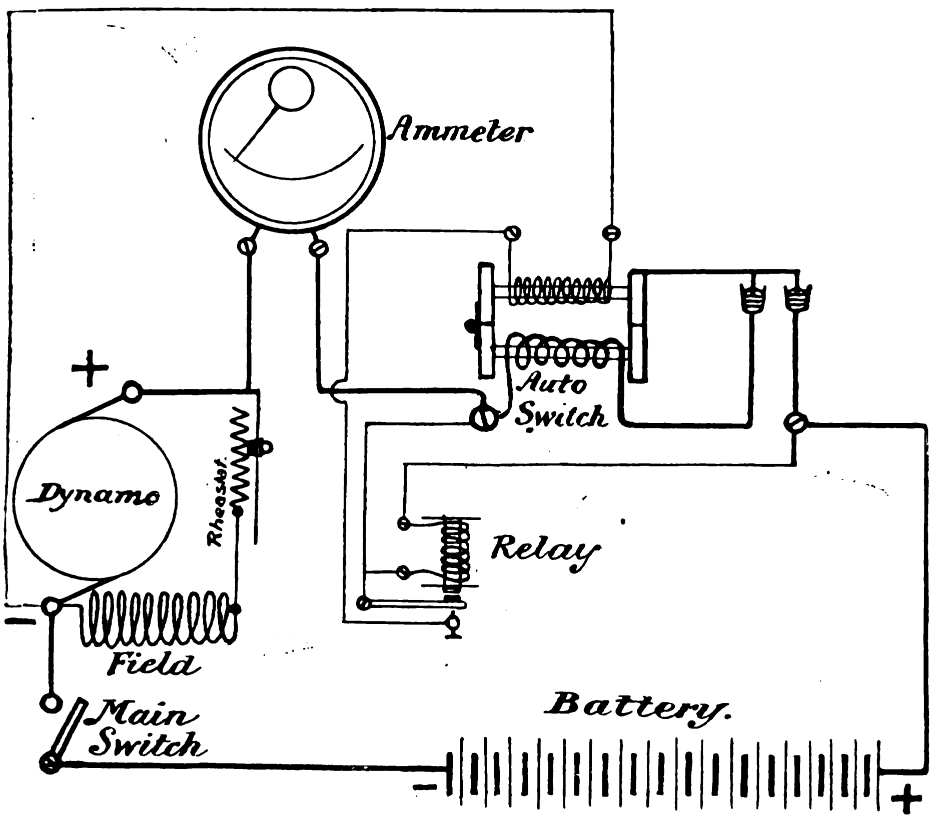
Let us suppose that an engine is erected and put under steam (or gas, or oil, &c.), and that a "knock" becomes audible. The culprit joint is *very* probably the "big end," and this will always knock unless most accurately adjusted. To test the joint, and gain perfection of adjustment, I attach a flexible wire—insulated—to, say, one of the crank-head nuts, or by other means connect it to connecting-rod. Fix a bit of springy brass or copper to bear against crank-shaft, but in such position that no keyway or projection passes spring when shaft rotates. A wire from spring is joined to a single dry or Leclanché cell, and the other wire to a telephone-receiver, the latter being joined to battery in usual way. On running engine and putting telephone to the ear, the slightest "knock" or looseness becomes audible as a violent "banging." The joint should then be carefully tightened until the sound is simply a loud, grinding noise. Oil should be used.

Every moving joint of almost any kind of engine or pump can be easily tested in this way, and very perfect adjustment insured.

I do not know whether this is original. I have never heard of its being used before, and if you consider it of sufficient use use to publish, please do so.

May I take this opportunity for making a remark *re* automatic accumulator switches? The usual kind consist of an electro-magnet wound with two coils: one a shunt-coil of high resistance, joined permanently across the dynamo terminals, and the other a series coil of thick wire, through which the charging-current passes. By means of springs or weights the switch can be set so that it cuts in when the voltage of dynamo reaches a certain value, and cuts out when, for any reason, the voltage of dynamo falls below that of battery.

Mr. Bottone's recent simplification of the type,



by substituting his dynamo-magnet for the shunt-coil, and a spring for the series coil, is a great step in advance; but even that leaves something to be desired. All these kind of switches have one failing. That is the knack of cutting in quite regardless of any abnormal variation from the usual battery voltage.

Suppose a switch is set to cut in at, say, 100 volts, and suppose the battery voltage, on this particular occasion, to have fallen to, say 85 volts for some unhappy reason. On the cutting in of switch an enormous current will pass for a few seconds, and I have known gas and oil engines to be pulled up dead by it, and often belts have been thrown off, and armatures strained.

I have lately been using a switch of this kind with a very ill-used battery, and had so much trouble from this cause that I tried the following dodge, and can most strongly recommend it to anyone who has a good auto. switch which he does not want to get rid of and to replace with one of the expensive trade-made variety. Break one of the connections (preferably the + one) from dynamo to shunt-coil of switch, and connect up to contacts of a high resistance (300 or 400 ohms) relay, so constructed as to *break* contact when magnets are excited, and to *make* contact when they are not. The relay magnets are connected between the + dynamo and + battery terminals, as is the auto. switch. A switch of ordinary pattern is put between – dynamo and – battery terminals, as shown in sketch.

To work the apparatus, proceed thus:—Close negative switch. This causes a current of very small volume to flow through relay magnets, dynamo armature, and back to battery. The arm of relay is instantly raised, *disconnecting shunt-coil* of auto. switch from dynamo. Run dynamo up to speed. As voltage increases *in correct direction for charging* it opposes the current through relay magnets more and more, until that current becomes zero at the moment when dynamo and battery voltages are *equal and opposite*. The arm falls, connects shunt-coil of auto. switch to dynamo, and auto. switch instantly connects battery to dynamo, the switching causing no current whatever to pass at the moment. Dynamo is then run up till required charging-current is attained.

Assuming that the auto. switch requires, say, a minimum voltage of 50 to close it, this method causes the switching-in to take place at *any* voltage above 50 (up to that prohibitive for switch-windings, owing to overheating); and the switching can *only* take place when the battery and dynamo voltages are exactly equal and opposite.

Ivon M. de Havilland.

LATHE MATTERS.

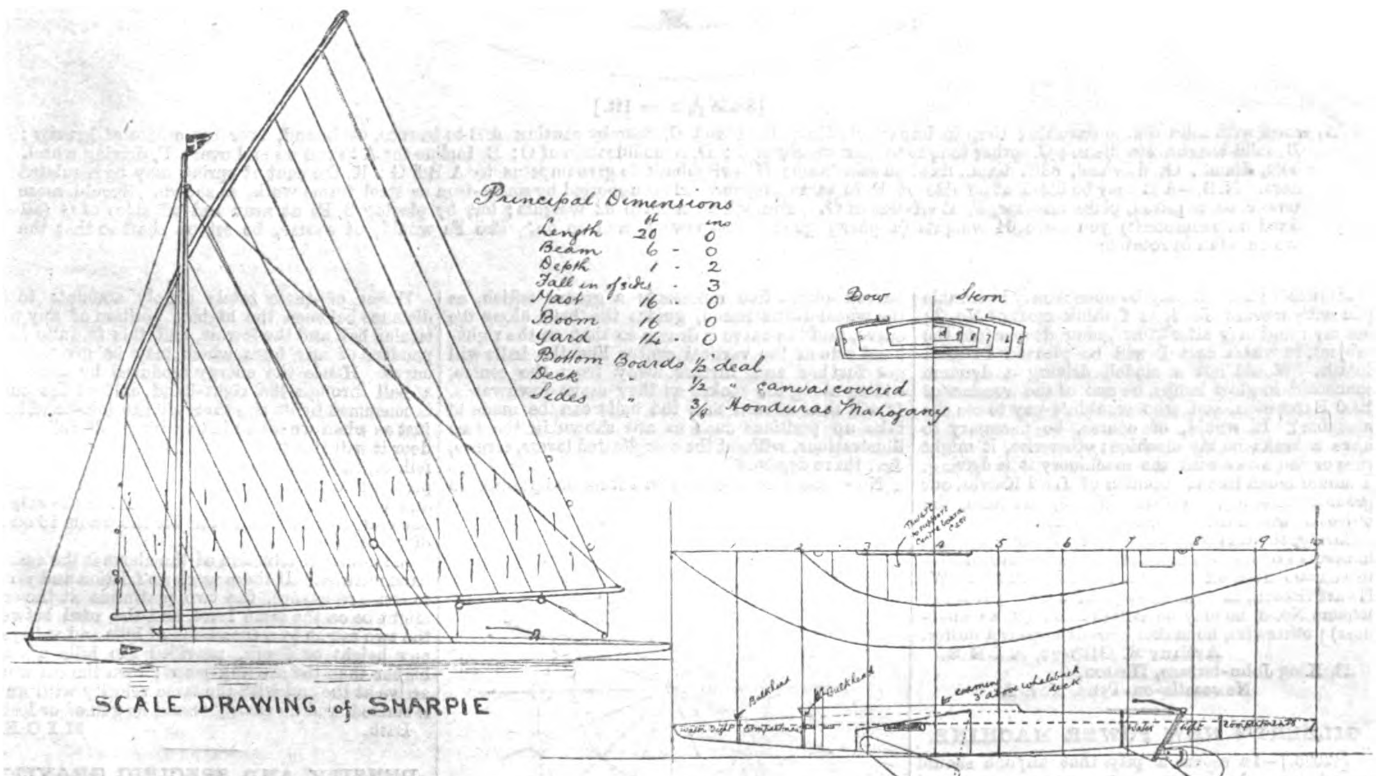
[43033.]—Having used a 4½in. back-geared, non-screw-cutting lathe for some years, I am thinking of supplanting it with a No. 16 screw-cutting lathe, 5in. centres, of the Britannia Co., but before doing so would like some kind reader of the "E.M." to tell me whether I should find the treadling of such a size to be heavy work? Would someone say if the above size is too large to be worked without tiring one's-self, and, if so, suggest a better? Of course, I should not be using it continually, nor is the rate of working any serious item. Also, I should like a sketch of some arrangement whereby one could sit down to the work, as, I believe, is done in some of the American lathes—Barness', for instance—though I have an idea that such an arrangement is only suited for small machines. Is this so? Lastly, having read in the "E.M." more than once that the Willis tool-holder is the best for general work, I should be pleased to have a rough description of it. Screw-Cutter.

BOAT FOR RIVER WORK.

[43034.]—Some weeks ago I put a query in these columns asking for the lines and dimensions of a sharpie 20ft. long, but received no reply. I have since made various inquiries, and as a result have plotted out the accompanying drawing, which is to scale. The principal dimensions are:—Length 20ft., beam 6ft., depth 1ft. 2in., fall-in of sides 3in., mast 16ft., yard 14ft., boom 16ft. Bottom boards and deck ½in. deal, the latter canvas covered. Side boards ¾in. Honduras mahogany. Sail area 160ft.

I may add that the boat is for up-river work only.

W. J. Shaw.

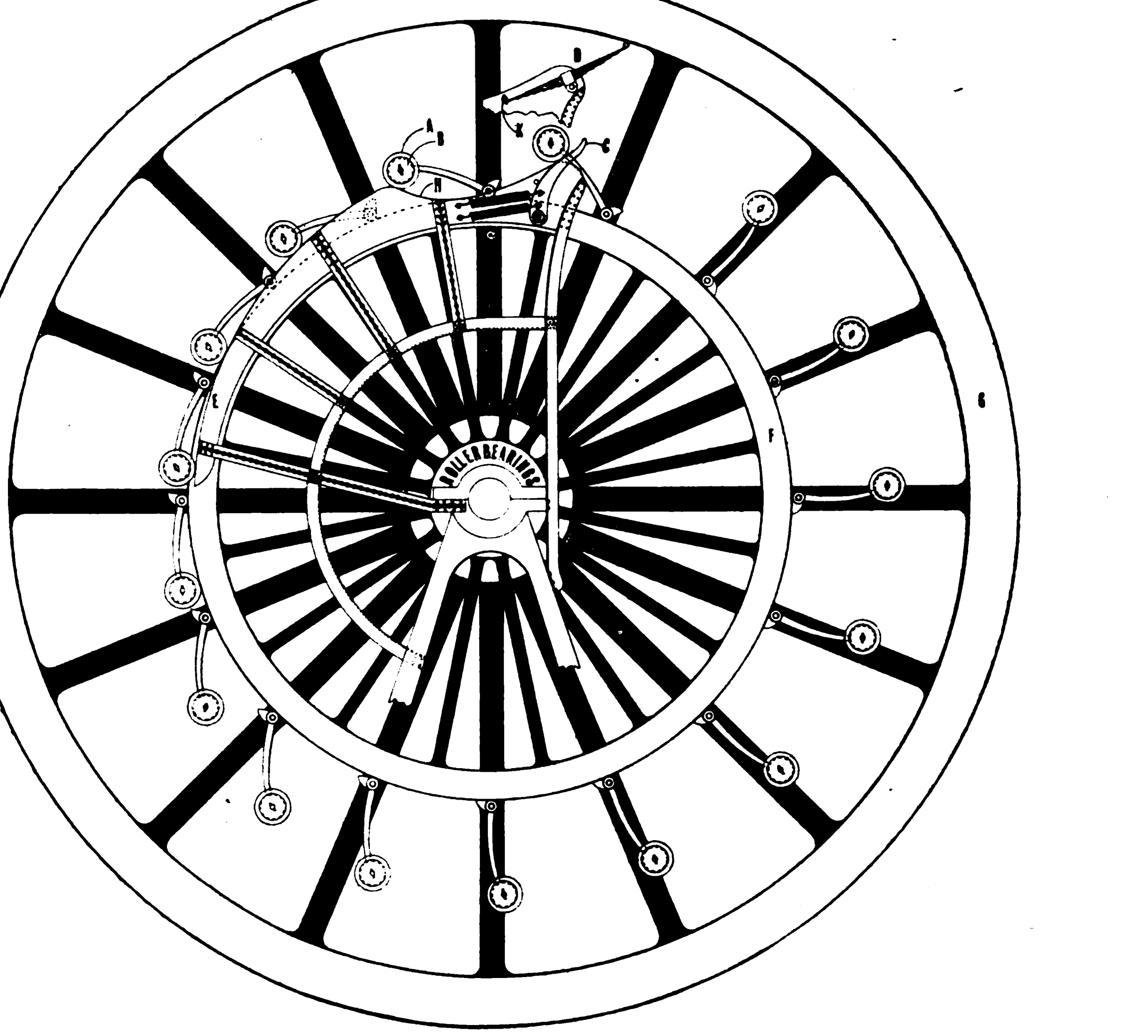


SCALE DRAWING of SHARPIE

GILBERT'S NEW POWER MACHINE.

[43035.]—I beg to forward block and particulars of my No. 3 machine, and to ask you to kindly

No. 3.



[Scale $\frac{1}{16}$in. = 1ft.]

A, wheel with solid 6in. indiarubber tire, to impart elasticity at H and C, thereby causing A B to bounce, or bound, over the centre of gravity; B, solid weight, 2ft. diam.; C, spring tongue to kick weight over; D, a modification of C; E, incline for A to run on and over; F, driving wheel, 50ft. diam.; G, flywheel, 88ft. diam., fixed on same axle; H, switchback to give impetus to A B F G; K, the cant of spring may be regulated here. N.B.—A E may be fitted at off side of F, in same manner. E is supported by angle-iron or steel frame work, as shown. Should more power be required, place another, F, at off-side of G. You will then have 32 weights; but by placing 2 Fs at near and off sides of G (all fixed on same shaft) you have 64 weights (a pretty good horse-power), and so on. The Fs would, of course, be set on shaft so that the weights fall in rotation.

reproduce same. It may be unnecessary to trouble you with scheme No. 4, as I think most of No. 3; but my mind may alter after going deeper into the subject, in which case I will be pleased to send details. Would not a model, driving a dynamo connected to glow lamps, be one of the wonders of 1900 Exposition, and who wouldn't pay to see the machine? It would, of course, be necessary to have a brake on my machine; otherwise, it might race or run away with the machinery it is driving. I should much like the opinion of Lord Kelvin, our greatest scientist, on this (No. 3) machine, the object of which is to dispense with fuel.

Surely, sir, it is less wonderful to cause a wheel to revolve by its own mechanical parts, than to hear speech 500 miles off *through a solid wire!* If W. Ewart Gibson, in your issue of 27th ult., will study scheme No. 3, he may be enlightened (if an engineer); otherwise, he makes himself appear a duffer.

Arthur E. Gilbert, A.I.E.E.

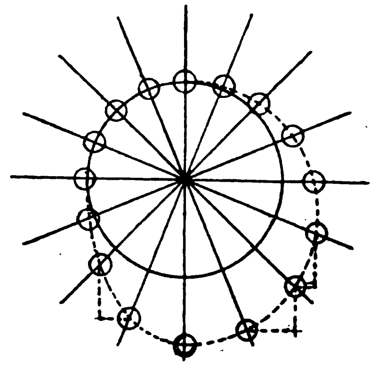
23, King John-terrace, Heaton,
Newcastle-on-Tyne, Nov. 2.

GILBERT'S NEW POWER MACHINE.

[43036.]—It seems a pity that anyone should spend his time in trying to produce perpetual motion; it has been proved over and over again that it is impossible. The two large illustrations on p. 210 are founded on the old idea that, if by any combination of levers, &c., you can remove certain weights on the rim of a wheel to a greater distance from the centre, *during the descent of the weights*, perpetual motion must be the result, owing to the greater leverage exerted by the weights.

In my diagram, the spokes of the wheel are supposed to be continued beyond the rim, the weights, or balls as I have drawn them, have holes through which the spokes pass, the balls sliding without friction along the spoke. In addition to this, the curved dotted line represents a groove which, as the wheel turns round, guides the balls along the curve, and the curve is drawn so that on the right-hand side of the vertical centre line the balls will get further and further away from the centre, sliding along the spokes as they move downwards. It will thus be seen that the balls can be made to take up positions such as are shown in the two illustrations, without the complicated levers, screws, &c., there depicted.

Now, the motion of any ball from one position to



the next may be resolved into components, a vertical and horizontal: these would appear as steps on the diagram. I have drawn a few, and if these steps were drawn all round, it would be seen that, although all the steps differ from each other, yet the total of all the *vertical* elements of the steps on one side of the centre line is equal to the same total on the other.

Either of these totals simply amounts to the distance between the highest position of any particular ball and the lowest, and this is quite independent of any form which may be given to the curve. Hence the energy produced by the fall of a ball through the right-hand half of the curve is consumed by its rise through the left-hand half, just as when we let an indiarubber ball fall on the floor it will rise to the same height from which it fell, or, rather, it would do so if the elasticity were perfect; so that the energy resulting from the fall and rise is nothing at all. If this is the case for one ball, it must be the same for the whole 16 on the diagram.

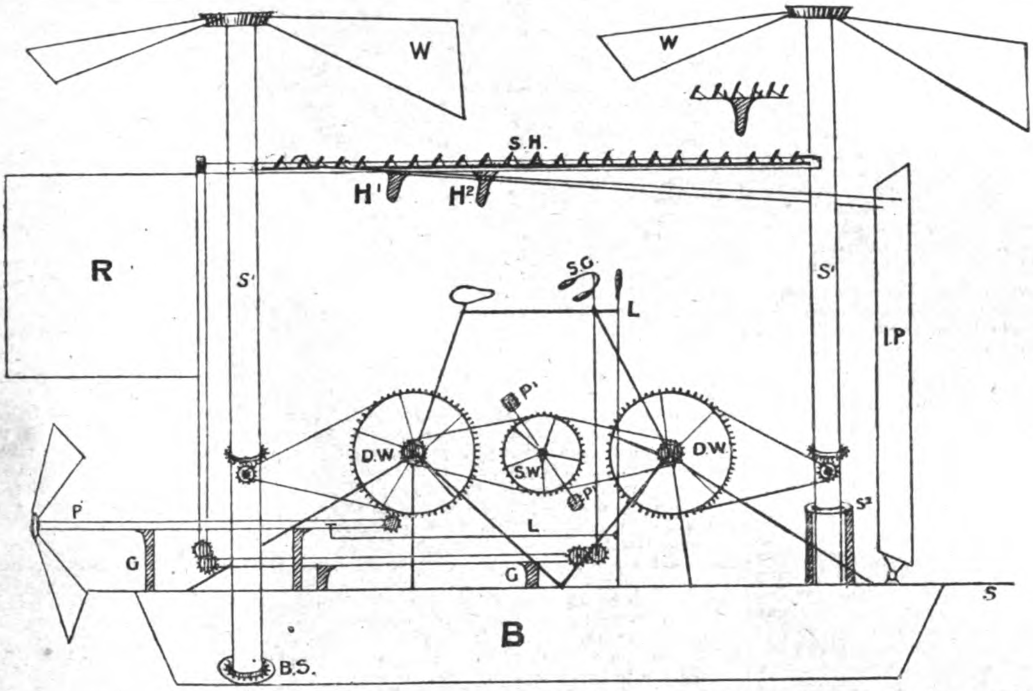
A familiar illustration of the above is the switchback railway. If there were no friction and no air to cause resistance, the two platforms at the ends might be on the same level, and the road between the two might be a succession of hills and valleys of any height or depth, provided the hills are not higher than the starting-point; then the car would arrive at the end with the same velocity with which it started, and no energy would be gained or lost.

Bath. M.I.C.E.

DENSITY AND SPECIFIC GRAVITY.

[43037.]—I am puzzled over the terms "density" and "specific gravity." By the latter term I understand the weight of a body compared with an equal volume (in case of liquids and solids) of water at 4° C. (gases) of hydrogen under similar conditions of temperature and pressure.

So far, so good; but I read in another textbook that "the specific gravity of a gas is its weight compared with an equal volume of air; the density of a gas is its weight compared with an equal volume of hydrogen." Now, the use of these terms seem to me loose and inexact. Both terms refer to the same quality or property, but using



B, body; B S, bottom of shaft; D W, driving-wheels; G, grooves for propeller and rudder shafts; G W, gear-wheels; H, hinges; H^1, handle for stays; H^2, handle for stay-holds; I P, inclinable plane; P, propeller; P^1, pedals; R, rudder; S, stays; S^1, shafts; S^2, socket for shafts; S G, steering gear; S H, stay-holds; W, wings or helices, each one at an angle of about 40°. I should have the body, wing and propeller blades, rudder, and inclined plane of aluminium; but all the other parts of steel, and it should not weigh more than 60lb., in my opinion.

different standards of comparison. Further, of the two terms "specific gravity" seems to be the most natural, since the property of weight is derivable from the action of gravitation.

Again, taking the term "density" in its common meaning—i.e., degree of closeness, I get a seeming contradiction of Avogadro's law. This law proposes that equal volumes of gases (similar temperature and pressure being assumed) contain the same number of molecules. Well, since "density" means the degree of closeness with which these molecules are packed, then all gases will be of the *same density*.

Thus, supposing we have a quart of each of the following gases—hydrogen, hydrochloric acid, carbon dioxide, and ammonia. Each measure contains, say, a million molecules. Then, since the molecules are equally closely packed, the densities of the four gases are the same. Their specific gravities are, of course, in the proportion 2, 36½, 44, 17, or, 1, 18¼, 22, 8½.

Again, with regard to molecule weights. Are these taken as the sum of the atomic weights, or half this quantity? That is to say, do we regard hydrogen as 2 or 1? Of course, the *proportion* is unaltered; but the actual number is. Hence, are the molecular weights of hydrogen and carbon dioxide 2 and 44, or 1 and 22? Will "Sigma" or other scientist kindly help? **Technicus.**

FLYING MACHINE.

[43038.]—Will you kindly publish this sketch of a flying machine in your paper, as I would like the opinion of some of your correspondents on it? **Roderick D. Hall.**

457, Rooley-lane, Bradford, Yorks.

A SIMPLE WATER-MOTOR.

[43039.]—Mr. Foreman's motor is practically the same as Bailey's "Thirlmere," and many others; but their consumption of water is considerable and power small. Water to work them would have to be paid for by meter, according to the usual conditions of supply; and at, say, only 1s. per thousand gallons the cost would soon mount up to pounds. I do not consider wood is a suitable material for any part of such a machine. **A. S. L.**

JIG FOR PLANING CLUTCH.

[43040.]—The following note on a method of making a jig for planing clutch is by Mr. Ned Wilson, writing to the *American Machinist*, and I think it may be useful to your readers. Mr. Wilson says:—

It looks queer in these times to see a man trying to make duplicate parts without jigs. I have a vivid recollection of a job of this kind which I had to do in a traction-engine shop. The engine was thrown in gear with drivers by means of the old-fashioned three-tooth clutch. The job was the planing up of about twenty of these clutches for stock. The foreman gave me a sort of an excuse of a jig, which, although it helped to hold the job, was absolutely useless for accurately spacing the teeth. The job is shown at Fig. 1, and the jig at Fig. 2. The work was to be planed by means of a side tool on the line *a b*, Fig. 1. The way I was compelled to do it was to first fasten Fig. 2 to the planer by means of a couple of bolts in the notches. Then I had to put the work on the boss *c*, and clamp it to the planer. After one face had been planed, the work was unclamped and turned about on the boss *c*. Then by a cut-and-try method the next cut was started so as to make it correspond to the sheet-iron templet, Fig. 3. The clutches made by this method nearly always had one tooth slightly larger than the rest. Consequently, the clutch

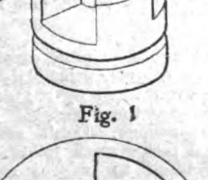


Fig. 1

Fig. 2

Fig. 3

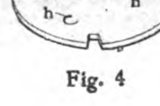

Fig. 4

drove with only one tooth. I asked the boss to let me make another part of the jig similar to Fig. 2, but larger. This part, shown at Fig. 4, was to be clamped to the planer bed and a hole drilled in Fig. 3 to fit snugly over the boss *d*. Three holes *h h h* were to be drilled in Fig. 4, 120 degrees apart, and a similar hole in Fig. 2 at *i*. The holes were then to be reamed to fit a taper pin. The work could then be clamped to the piece Fig. 2, and after the first face had been planed, it could be rotated and the pin inserted in the next hole. Such a jig would have shortened the time necessary to finish the job, and at the same time have made all the clutches alike. But the boss wouldn't listen to my scheme. He had always planed the tooth faces with the old jig, and he guessed it would do. It is needless to say that that boss got no more suggestions from me.

The jig question is a study of itself. The jig is as important a factor in a shop turning out new work as is the milling machine. I always proceed on the assumption that there is no job for which some kind of a jig cannot be devised. There are lots of jobs which necessitate a good bit of thinking before reasonably reliable jigs can be designed for them; but perseverance in the right direction will overcome the obstacle at last.

I send this mainly to wake up your readers, many of whom can give better hints than the above.

Springfield, Ohio. **C. P.**

USEFUL AND SCIENTIFIC NOTES.

The mileage run by trains on the London and North-Western Railway last year was 47,548,652.

With electric energy at 3d. per unit, it is calculated that an electric lift of the direct-coupled high-speed type can be operated on average duties in a block of offices, making, say, one hundred trips per day, and having a maximum carrying capacity of five persons, for a cost of 6d. per day, or 4d. per day if electricity is 2d. per unit.

According to a return recently issued with regard to flax culture in this country, the acreage has fallen off from 895 acres in 1898 to 465 acres this year. Lincolnshire has dropped from 109 to 20 acres, and Norfolk from 10 to 5 acres. Even the East Riding, the largest flax-growing country, has reduced its area from 258 acres in 1898 to 106 acres now.

The principal mining counties in the kingdom, whether judged by the mineral produced or number of persons employed are:—Durham, with an output of 34,737,347 tons of coal; Yorkshire, with 25,639,021 tons of coal, and 5,785,588 tons of iron ore; Lancashire, with 25,324,685 tons of coal, and 749,427 tons of iron ore; and Glamorganshire, which yielded no less than 19,140,742 tons of coal in spite of a strike lasting five months. The above figures are the official returns for 1898.

Instinct in Birds.—Dr. W. T. Greene, writing in the November number of the *Pall Mall Magazine*, remarks that within the last few years thrushes belonging to several species, and blackbirds, have greatly increased in London, no doubt in consequence of the secure retreats they have been able to discover in the parks; so that in some places their numbers are really considerable, in spite of the cats which persistently stalk them in the early morning, and disturb their repose at night, if they are foolish enough to roost among the bushes or on the lower branches of the trees. There is no doubt that birds, like other bipeds, gain wisdom by experience, and profit by it too; for I have noticed that the thrushes especially, but also the blackbirds, have taken to sleeping on the topmost boughs of trees instead of near the ground. No doubt the latter position was adopted in the first instance as the safest when hawks and owls abounded, but since these winged police have almost totally disappeared and cats have become the most dreaded enemy, the position chosen for sleep has been, or rather is in course of being, gradually changed.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[96712.]—**Lantern Slides.**—Any good hand camera that will give a good picture for printing will do well for lantern slides. I use a Lancaster's "Stopit," magazine camera. You will find that the production of good lantern slides depends a great deal more on the operator than upon the camera.
S. Bottone.

[96712.]—**Lantern Slides.**—From your query I gather you have had little practice in photography, and as you want to take the photos the same size as lantern slide, I should advise you to get a ¼-plate focussing camera, and mark in pencil on the focussing screen the size of the lantern-slide mask, and before taking a photo arrange that the subject is the right size on the screen. I think it is better to take the photo the size of the plate you are using, and reduce in a lantern-slide camera, one of which can be bought at small cost. It is better to use ¼-plates than the 3¼ by 3¼ size, as the former are obtainable anywhere. The films used in the Kodaks are easily developed, and can be cut off and developed singly as exposed; but this causes waste of material, as when the film is cut it has to be again attached to the roller, and this operation wastes an exposure every time the film is cut, so that it is more economical to wait until the whole is exposed. I have had some experiences with both plates and roll films, and should advise you to use plates. There is no easy way of developing a negative as a positive, and even if there were the result would not approach the ordinary lantern plate for brilliancy and variety of tone. I think it was mentioned in the "E. M." some time since that a parallel ray is a practical impossibility. W. C. C.

[96712.]—**Lantern Slides.**—Each can only answer from his own experience. Mine, which has ranged over half a dozen cameras of varied makes, leads me to prefer the "Frena," advertised in "E. M."—that, in fact, is how I came to try it. Get the No. 1 lantern size, and learn to compose your slide on the finder. You have no further trouble when this knack has been acquired. Slides are printed by contact, which avoids fussing round when enlarging or reducing. Armed with one of these cameras, I made some hundreds of fine slides of street life in Paris, that travelled round England with a lecture, and were then sold at a good price.
H. H. S.

[96712.]—**Lantern Slides.**—Try Lizard's "Challenge" ¼-plate magazine, for plates or films, price 42s.; the address is 101, Buchanan-street, Glasgow. I have found it most reliable. I think you will find plates better than films; they are certainly easier to work, and are less expensive. You make your lantern-slides from ¼-plate negatives by contact printing. The difference in size (4¼ by 3¼ for the negative and 3¼in. by 3¼in. for the slide) allows of the latter being shifted in the printing frame so as to get the most pleasing effect. If it is too much trouble to print lantern-slides by contact, it is infinitely more difficult to get good snap-shot negatives, and if this is your first attempt at photography you had better start with a stand camera. Tylar, of Birmingham, if I recollect rightly, has plates for taking positives directly in the camera; but I think they are only suitable for time exposures. Read Ganot's "Physics," or other kindred works on light, which will, I think, answer the remainder of your query. Engineer.

[96712.]—**Lantern Slides.**—I should think Spiers and Pond's "A. B. C." lantern camera would meet your requirements. I have had a ¼-plate "A. B. C." in use for over a year, and am well satisfied with it. I would not advise you to touch films of any description unless you have had plenty of experience in photography. Kodak films can be detected and developed before the whole spool is exposed, but it is a ticklish jobs, and the case would have to be an urgent one to necessitate it. The principal objections to films are:—They are difficult to develop; more liable to defects than plates are; and more expensive. I do not know whether such a plate as you suggest can be devised, but there is not much demand for such a plate at present. You will find it the best way to make your slides in the ordinary manner.
Earlsfield, S.W. Silverplume.

[96730.]—**Curl in Photo Films.**—If you are referring to roll films, these should be given a soaking for one minute in a three per cent glycerine bath after washing, and then put aside to dry, removing any superfluous wet with a piece of blotting-paper. The films should be stored flat under slight pressure.
W. C. C.

[96934.]—**Motor Tricycle.**—It is difficult to tell without seeing machine cause of trouble. It may arise from leaky crank-case or screw-plug in same, or perhaps you keep vapour open too far. This tends to get motor very hot quickly. Something may be binding or galling, causing extra work on engine; hence the heating. Examine all bearings on engine or tricycle, especially ball-race next to engine. Try tricycle without engine on it. After, next see if eccentric bolt that carries engine in brackets has loose nuts. If this is case, engine will drop, and hang heavily on large spur gear-wheel, making it grind. The machines you mention are not water-jacketed, the tank you refer to being carburator, battery box, and reserve supply-tank combined in one case. You can get a Dion with a water supply made in form of a small copper coil outside cylinder, connected at top and half-way down, which is depth of jacket. This has a small relief valve on top. For a tricycle-motor water is not required ordinarily. The new French tricycle for next year is a water-cooled motor of 4½H.P., capable of doing 40 miles per hour; it works well.
Monty.

[96935.]—**Motor Cylinder.**—You should give more particulars. For a cylinder, it should be about 8 or 10 B.W.G., if it is good solid-drawn tube. I have seen some quite clean inside and out. If lap-welded, I am afraid you will have all your work cut out. If it is good, it will make a cylinder for an engine or motor. By your saying "motor," you mean for a car—i.e., oil-motor. At any rate, you will not bore it out, to make a job of it; but you must lap it out, and that can be done with a hardwood lap—Spanish mahogany, birch, beech, sycamore, plane-tree, or heart of oak. The lap will have to be 2½ times the length of the tube. About one-third of the length of the tube upon the lap should be slack, then two-thirds tight, and the rest slack, so that you can pass it over the brow to and fro to feed with No. 1 emery, if the inside is good; but if black and rough, No. 2. Finish with pumice-powder. But before you start grinding, see that your tube is true at the ends; if not, take a wooden mallet and dress it into shape over the beak of an anvil, and scrape the ends out bell-mouth, that it will not sheer the emery off. Let some plates into the end of your lap with good centres in, then a piece of iron about $\frac{3}{16}$in. thick and an inch square, with four or five ¼in. screws at the corners.
Jack of All Trades.

[96805.]—**Geological.**—It is quite probable that there is a fault, and the sea-water finds its way to the pump sump. It is a fact that salt water is found below 1,000ft. of chalk, that is about the only explanation—there is a rift in the chalk through which the sea-water finds its way. L. M.

[96938.]—**Question in Arithmetic.**—Lay out field with walks required. It will then be found there are four equal square portions ungravelled. The area of each of these squares will be the fourth part of 2½ acres—that is, 3,025 yards, and, therefore, the side of each square will be 55 yards or 165ft. But the wall of the inclosure is equal to the length of two squares and three walks, one at each end and one in the middle. Therefore, length of wall equal $2 \times 165 + 3 \times 13 = 369$ft., and length of four walls = 492 yards. Arithmos.

[96942.]—**Motor Tricycle.**—Crank cases frequently leak and cause trouble, principally from careless treatment received when apart; a dent, blow, or bruise will render them useless. Yours must be damaged somewhere. Don't use any packing at all, as in all motor work joints should be metallic—only blacklead to prevent seizing, though this would not happen with crank-case. Have it carefully examined, and put on mandrel, and very light cut taken off same; then put cases together on their own shaft, with spot of oil on, and work about to get a face. You may use a scraper lightly on hard lumps, but don't touch with a file. Back off bosses from thickness of case a one-sixty-fourth to outer edge, both sides. This will allow bolts to draw on faces only, and give it a better chance for tightening. All early cases were made with seven bolts, which was insufficient. It should run twenty miles at least with one charge of oil, which should not exceed two tablespoonfuls at a time. Monty.

[96954.]—**Motor for Car.**—The best carburator to use for car is Longuemare, which is essentially same as described by "Writer of Articles." These are better suited for a car than a tricycle, as you can only get one set mixture from them; whereas you can usually get an extra spurt out of Dion type for a short time by giving a shade more vapour. One reason for this is, as a rule this type of carburator when put on a tricycle is far too small, and wick surface is not sufficient to supply vapour fast enough. Make it twice as large as example given, and with a wick surface three times as large. You must supply the air for these heated up by exhaust, and don't forget that the hot-air supply pipe should be slightly larger than if ordinary air was drawn in. Your dynamo is too small for any practical use; you might charge accumulators in about a week with it, though if it has a Siemens armature with a two-part commutator it will be next to useless for charging purposes, owing to changes of potential. I described and sent sketch of a silencer that would suit you about two months ago, which you can get full particulars from. Monty.

[96962.]—**Multiple Wimshurst.**—To Mr. Bottone and "J. W."—Many thanks for replies. I find that the fault is not in the neutralising circuit. I mounted two glass plates with 24 sectors on each, and it excited at once. It does not appear to be the knotting (which is a mixture of methylated spirit and shellac, and, I am afraid, sometimes resin), although this was, as Mr. B. suggests, wet, this is a good non-conductor when dry. I have taken off the 15in. discs and cleaned as suggested, but without any better result, so that I am forced to the conclusion that it is the ebonite. Assuming this to be the case, it will, I suppose, be due to some substance in the composition of the ebonite that should not be present, and that is a conductor of electricity. What is it likely to be? and is it possible to get rid of it by treating the material in any way? On rotating the plates in the dark, I get very small sparks at the neutralising brushes, but this seems to be due to friction from a piece of string that I have between the plates to prevent them rubbing, for when I take the string away the sparks disappear. There was a slight error in the size of the sectors given; they are 4½in. long. My reason for putting so few was to get a long spark from the machine, and to avoid leakage to the bosses. I covered the sectors half-way up. I am not an authority, but it seems to me that in Mr. Bottone's machines the shortening of the sectors is partly nullified by there being so many of them creating leaking one to another. Will not more rapid rotation of the plates make up for a smaller number of sectors (when once excited)? Is not the width at the wide end of the sectors regulated by the distance they are apart at the narrow end? What I mean is, cannot you have any width (say from ½in. to 1½in.), providing you keep the edges of the sectors parallel? I have been very unfortunate with this machine. I started with glass plates, but have had no less than six plates out of eight fracture. It appears that the common glass is in a constant state of strain, and when the hole is cut in the centre the strain is partly released and ready to fracture the glass on the slightest touch; in fact, I have had plates go without being touched. All the fractures start from the centre hole—none from the outer edge. Could one have the glass annealed, or would this spoil its electrical efficiency? I find it is an advantage to bed the plates on the bosses on a soft bed of thin leather. F. W.

[96973.]—**Sand Blast.**—Tilghman's process for glass, &c., engraving:—A common fan is used, 30in. diameter, with 1,500 revolutions per minute, giving blast of air of pressure of about 4in. of water through vertical tube, 2ft. high by 60in. long, and 1in. diameter. See Dr. Ure's Dictionary, Vols. II. and III. Regent's Park.

[96983.]—**Steam Motor Waggon.**—1. The pressure is rather low for the purpose; 100lb. is not much use for a compound engine, and it is perfectly evident that as a single engine the power is much too low. By all means compound low-pressure cylinder, 6in. bore by 4in. stroke. 2. To enable the back wheels to take corners, some kind of differential movement is required; the usual plan applied to traction-engines is generally used, and (as I understand "E. D. T.'s" proposed arrangement) it would be best applied to the countershaft, from which I presume he means to drive his road-wheels by a chain to each. If he can manage it, it would be desirable to box in these, as they wear very rapidly if unprotected. 3. Nothing equals the "Ackermann" system for locking the front wheels. Almost all the heavy motor vehicles, as well as the light cars, are so fitted; but it requires great care in design. "E. D. T." ought to carefully examine a heavy motor waggon if possible; but, briefly, each fore-wheel runs on a stout arm, which is hung in a horizontal knuckle-joint. 4. The *simplest* form of speed gear is one arranged like the back gear of a lathe. I do not say this is the *best*. The sizes of the wheels must depend on circumstances, and can be easily calculated from any mechanical pocket-book of tables. Bear in mind, however, that small pinions are as far as possible to be avoided. 5. As to load, two tons is as much as "E. D. T." will be able to *economically* manage if he has gradients of 1 in 6 to negotiate. 6. Fletcher, "Steam on Common Roads," back numbers of *The Automotor Journal*, in which see also Mr. Thorneycroft's article on the subject read before the British Association at Dover (in the October number, I think), and also see the August number for the Liverpool trials; Farman's "Autocars," Wallis Tyler's "Motor Cars," and many others. If "E. D. T." can obtain access to the back numbers of the English Mechanic, he would also find several steam carriages. In conclusion, if "E. D. T." will advertise his address, I should be able to go far more fully into the matter. Precursor.

[96989.]—**Polish for Brown Shoes.**—Waterproof:—Garnet shellac 7lb., methylated spirit 3½ gallons, Venice turps 2½ gallons, castor-oil 6oz., camphor 2lb., yellow spirit aniline 1lb., oil of cassia 1oz. Add spirit to shellac in mixer, dissolve; add

turps, camphor, castor-oil, rub up aniline in spirit till smooth; add this to mixture, run all day; add oil of cassia, leave to settle for one day, draw off, strain, and bottle. Add or reduce quantity of colour, according to the shade required. Brown or yellow tan cream:—Turps 2 gallons, distilled water 2 gallons, yellow beeswax 4½lb., castile soap 8oz. Yellow aniline colour (water), or for darker shade use Bismarck brown, 8oz. Melt beeswax, add turps, then soap (dissolved in two gallons of boiling water, distilled), with colour well mixed in, pouring in gently, well stirring until cool; then tin or bottle off. Or yellow beeswax or part ceresine 17lb., yellow aniline dye 1oz., turps 2 gallons, oil of citronelle 3oz. Melt wax, rub up colour with a little turps, and add remainder of turps to wax. Now stir in colour (have very little heat on copper), add citronelle, stir well for quarter of an hour, turn off heat, stir till cold, fill off with knife. Or, beeswax 4lb., turps 1 gallon, water 3 gallons, pearlash 2oz., soft soap 4lb., Bismarck brown 2oz. to 3oz. Melt wax, add turps; have water, soap, pearlash, and coloured mixed and boiling, pour wax and turps on top of water; stir till cold. Or, beeswax 6lb., ceresine wax (yellow), 2lb., turps 2 gallons, washing soda 24oz., Bismarck brown 1½oz. Melt waxes, add turps, dissolve soda in water, add colour, well mix, add to melted waxes and turps; stir well, and fill off hot. REGENT'S PARK.

[96992.] — **Petroleum-Drinking.** — L. Lewin has investigated the action of petroleum, and he has come to the conclusion that it is a poison, showing irritation and inflammation of the stomach, lacerations at bottom of stomach and vessels, and prominent black spots or points filled with blood on the mucous membrane of the stomach. Petroleum vapours when inhaled are not poisonous, injurious effects being produced only under extraordinarily bad external and individual conditions. Skin diseases are, however, of frequent occurrence among workmen handling petroleum, especially the heavy oils, and hence the utmost cleanliness and frequent warm baths are advised. Skin diseases appear as acne in forms on thighs, knees, arms, trunk, neck, face, ears, scrotum; as a rule only caused by heavy oils. Officinal petroleum reddens skin, causing scaling off, and hair to fall out; the action is weaker than that of oil of turpentine. The hair, however, grows again rapidly. Taken internally in excessive doses, it has caused oppression, giddiness, palpitation, faintness, and headache. Absorbed by the blood it acts similarly to oil of turpentine. It kills tapeworm, lice, &c., but does not destroy bacteria. Preferably used in veterinary practice. See W. T. Braunt on "Petroleum" (S. Low and Co.)
REGENT'S PARK.

[97006.]—**Metallurgy.**—Prior to the invention of puddling (circ. 1784) the conversion of cast-iron into wrought-iron was uniformly effected by a process which, though differing markedly in certain details, yet in all cases essentially consisted of exposure to oxidising atmosphere and agitation until practically all the carbon and silicon, &c., was removed. As the iron becomes purer its fusibility lessens, so that ultimately it collects into pasty semi-solid masses, which, when united together, form a ball, which is taken out and forged into a bloom. The ancient bloomeries and the blast furnaces of the present-day primitive iron workers—those of India, Burmah, China, Borneo, Africa, &c., as well as the Corsican or Catalan furnace, still used in the Pyrenees and other part of Southern Europe—are all of very small height, not merely low on account of the smallness of the charge, but very low even in proportion to this. Their height but slightly exceeds their breadth. The reason were and are only used for the reduction of the richest and purest ores by means of nearly pure carbon—i.e., wood charcoal, &c. See "Encyclopedia Britannica," Mattieu Williams, Crookes, and Rohrig and Fairbairn, &c. REGENT'S PARK.

[97009.]—**Cleaning Paper.**—F. Andrews places one or two papers at a time in shallow dish, pours water over them till saturated; then carefully pours off water, pours on prints solution of chloride lime, 1 of Cl to 39 of water. As a rule, stains go off; if not, he pours on spot pure liquid calcis chlorate; and if this is not quite effectual, adds a little dilute nitromuriatic acid. Has never failed. If anything, they become too white. As soon as clean, carefully wash with successive portions of water until all chlorine is got rid of. Then place in very weak solution of isinglass or glue, and many collectors colour this solution with coffee-grounds to give a yellow tint. Dry between folds of blotting-paper either in a press or under a heavy book, and, finally, ironed with flat-iron to restore glass, placing clean paper between iron and print. For grease stains, benzine best, French chalk powdered over, a piece of clean blotting-paper over chalk, and work over that hot iron. REGENT'S PARK.

[97009.]—**Cleaning Paper.**—If the paper is merely surface soiled, probably rubbing over with a bit of bread will clean it sufficiently. If not, make up a solution of chloride of lime, and dip the sheets in that; then afterwards in water that has been boiled. The chloride of lime will flush all the dirt that is likely to be on the paper, but it must be washed out carefully afterwards by soaking in boiled water, and then drying. M. T.

[97012.]—**Accumulators.** — You do not say whose make of cell you are using; but after being fully charged the cell should discharge 12 ampères for 10 hours at 2 volts. The specific gravity of acid should be 1,190. The cells will take a charge and discharge with acid of a lower density; but years of experience have proved that the above specific gravity is the best.

WEBSTER MICHELSON AND CO.
Dudley. Electrical Engineers.

[97012.]—**Accumulators.** — (1) Depends altogether upon the type of cell; roughly, about six ampères for 20 hours. (2) The specific gravity of the uncharged cell should be 1·190; when charged, 1·2. (3) Not satisfactorily. Any great variations, either above or below the correct specific gravity, will destroy the plates, and necessitate repasting.
W. J. G. FORMAN.

[97012.]—**Accumulators.**—You do not mention the type of cell, so that it is not easy to say the ampère hour capacity. Roughly speaking, about 36 ampère hours. If these cells are coupled in series, the volts increase by 2 for every cell, while the discharge capacity remains the same—viz., 36 ampères for 1 hour, or 1 ampère for 36 hours. But if any number of cells be coupled in parallel, the voltage remains 2, but the amp.-hr. capacity increases directly as the number of cells so joined up; hence 2 cells = 72a.h., 4 cells, 144a.h., and so on. The specific gravity of acid should be 1·190. This can be got by mixing 4 parts by measure of good brimstone oil of vitriol (sp.g. 1·84) with 21 parts of water. The cells will work even when the specific gravity of the dilute acid is lower or higher than this, but not so well. Take the sp.g. of your suspected acid by means of a proper hydrometer, and add water or acid until it registers the right sp.g. When the cells are fully charged electrically, the sp g. rises to 1·200 or 1·210. S. BOTTONE.

[97013.]—**Ice Storage.**—1. Build round brick wall with small grating for drain at bottom for escape of water from melted ice; cover the bottom with a thick layer of good wheat straw; pack the ice in layers of ice and straw; fix a wooden cover to well. 2. Firebrick lining to walls circular shape, larger at top than at bottom, where drain should be provided. Some make of wood, double lining with core of insulating material. If in Gray's Inn-road, look in at one of manufacturers on east side opposite Gray's Inn, corner house. REGENT'S PARK.

[97017.]—**Gas v. Steam.**—We have no hesitation in saying that a gas-engine is far preferable to a steam-engine for the small power you require. Assuming you use 6cwt. of coals per day of eight hours at 18s. per ton, will amount to about 5s. 6d. Now, a good gas-engine consumes 22c.ft. to 24c.ft. of gas per H.P. per hour, 24 × 8 × 8, at 4s. 2d. per 1,000, = 6s. 4d., which is 10d. per day more for gas consumed than cost of coal; but against this extra cost of 10d. per day you save a boiler, stoker's wages, wear and tear of boiler and brickwork setting, cost of water, and cost of carting away ashes. Moreover, the greatest advantage of all is that a gas-engine is ready to start in three minutes, and when done with no further waste of fuel occurs. We are makers of both gas and steam-engines, and use both, but never steam if we can help it. Our candid opinion being, after years of experience with both gas and steam, that for any power under 100H.P. gas is far preferable and much cheaper, all things being considered.

WEBSTER MICHELSON AND CO.
Dudley. Electrical Engineers.

[97017.]—**Gas v. Steam.**—Taking Otto gas-engine as good type:—Revs. per minute 160·10, explosions per minute 78·40, mean initial pressure 196·9, mean effective pressure 67·90, I.H.P. 17·12, brake load net 177·40, B.H.P. 14·74, mechanical efficiency ·861. Gas per hour, main, 351·80; ignition, 3·50; total, 355·30. Gas per I.H.P. per hour, main, 20·55c.ft.; gas per I.H.P. per hour, total, 20·76c.ft.; gas per B.H.P. per hour, main, 23·87c.ft. Steam: 1lb. of good coal will evaporate 9lb. water raised to 212° Fahr. Total heat of combustion of coal is—

		Units of Heat.
Carbon 14,500 × ·80	=	11,600
Hydrogen 62,032 × (05 − ·08 8)	=	2,481
Sulphur 4,032 × ·0125	=	50
Total		14,131

The consumption of coal per I H P. per hour in first-class triple-expansion surface condensing engines is about 1½lb., in double-expansion condensing engines from 1¾lb. to 2lb., in single-cylinder condensing engines 2½lb. to 3lb., in locomotives 2½lb., in high-pressure non-condensing simple engines 3lb. to 4lb. By dividing the 14,131 previously given by units of heat to convert 1lb. water of 212° Fahr. into steam of same temperature (14,131 ÷ 966) there shows 14·63 units of evaporation, or 14·631b. evaporated from and at 212° Fahr., a possible aid. REGENT'S PARK.

[97017.]—**Gas v. Steam.**—I should strongly advise you to use a modern gas-engine, say, National, Crossley, or other good make, which would consume average about 15c.ft. per horse-power per hour, and require no further attention, is ready to start at a moment's notice, and has other obvious advantages too numerous to mention. With gas at price you mention, the steam-engine would cost about same; but from the commercial point of view, at end of twelve months you would be pounds in pocket by use of gas-engine. The Fielding new engine is another type that is giving excellent results for consumption and steady all-round working. For intermittent work a steam-engine cannot compare with gas for any size or power. MONTY.

[97019.] — **Wireless Telegraphy.** — To MR. BOTTONE.—If you can erect metal rods, both at the sending and receiving ends, to clear the tops of the intervening houses by about 10ft., a coil giving 1in. spark, with sparking balls about ½in. apart, will do nicely. You can make a coherer by procuring a piece of glass tube about 1in. long $\frac{3}{16}$in. bore, and fitting it with a well-fitting cork at each end, through which must pass a piece of silver wire. In the tube put rather coarse nickel and silver filings. Dry the tube carefully over a gas flame before introducing the filings. Then work up, taking care that the filings do not quite fill the tube, so that they can move freely. Seal up the ends with sealing wax. It would be better if the tube were exhausted and sealed with a blowpipe, but I am afraid you could not manage this. The vacuum prevents the filings rusting, but the plan given above answers very well, and for a long time. Besides it is easy to change the filings if this do rust. A good dry cell or two should be placed in circuit with relay wires and coherer. A 10ft., D 10ft., B two larger balls 2½diam., two smaller 1in. diam., C, already given, E, cores ⅜in. diam., 1½ long, wound with 2oz. of No. 36 silk-covered wire. S. BOTTONE.

[97020.]—**Dynamo.**—To MR. BOTTONE.—Using fields of the shape you indicate at B, standing about 5in. high, 4in. wide, with cores and yoke of about ⅝in. substance, with tunnel bored out in pole-pieces $2\frac{1}{16}$in. diameter by 2in. deep, you will get the best results from a tripolar laminated armature 2in. diam., 2in. long, fitted with a tripartite commutator. This will enable you to charge accumulators, &c., if shunt-wound. For the armature, use about ¼lb. No. 22 d.c.c., and for the field-magnets about ½lb. No. 24 d.c.c. S. BOTTONE.

[97021.]—**Bromide Printing.**—Try longer exposure. The print should be fully developed in less than five minutes, or it is greatly under-exposed. If you are a beginner you cannot expect to get on with ferrous-oxalate. Buy another packet of paper and develop a print on a fresh sheet. This will prove whether your developer is contaminated or not.

Earlsfield, S.W. SILVERPLUME.

[97021.]—**Bromide Printing.**—"Faineant" has succeeded in "fogging" his paper as one would a plate, or, even more probably, does not wash it properly before fixing. If paper is of good make and has not been stored in damp or over-heated place, age would make little or no difference. I am now using with perfect success, amongst other papers, some "Barnet" rough bromide paper which is five years old at least, and has been knocking about the world with me ever since. It has undergone a sea-voyage three times without special packing, which goes to throw doubt on "Faineant's" methods. At first I used to have the same sort of trouble, but a friend came along and said: "You lack the necessary forces"—i.e., four C's = double care and double cleanliness. After many trials I now work only with the following metol developer, with which any tone can be got at will.

Metol Developer.

(A)	Metol	400gr.
	Sodium sulphite	8oz.
	Potass bromide	50gr.
	Water	80oz.
(B)	Potass carbonate	8oz.
	Water	80oz.

Take 3oz. of A and 1oz. of B. The image should appear in a few seconds, and development will be complete in about two minutes. Rinse in at least three changes of water and fix in ordinary fixing bath (no acid bath is necessary with this developer). To produce softer results dilute with an equal quantity of water. After fixing, wash thoroughly in several changes of water for at least two hours, squeegee off the superfluous moisture, and hang up to dry. H. H. S.

[97021.]—**Bromide Printing.**—May be stale paper; expose fully, developing with a strong solution, so that the operation may be completed in a short space of time. Remove your ruby light only after fixing, then disperse stain or surface fog with a weak solution of potass ferridcyanide.
J. P. N.

[97022.]—**Metric System.** — "Inquirer" has only to multiply the number of square yards in the triangle by ·8361259, and the product will be its

area in square mètres. Call the sides A, B, C, multiply them by ·22 to bring them to yards. Thus—

A = 1,660 links = 365·20 yards
B = 1,454 „ = 319·88 „
C = 1,372 „ = 301·84 „

Add them together, divide their sum by 2, and call the result S. Thus S = 493·46.

From S subtract A, call result D = 128·26
„ S „ B, „ E = 173·58
„ S „ C, „ F = 191·62

Multiply S by D by E by F, call the product G. Thus, G = 2,105,153,211·391. Extract the square root of G, and call the root H. Thus H = 45881·9486 square yards. Multiply H by ·8361259, product = 38363·0856 square mètres = 3·8363 hectare. Note.—·8361259 is the new coefficient determined by the order of the Board of Trade in 1896. E. N.

[97023.]—**Engraving Tools.**—Two or three drops of alcohol to almost pure glycerine. Temper in mercury or lead; lead lessened about ¼in. Instrument made light red hot is pressed into cut; melted lead then surrounds it. REGENT'S PARK.

[97024.]—**Horse-Power.**—Nearly 1¼I.H.P. at 30lb., 3 at 60lb., and 6 at 120lb. boiler pressure.
WEBSTER MICHELSON AND CO.
Dudley. Electrical Engineers.

[97024.]—**Horse-Power.**—30—3lb., 62,000ft.-lb per min.; 66—3lb., 130,930ft.-lb. per min.; 120—3lb., 263,760ft.-lb. per min.; 3lb. allowed on boiler pressure for friction; 33,000ft.-lb. equivalent to 1H.P. Above approximations should be reduced by about 10 per cent. for clearance volume of cylinders and steam passages.
Sevenoaks. F. SEA.

[97027.]—**To "M.I.C.E."**—A chapter on the calculus of variations will be found at the end of Todhunter's "Integral Calculus"; in this there are other works on the subject named, should you wish to pursue the study. The "Calculus of Operations" is, I think, another name for the symbolic method, which you will find explained in Boole's "Differential Equations," Chapter XVII. The curve of sines must be represented by y = sin. x.
Bath. M.I.C.E.

[97027.]—**To "M.I.C.E."**—I do not think that an easy book upon calculus of variations exists, unless there should be an American one in Messrs. Ginn and Co.'s list. As to calculus of operations, the symbol *sin.* may be looked upon as an operator changing x into sin. x, and y into sin. y. D or $\frac{d}{d\,x}$ may be looked upon as an operator changing y into $\frac{d\,y}{d\,x}$, and so on. In so far, then, as these operators are found to obey the laws of algebra, they may be manipulated like algebraical quantities to the great abbreviation of certain sorts of work. Example:—Suppose we wish to integrate e^{mx} cos. $n\,x$—that is, we want $\frac{1}{D}$ (e^{mx} cos. $n\,x$) where D is the operator $\frac{d}{d\,x}$. Now this operator is clearly made up of the two operators $D_1 + D_2$. Where D_1 affects only e^{mx} and D_2 affects cos. $n\,x$, so that—

$$D_1\ e^{mx}\cos.\ n\,x = m\,e^{mx}\cos.\ n\,x$$
$$D_1^2\ e^{mx}\cos.\ n\,x = m^2\,e^{mx}\cos.\ n\,x$$
$$D_2\ e^{mx}\cos.\ n\,x = -\,n\,e^{mx}\sin.\ n\,x$$
$$D_2^2\ e^{mx}\cos.\ n\,x = -\,n^2 e^{mx}\cos.\ n\,x$$

and so on. Now what we require is—

$$\frac{1}{D_1 + D_2}\,(e^{mx}\cos.\ n\,x)$$

That is— $$\frac{D_1 - D_2}{D_1^2 - D_2^2}\,(e^{mx}\cos.\ n\,n)$$

That is— $$\frac{D_1 - D_2}{m^2 + n^2}\,(e^{mx}\cos.\ n\,x)$$

That is— $$\frac{e^{mx}}{m^2 + n^2}\,[m\cos.\ n\,x - n\sin.\ n\,x]$$

This takes some time to explain, but is easy in reality, and when once understood enables you to do in your head a most inconvenient piece of integration, and so affords a fair illustration of the elementary use of operational calculus. For curve of sines take a book of four-figure logs., such as Bottomley's, and write down three columns of figures as follows: The first column is headed *angle in degrees*, and contains the numbers 0, 5, 10 . . . . up to 360; the second is headed *angle* in radian measure, and contains the numbers found in the tables to correspond to those in column one; the third is headed *sine of angle*, and contains the sines found in tables to correspond to angles in first column. If, now, a curve be plotted on squared paper by points having the numbers in second column for abscissæ, and those in third column for ordinates, a part of a sine curve will be obtained. The complete sine curve is the unending wavy line made up of such parts tacked on one after the other, and its algebraic expression is y = sin. x. The use of radian measure is not all-essential, but it is the way to get the scale right. QUIVIS.

[97028.]—**Honey.**—In reply to "Merchant," Dr. Hassall gives the following as the results of the analyses of three samples of honey:—

	Per cent.	Per cent.	Per cent.
Water	17·48	16·88	13·63
Cane sugar	none	1·82	5·29
Glucoses	82·50	81·00	81·04
Insoluble matter	trace	trace	trace
Mineral matter......	0·02	0·30	0 04
	100 00	100·00	100·00

BAZIN.

[97028.]—**Honey.**—Honey contains three distinct sugars—sucrose $C_{12}H_{22}O_{11}$, glucose (dextrine or grape) $C_6H_{12}O_6H_2O$, lævulose (fruit-sugar) $C_6H_{12}O_6$. The flavouring (essential oils) will vary according to source—i.e., according to what flowers are most prevalent where the honey was obtained. Pure honey should answer to the following tests:—When incinerated it should not leave more than 0·25 per cent. of ash, the solution of which ash in water should yield, when acidulated with nitric acid, but a slight turbidity with a solution of barium chloride (absence of more than traces of sulphates). The same solution should yield no reaction with iodine (absence of starch).
Jersey. J. SINEL.

[97028.]—**Honey.**—A good sample may give thus: Water, 22·0; crystalline glucose (dextrose), 38·0; vitreous glucose (lævulose), 36·0; mineral matters, 0·2; wax, pollen, gluten, essential oil, colouring matter, 3·8; total, 100·0.
REGENT'S PARK.

[97029.]—**Pumping Boiling Water.**—How shall a pump lift "boiling water"? If the water is boiling it will fly into steam when the pump produces a vacuum, and how, then, can the pump lift water? What has a "farmyard boiler" to do with it? The principle is the same with any boiler. Boiling water must be forced, not pumped. How long the leathers will last depends on circumstances.
M. T.

[97028.]—**Pumping Boiling Water.**—Should think not much, but have valves fitted to pump such as brewers use. REGENT'S PARK.

[97029.]—**Pumping Boiling Water.**—An ordinary lift pump will pump the boiling water once, provided boiling liquid ran into pump—i.e., pump and valves must be on a lower level, as if on higher, vapour given off will destroy vacuum. You must substitute vulcanised fibre for the leather all round. After using hot water and allowing it to cool, leather would set like iron. MONTY.

[97029.] — **Pumping Boiling Water.** — To pump water is to lift it from a lower level. No pump in the world will pump boiling water—i.e., lift boiling water from a lower level.
WEBSTER MICHELSON AND CO.
Dudley. Electrical Engineers.

[97030.]—**Dry Cell.**—I have tried nearly every dry cell for this purpose, and find practically no difference. Any good cell that had long life with a bell, such as the Obach, the Hellesen, the E.C.C. (Burnsley patent), the I.E.C., and the "British" does well. Latterly I have been using the last named, and find them give me every satisfaction. I do not know the exact composition of the paste in the Obach cell. S. BOTTONE.

[97034.]—**Trellis.**—Should think there was less pressure per square when expanded than when closed. REGENT'S PARK.

[97036.]—**Position of Planets.**—A diagram of the position of the planets for the middle of November was printed by the British Chronological and Astronomical Association. From this "Neptune" can easily determine their positions at any other time. They are depicted in the signs of the Zodiacal circle. The diagram can be had gratis from Observatory House, Wanstead, E., on receipt of a stamped envelope. J. B. DIMBLEBY.
Observatory House, Wanstead, E.

[97037.]—**Copying Drawings.**—Soak drawing or tracing with benzine by means of cotton pad; makes it very transparent. Indian ink, colour, pencil take equally well upon paper thus treated. Any opaque drawing paper answers stretched over drawing to be reproduced. The benzine rapidly evaporates. REGENT'S PARK.

[97039.]—**Colouring Oil.**—Iodine and sulphur suggested. REGENT'S PARK.

[97040.]—**Solio Paper.**—The best thing you can do with them, if you can print fresh ones, is to throw them away and done with it. If, however, you can obtain no more, you may try leaving them in the hyposulphite solution all day; or until sufficiently reduced; but the result will hardly be satisfactory. Another method is to add two drops of a solution of potassium ferricyanide (poison) to a weak hypo. solution; immerse the prints one at a time, and take them out quickly when light enough and well wash. Be careful. Do not expect to get expect to get excellent results.
Earlsfield, S.W. SILVERPLUME.

[97041.]—**Motor Bicycle.**—I cannot waste the time over what I know to be a useless article—to wit, a motor bicycle. I have seen and tried four different ones and found them far inferior to a tricycle, and too prone to side-slip in wet to my liking. As to a motor for same, there is a Coventry firm advertising week after week in this paper sets of ¾H.P. Dion castings, everything complete about £4. These have cylinders 2⅝in. diameter by 2¾in. stroke, and should suit your purpose; but you will find there is absolutely no end to wants when you start to make one, so that I feel sure you could buy one cheaper if you advertised for one in any of the papers devoted to motors. At outside you could get one for £15, perhaps less from some weary individual. To make drawings of complete machine would mean ten or fifteen different drawings, and would take some time, which I have not at my disposal at present. MONTY.

[97043.]—**Flue Tubes, &c.**—All water contains certain amount of air, and consequently oxygen, &c., very active in corroding. It can generally be remedied by scraping and cleaning with solution of soda. Many lubricants decompose at 220° Fahr., and numerous cylinder oils at 33° Fahr., forming compounds which combine with mineral substances precipitated in boiler, and form soft greasy deposit containing from 60 to 85 per cent. iron oxide, lime, silica, magnesia, iron, zinc, and 15 to 40 per cent. of oil. Some of this forms scum, remainder settles at bottom as sludge. Deposit frequently carried into cylinder, forming black paste, gets baked on ends on piston, causes wear and scouring, &c.
REGENT'S PARK.

[97046.]—**Steam Exhaust.**—The only way is to surround the exhaust with a constant flow of cold water—in other words, take the exhaust steam into a condenser. It is a troublesome business, because if anything is done to condense the steam as it issues after doing its work there is "back pressure," which is an important "item" in steam-engine economy. Possibly the exhaust steam might be utilised in some way, for while water is in the condition of steam it contains heat, and that should not be wasted, if it can be utilised in any way. The querist must have a condenser if the steam is not to be seen. M. T.

[97046.]—**Steam Exhaust.**—Heat feed-water; by this water-heater you may save 10 per cent. See Hutton, "Steam-Boilers." REGENT'S PARK.

[97047.]—**X Ray.**—To MR. BOTTONE OR OTHERS.—Using the jars on, and taking the current from the outsides of the jars, the dischargers being set at about 1in. apart, you will be able to work nicely a tube that would require a 6in. spark from a coil to work it. There is no difference between the prices of a 3in. and 6in. tube. If of the old Jackson type, the price will be about 15s.; if of the bianodic type, 30s. A 3in. tube will show the bones in a man's leg. See my book on "Radiography."
S. BOTTONE.

[97048.]—**Fluorescent Screen.**—Procure some good crystallised calcium tungstate. Procure also a copper gauze sieve, or similar, having 60 meshes to the inch linear. Get a sheet of stout Bristol board, 12in. by 9in. Pin it flat on a drawing-board, and with a wide camel-hair brush dipped in good clear gum-water go carefully over the surface, so as to put on an even coating, without bubbles. Now sift over the surface, from some height, sufficient tungstate to cover evenly the gummed surface. When quite dry, shake off the superfluity, remove the pins, and mount the screen in a frame.
S. BOTTONE.

[97049.]—**Ohm's Law and Decrease of Voltage.**—J. Brown does not appear to have "grasped the principles of Ohm's law." How does he make out that "the voltage would remain the same if the current was transmitted one thousand miles or only one mile?" It is just here that he is wrong, as there is no known substance which will permit the electric current to pass through it without offering some resistance. Hence the formula $C = \frac{E}{R}$ is absolutely correct, and no further investigation can be needed. It stands to reason that the greater the distance through which the current is transmitted the greater is the resistance, consequently E may have to be divided by so many multiples of R as the case may be, and C diminished in corresponding ratio.
Clapham. J. H. WEBSTER.

[97049.]—**Ohm's Law and Decrease of Voltage.**—You are quite right, and Ohm's law still holds good, notwithstanding the muddle which some people make by talking of lost volts, &c. If your source of current had a voltage of 1 volt and your circuit a resistance of 1,000,000 ohms, the volts are still 1, but the current in ampères cannot exceed $\frac{1}{1000000}$. You must remember, however, that the word potential is very often used to indicate the working energy of the current. And, since this is

equal to volts multiplied by ampères, it follows that the potential differences at the farther extremities of a long circuit presenting much resistance must be considerably less than at any points nearer the source where, of course, the resistance is less.

S. BOTTONE.

[97049.]—**Ohm's Law.** — Assuming that the words "competent reader" are only meant to exclude—we all know whom—I will try to clear up J. Brown's difficulties, which are clearly those of a beginner. The earliest electrical notion is that of electrification, as the state of a piece of freshly rubbed amber or sealing-wax. The second in logical order is to make "electricity" into a measurable quantity by the help of the inverse square law. In this way the definition of unit quantity of electricity is implicitly involved in the statement that two unit charges concentrated upon tiny bodies separated by one centimètre distance in air repel each other with a mechanical force of one dyne. We then pass to the difficult conception of potential, which I shall not try to explain here. It is a quantity that varies from point to point in very much the same sort of way as that in which height above sea-level varies. All along a level road the height above sea-level is constant, and all over an electrical conductor in which there is no current the potential is constant. Further, just as it is much easier to find the difference of level between two inland points than the height of either of them above sea-level, so it is much easier to determine the difference of potential between any two points than to assign a value to the potential of either; the name given to such a difference of potential between two points in the voltage between those points—for instance, between the copper and the zinc of a Daniell cell the potential difference or voltage is about 1·1 volt. We are now coming to Ohm's Law. When two places at different potentials are connected by a wire, a current passes to equalise the potential; but only a transient one, unless some apparatus is at hand (such as a battery or dynamo) for maintaining a difference of potential. A current such that one coulomb of electricity passes each point of a wire in a second is called one ampère. Note that a coulomb is the ordinary practical unit of electricity, and is a very high multiple of the electrostatic unit mentioned above. Ohm's law expresses the experimental fact that the number of ampères that go through a wire is directly proportional to the voltage applied between the ends of the wire—i.e., if you put on twice as many volts, you get twice as many ampères, and so on. I think that if J. Brown can make out the above, he will see that the writers of books are not so muddleheaded as he imagines. At any moment the current must be the same all along a wire, or else the electricity would be heaping up in the middle somewhere, so the ampères must be the same everywhere; but as the potential in the wire has to drop from the high value one end to the low value the other, through the amount of the voltage, there must be a steady fall all down a uniform wire, and there is no meaning in saying that the potential always remains the same, and still less in charging Ohm's Law with supporting such a heresy. If $C = \frac{E}{R}$, shows that E remains constant. I suppose $\frac{1}{R} = \frac{C}{E}$ would show that C remains constant, and so on; but of course this is mere fooling.

QUIVIS.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered, are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

THE total value of the gold production of the Transvaal in 1898 was £16,240,830, and the working expenses amounted to £11,489,752.

QUERIES.

[97053.]—**Carbon Paper.**—I wish to make a quantity of carbon transfer paper, as used for duplicating writing. Will someone oblige with recipe of composition, and method of application?—H. H. Z.

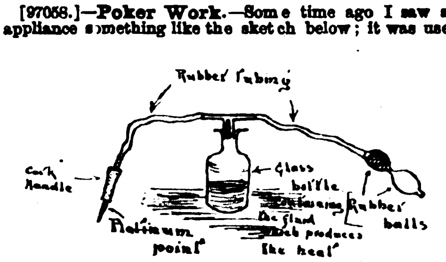
[97054.]—**Mandoline.**—Will some reader inform an amateur how to make the belly of a canoe-shaped mandoline?—F. SMITH.

[97055.]—**Californian Grape Growing.**—Can some reader give me any information. Yield, average, per acre of good selected vines of well-established growth? Number of plants per acre? Cost of raising, gathering, curing, and packing the fruit? Usual quantity contained per "box," as quoted in wholesale produce price lists of nearest towns? Price obtained on the spot per box? Whether irrigation is working successfully? And if grape growing is likely to be permanently established as at all a profitable industry? The British Consular reports are very feeble efforts. What reliable literature on the subject? I refer to existing vineyards, not to prospective ones on virgin soil.—LINCOLN FARMER.

[97056.]—**Xylonite.**—Would any reader be good enough to tell me how to polish xylonite? Also the best way to fix it on wood—whether glue would do or not, or whether there is any special cement for the purpose?—T. HENRY.

[97057.]—**To Mr. Bottone.**—I have an induction coil which is working very badly, and, I fear, leaking heavily. The length of the coil is 5½in. winding space, and the outside diameter is 3in. At present I can only get a ⅜in. spark when using three quart chromic acid cells. I think of rewinding it, and would you kindly tell me the gauge of wire for primary and secondary, and how much to put on, also the length of spark it should then give?—INDUCTION.

[97058.]—**Poker Work.**—Some time ago I saw an appliance something like the sketch below; it was used



for doing poker work. Could any reader inform me, in detail, how to make a similar appliance?—LITTLE WILLY.

[97059.]—**Celluloid.**—I should be pleased if any of your readers could inform me, or refer me to any book containing the information, as to how celluloid is prepared commercially, and how it is moulded into shape? also where I could obtain information as to the nature, properties, cost, &c., of vasco id?—NITRO-CELLULOSE.

[97060.]—**Alpha Orionis.**—Will readers kindly give me information about this star? Sir R. Ball writes as follows:—"The brightest star in Orion is known as α Orionis, or as Betelgeuse." Proctor, speaking of the spectra of variable stars, has the following:—". . . . Betelgeux, the singularly variable orange star, which is ordinarily the leading brilliant of Orion, but is sometimes surpassed by unchanging Rigel." Now, I have Peck's "Observers' Atlas of the Heavens," which contains a catalogue of stellar magnitudes, in which the two stars figure thus: β Orionis 0·8 and 0·9; and there is also a catalogue of variable stars which contains no mention of α Orionis as a variable. In the list of fixed stars in *Whitaker's Almanack* I read thus: α Orionis (Var) 1. Can it be that two such authorities as Ball and Proctor are mistaken? Or is Betelgeux in the course of a waning period? For, last night, in a clear, moonless sky, 10.50 p.m., Rigel was perceptibly brighter, though Betelgeux appeared many steps, perhaps half a magnitude, brighter than Aldebaran. This was before the rising of Sirius, whose surprising splendour seems to make more difficult the comparison of other neighbouring stars.—G. J.

[97061.]—**Tommy Atkins.**—Will some reader tell me the origin of this name, as applied to the private soldier?—E. L. H.

[97062.]—**Ether Freezing.**—Can any reader tell me how to make an ether freezing apparatus to use with an embedding microtome, and give sketch showing clearly how it works?—H. BAKER.

[97063.]—**Utilising Surplus Power.**—Having purchased one of the "B" oil-engines from Barker, Leyton, I find that I have got plenty of surplus power. Can any of your readers inform me of a way to fix a pump to the engine to lift 20ft. from a well 20ft. deep? I want, if possible, for the pump to be fixed on the engine, and driven direct from gearing. The engine is ½B.H.P., and gives 350 revs. per minute when driving my dynamo, and I can spare quite half of the power.—INKSPLASH.

[97064.]—**Mitre Blocks.**—Perhaps some of "ours" would oblige with their notions of the making of mitre blocks? How to make the blocks accurately would be a thing worth knowing. This is apparently not so easy as it looks. I have not been able to buy a ready-made one accurate enough to make an ordinary frame. Many of the articles appearing in "Ours" on carpentry and joinery generally instructed us to get a mitre-block, "which can be obtained in any tool-shop." These are chiefly a fraud, and, being of wood, make matters worse by warping. I suggest that a heavy cast-iron block, made on the three-sides-of-a-square pattern, and with the two cuts accurately made, and a special fine-tooth saw to fit the cuts, this would do away with the necessity of a shooting board for amateur work, which requires some skill to use. I feel sure that blocks so made, but, of course, accurate, would sell well, and, moreover, should not be costly. Most tool-shops have some elaborate mitre-cutting machines which make only an amateur shudder to look at. Perhaps some of your advertisers would take the idea up?—C. A. P.

[97065.]—**Whitworth Standard.**—Will some reader please give the calculation for Whitworth spanner sizes?—YOUNG ENGINEER.

[97066.]—**Observatory Lamp.**—Can any of your readers put me in the way of getting a good lamp for use in observatory—something clean, handy, and that will give a good light? I use one which burns colza oil, and am not satisfied with it. Horne and Thornthwaite used to list that sort of thing, but I understand they do not now keep them. I want something not too expensive—at the same time not too cheap and nasty. Can any of our electrical friends assist me?—NEMO.

[97067.]—**Bluing Steel.**—Is there any other way of bluing steel other than by heat? I wish to blue a pair of small rook rifles, as the original bluing has worn off. I tried the second and last recipes given by "Regent's Park" (No. 96366, Aug. 4), but with no success. The steel was perfectly clean and free from rust or grease in both cases. The only effect seemed to be a slight yellow rust. Will "Regent's Park" tell me why this is so, and how I can remedy it? Is the bluing on rifles obtained only by heat? If so, how?—ROOK RIFLE.

[97068.]—**Iron Moulding.**—What is the latest and best practice in melting the iron?—J. F. SEFTON.

[97069.]—**Formula.**—Will some contributor kindly arrange the following in the form of an algebraic equation? A compound contains so much per cent. of a certain element; how much of compound must be added to mass so as to make it contain as much per cent. of the certain element?—BAZIN.

[97070.]—**Oil-Engine.**—I have a ½H.P. gas-engine, with cylinder 2½in. bore, and would like full particulars as to how to convert it into a paraffin engine without coming into conflict with any patents? Will some of our correspondents oblige?—ENGINEER.

[97071.]—**Age of Violin.**—I have a violin labelled "A. Hardie Annan," which, from tone and appearance, is a good old instrument. Can any "E.M." reader give me any particulars of such a maker, as to the quality and age of his work?—HANDEL.

[97072.]—**Rotation of Shell.**—A shell fired from a rifled cannon rotates upon its axis during its flight. When the shell explodes (still in the air) are the fragments still under the influence of the rotative force? If so, how are they affected? If not, what has become of the force?—HINEL.

[97073.]—**Bleaching Horn.**—Could any reader tell me the quickest way to bleach the surface of dark-coloured horn? I want to bleach it in a few minutes.—OBLIGE.

[97074.]—**Water Power and Electric Light.**—I have available full 3in. pipe, water with a head of 50ft., about 100 yards piping that I wish to utilise for electric lighting. How many ordinary lamps could I have supplied with this power, distributed in a small district of cottages near by the installation? What size and price dynamo and necessary fittings? Also, what type of turbine or water-motor best to use, and estimate cost of the above complete?—INVESTOR.

[97075.]—**Small Motor.**—A small motor that could be used in an ordinary room would be useful for many purposes; say, for driving small dynamo, &c. I once saw, at an exhibition, a small hot-air motor, called, I think, "The Bee Motor." It worked by a gas flame. I wonder if this is made now, and what sizes are made, or, rather, up to what powers?—LANCASTRIAN.

[97076.]—**Medical Batteries.**—For medical purposes primary batteries are very unsatisfactory, and I speak from thirty years' practical experience. They are constantly varying in efficiency, and deteriorate constantly, but irregularly, whether used or not. If a dynamo could be devised that would give a constant indirectional current, suitable as to voltage and ampèrage for medical purposes, and workable by a small motor or by hand-power, it would be very useful to medical electricians. The dynamo current ought also to be able to work an induction coil suitable for the application of the so-called Faradaic current. Can Mr. Bottone or any of your experienced and learned electrical correspondents help me with advice?—LANCASTRIAN.

[97077.]—**Pronunciation.**—What is the current pronunciation in English society of Which, When, Why, &c.? Is the "h" aspirated before the "w" (hwich, hwen, hwy, &c.) as in Scotland and Ireland, or is it silent? Also, is "sure" pronounced "shoor," as in Scotland, or as "shawr"? I am familiar with the dictionary rulings. A reply from "F.R.A.S." would be valued by—E. N. R.

[97078.]—**Acetylene.**—When burning acetylene gas I notice a blue haze is given off by the flame. Is there any remedy? If so, please give particulars.—A. M.

[97079.]—**Wimshurst.**—Will Mr. Bottone or Mr. Wimshurst kindly state what is wrong with my Wimshurst machine, which I have made by the instructions given by Mr. Bottone in his book "Radiography," with the exceptions that the frame is of oak, driving-wheels pine, bosses and pulley-wheels box, and glass plates, which I have varnished with shellac varnish between the sectors. They never would excite very well, although I had larger brushes, and I could not get more than a ⅝in. spark. Since then I thoroughly cleaned them with strong soda water, methylated spirit, and benzine, but cannot get any effect at all, although it is in a room with a fire nearly all day.—L. A. K.

[97080.]—**Soap.**—Would any reader kindly tell me how to make a soap that will not lather, as I want the fat the soap contains in the water to mix with whiting, but not the air bubbles caused by the frothing? Can a soap be made with wax only, instead of grease?—EMBOSSER.

[97081.]—**Strongest Adhesive.**—Would Mr. Bottone, or any reader that knows, kindly tell me the strongest adhesive soluble in water and keep liquid like gum? Dextrine, gum arabic, liquid glue, &c., no good for the purpose, which is to make a strong distemper paint to dry quick. I have seen the adhesive I want, but cannot get to know the name (it being kept very secret),

It resembles seccotine nearer than anything I know, and it is readily soluble in cold water.—EMBOSSER.

[97082.]—**Dry Cell.**—To MR. BOTTONE.—Is the dry cell described by you in the last issue suitable for intermittent lighting? Is the zinc cylinder soldered together? Also, could you tell me the construction of the "Carsak" wet cell.—ONA IGSA.

[97083.]—**½in. Spark Coil.**—To MR. BOTTONE.—I have just finished a coil consisting of an iron rod, ⅜in. diameter, 6½in. long, primary ¼lb. No. 20 cotton-covered, secondary 6oz. No. 36 silk-covered wire. Upon connecting it to the battery, I just manage to see a very tiny spark upon touching secondary terminals together; in fact, I can bear them in my mouth without being "shocked." I notice when the secondary terminals are brought in contact, the contact-breaker stops working. I took great care to insulate each layer with paraffin wax and paper. Can it be that I have wound the secondary in the wrong direction to the primary wire? The secondary I bought new. It has several joins in it, with "kinks" innumerable. Would that make all the difference? If I wrap the tinfoil of condenser round outside of coil, would that improve matters? How are sheets of tinfoil cut so that odd numbers are joined, and even numbers the same?—E. D. WAYLING.

[97084.]—**Imitation Gold and Silver Paint.**—Will any of your readers let me know how to make these paints, ingredients, quantities, &c.?—DECORATOR.

[97085.]—**Spark.**—What length spark would be probable limit for a coil, whose core is 10in. long, 1in. diameter, No. 22? Primary: two layers No. 18 c.c. (½lb.) Secondary: 2lb. No. 36 s.c. Condenser: 100 sheets 8in. by 6in. Using two pint chromic cells. What weight of iron wire (No. 22) is needed for core? Finished bobbin: 3½in. by 8½in. diameter. Screens: Has any of "ours" tried the following formula? If so, kindly give results. "A new mass phosphorescent under the X-rays, and is said to be more sensitive for screens than all substances known or employed. Dissolve 1 gramme uranium nitrate in 4 grammes of boiling water in a porcelain dish, adding 1½ grammes am. fluoride, and boil the mixture for a few minutes. The solution should not contain precipitate, and is cooled off and crystallised, which takes place in an hour. The octahedral crystals deposit on bottom of vessel, and the pale yellow solution turns perfectly colourless. The liquid is poured off, and the sediment is washed repeatedly with cold water (to complete removal of am. nitrate). The crystals are insoluble in cold, but readily soluble in hot, water. For production of screens the dried preparation is mixed with collodion or gelatine. The quality of the preparations depends upon the perfect development of the crystals = (uranium ammonium fluoride = $U_2O_2Fl_4(NH_4Fl)$. Will Mr. Bottone kindly give date of probable publication of the 7th edition of "Instrument Making" (electrical)? and will he also state reasons why the Carré's dielectrical machine is not more used? To quote from his book: "Machine having plates 15in. and 19in. produces sparks 6in. to 7in. long, and, if pair Leyden jars attached, this can be exceeded." A Wimhurst probably could not beat this length, having pair plates, say, 19in. or 20in.—DIFFERENTIAL.

[97086.]—**To Mr. Bottone.**—I am much obliged for your reply to my query (96997) *re* faulty dynamo, and inclose a few particulars. The form of machine is overtype. Size of armature 8½in. by 6in., exclusive of commutator; field-magnets about 5½in. diam.; size of wire on field-magnets about ⅛in. diam., including covering. The machine runs at 1,300 revs. per minute, and gives 16 amps. at 110 volts pressure. I cannot tell whether the armature is solid or laminated. I do not remember the machine ever running cool. The word "casts" should read "coils"; it was a printer's error. The machine was built by Rosling and Matthews, Bradford.—M. S.

[97087.]—**Watch Jobbing.**—A lever watch goes well when not worn, but when carried in the pocket it often gets some minutes slow occasionally. What is the reason of this? In examining wheel and pinion depths, sometimes a pinion is found too large. How should the depth be pitched to get the best action, as sometimes the piece will not allow much alteration?—COUNTRY JOBBER.

[97088.]—**Motor.**—Can any reader give me particulars as to motor, &c. (using oil, not spirit, so as to be able to replenish at any out-of-the-way village) best suitable for driving pleasure van, weighing about 30cwt. loaded, at a speed of, say, three and six miles per hour? Allowing for hills and soft roads, would 6H.P. be sufficient? I should probably build new van if above is suitable.—TOURVAN.

[97089.]—**Pneumatic Covers.**—How is the rubber stripped off these? I find soaking with benzoline very slow?—REPAIRER.

[97090.]—**Salt-Water Ice.**—I should be very glad if some of our scientific friends would give me a little information with regard to the above. A friend of mine assured me that the ice resulting from the freezing of salt water contained hardly any salt at all, and if that be so I should like to know what becomes of the salt. Does it remain behind as a solid when the water is evaporated, or is it still present in the ice, only in some different form? I must confess I am puzzled, but it must be a question that could be very easily settled by anyone having the means of producing the low temperatures possible at the present day, for with alcohol frozen the very strongest solution of salt could hardly be expected to remain liquid.—F. M. M.

[97091.]—**Defective Circuit.**—Can any of our electrical readers explain (with a view to remedy) the following defect? I have in use an electric call between two rooms on three wires, which answers perfectly; but taken from each pole are short pieces of wire connected with a clock, which at a given time makes contact, and rings the bell in my room on the circuit to the other room. I have plenty of battery power—viz., two Leclanché cells, which perform all I want for a time, but occasionally bucks up as far as the clock is concerned, and although the contact is made, no current passes, and no bell rings, but as soon as I ring from my push to the other room (and having switched on the clock again), I get a current through to the bell, viâ the clock. All connections are perfectly clean, and wires sound, and as it is most important that the clock should actuate the bell, I should be pleased to find out the remedy for the failure, which is only occasional, but very annoying.—ELECTRIC.

[97092.]—**Cranberries.**—Can any of your readers help me to understand one of those curious paragraphs which appear in the papers under the head of "Week-end Prices." I read in one that "It were wise in the cook to make every use of such seasonable cooking fruits as cranberries and pears while they are with us. They are both cheap fruits." I may be mistaken, but I have a recollection that I could buy cranberries all the year round in London. When do they go out of season nowadays? I have a recollection that cranberries are always in season, and that in the pie-shops in London you could always get cranberry pies when the home-grown fruits were "out."—R. H.

[97093.]—**Motor Cycles.**—Would some reader kindly say if phosphor bronze, or some similar metal, is suitable for an air-cooled cylinder? It could be made thinner than cast-iron ones, and be less liable to get the cooling ribs broken off. Also, what are the objections to ball-bearings for the crankshaft?—MOTIST.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries, put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Nov. 15, and unacknowledged elsewhere:—

TECHNICUS.—E. G. Woodhouse.—Alex.—T. B. G.—C. A. Naylor.—Jack of all Trades.—W. F. Stanley.—Gavin J. Burns.—Rev. J. M. Bacon.—Alex. Smith.—Medical.—F. Mason.—H. A. S. Upton.—Himer.—W. Maclachlan.

PHASS.—Quite out of our line to advise as to practicability of inventions or chance of Government adoption. Better look up specifications of existing magazine-rifles at Patent Office, and form your own conclusions.

OPTICAL L.—Surely you and other readers know that Dr. Aveling, the author of the series, is dead?

MEDAL.—Must ask a dealer. We can't deal here with values of medals and other curios.

DANIEL HANES.—The query was duly entered in the list of "Unanswered" on p. 143, and appears again on p. 237. Only the number and title of queries are given in the list. Possibly the query asks too much, or is not to be answered.

ENGRAVER.—Try such a firm as Brodie and Middleton, Long Acre, W.C. There are several works which give designs for monograms.

H. J. TREMLETT.—Directions for making accumulators have been frequently given. See the index of the last volume.

HOUSEMAID.—If medical men fail to help, how can those who have never seen you? State the query to Dr. Allinson, through the *Weekly Times and Echo*.

W. H. BLAND.—Do not care for first subject. Descriptions of processes only to be carried on in large works are, as a rule, only of second-rate interest to amateurs. As to the second, much depends on the nature of the articles, but it sounds more in our line.

S.—No more risk than with any other grinding machinery. A respirator will prevent any of the consequences you refer to.

W. H.—The loss of taste or smell is a symptom of several maladies—not a disease in itself. It would be ridiculous for anyone but a medical man who had not personally examined you to offer an opinion.

C. W. CROSBIE.—Please see many replies in back volumes. The lenses are not suited for the purpose; but for directions as to how to construct the optical lantern see a series of articles beginning in No. 1377, Aug. 14, 1891. There are many hints on the subject in back numbers; but the series of articles mentioned practically exhausts the subject of the "magic" or optical lantern.

R. H. SPENCER.—The British Commissioner-General for the Paris Exhibition is Col. H. Jekyll, C.M.G., St. Stephen's House, Westminster, S.W.

A. T. M.—"Mineralogy," by J. H. Collins, published by Collins, price a shilling, will serve as a guide; then possibly the most useful work would be "The Geology of England and Wales," by H. B. Woodward, published by G. Philip and Son, Fleet-street, E.C. For general mineralogy, Dana's works.

G. B. ELLIS.—Thanks; but we gave not long ago an exhaustive series on the subject, and cannot spare more space yet awhile.

NEW READER.—It is impossible to answer your question without dimensions are given, and it is equally impossible to spare space for, and cost of, engravings of model dynamos, simply that the individual reader may be told how much wire they will take.

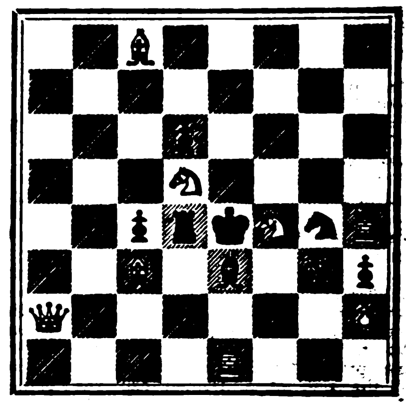
ARTHUR BRIANT.—These lectures are usually copyright. If we can publish them we will do so. If not, you will probably be able to get them later on in the *Journal* of the Society of Arts, but not till some months, as a rule, after their delivery.

CHESS.

All communications for this column to be addressed to The CHESS EDITOR, at the Office, 332, Strand.

PROBLEM No. 1701.—By C. FARAFFINI.

Black. [7 pieces.



White. [9 pieces.

White to play and mate in two moves.

(*Solutions should reach us not later than Nov. 27.*)

Solution of PROBLEM No. 1699.—By C. A. GILBERG.

Key-move, B-K B 6.

NOTICES TO CORRESPONDENTS.

PROBLEM No. 1699.—Correct solution has been received from J. E. Gose, Richard Inwards, A. Tupman, Rev. Dr. Quilter, Alfred E. Oxley, Quizco, F. B. (Oldham), T. Clark, J. Mason.

E. THOMAS, H. HILBRAND, W. H., P. H.—Only solution as above.

P. H. (Dundee).—With every desire to assist, it would still be impossible to give satisfactory explanations in problem-solving within the limited space at our command. From the nature of your questions, it is evident that you are in the very early stages of Chess, and a little personal advice from a friend would be the best at present.

J. H. BLACKBURNE'S "Games at Chess" have just been published by Messrs. Longmans and Co. in one handsome volume, and chess lovers have put before them a carefully edited and complete collection of this popular master's games. The editor, Mr. P. Anderson Graham, has written a sympathetic life of Blackburne, and has added a brief history of Blindfold Chess. The editor claims that the book presents a picture of the Chess of the whole world during the time of the present generation. Examples from the games of every great master, from the day of Staunton to that of Pillsbury, will be found within its cover; examples, too, from nearly every land, and culled from many different languages. Nor is this all that is claimed for the volume: There is scarcely a local club in the British Islands, scarcely a local champion who does not figure there, so that we cannot be wrong in saying that the book contains specimens of every extant style of play. With this claim we think there will be none to cavil after a slight perusal, and it will be found a source of continual pleasure to the numerous admirers of Blackburne's brilliant play. The only fault that can be found with the book is the price—viz., 7s. 6d., which, in these days of cheap production, is unfortunate, if not prohibitive.

AND WORLD OF SCIENCE AND ART.
FRIDAY, NOVEMBER 24, 1899.

INLAYING.—VII.

THE accompanying designs (Figs. 112, 113, 114, 115, 116, and 117) are mainly for creasing, by the aid of tracings laid upon the work, and creased over with the tools. Where straight lines are mainly in demand, it will be as well to gauge for widths, either from the outer edge of the work, if permissible, or resorting to a temporary fixture of some kind. We have made good use of thick cardboard or millboard. Much must be left to the student.

Where corners have to be done, cutting the design out of the thick millboard, and using the same as a guide for the creasing-tool, will certainly give the best results and exact form throughout.

It will be necessary to warm the iron tools so much that they indent the leather and polish it at the same time. If the leather should happen to turn up brown, then the iron is too hot. If there is no gloss, the heat of the iron is too low. Although we have advised the use of card or millboard, it does not follow that metal is not used as guides. In fact, where much has to be done, the use of metal gauges and straightedges will be the cheapest in the long-run. For narrow edges there are special irons made with a side lip, and for sharp turns narrow tools are much in vogue; and where circles are called for, different diameters and thicknesses of brass tubing will prove of value. If the tubes should happen to be short, they can be mounted on wood handles. Square drawn brass tube can also be purchased, and mounted as above stated, for squares of all sizes.

Just a few words as regards the gluing of leather work. If the work is of such a nature as to permit of quickly glue the same, then moderately thin glue, pure and simple, is only needed, not too hot. If the glue is too hot, it is liable to diminish the high relief or embossing that some leathers carry. In gluing leather of the above description, it

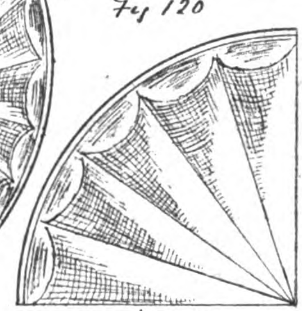

Fig 121

Fig 123

will be needful to lay the cut-out piece on a sheet of newspaper, and stipple the glue on to it. The groundwork must perforce be also glued. Too much rubbing down is not needed, in fact, a moderately stiff shoe-brush will be most useful with hard-grain leather; but where the leather is very thin and highly embossed, a softer shoe-brush must be used; but with morocco or seals, the use of a rolling pin of soft wood will help mat rially to gain perfect adhesion, and yet not injure the face. Where joints are required, whether on the flat or near the edges, paring must be done; otherwise unsightly ridges will be perceptible. When gluing the leather that lies face downwards, watch narrowly that no glue creeps under, and so on to the face.

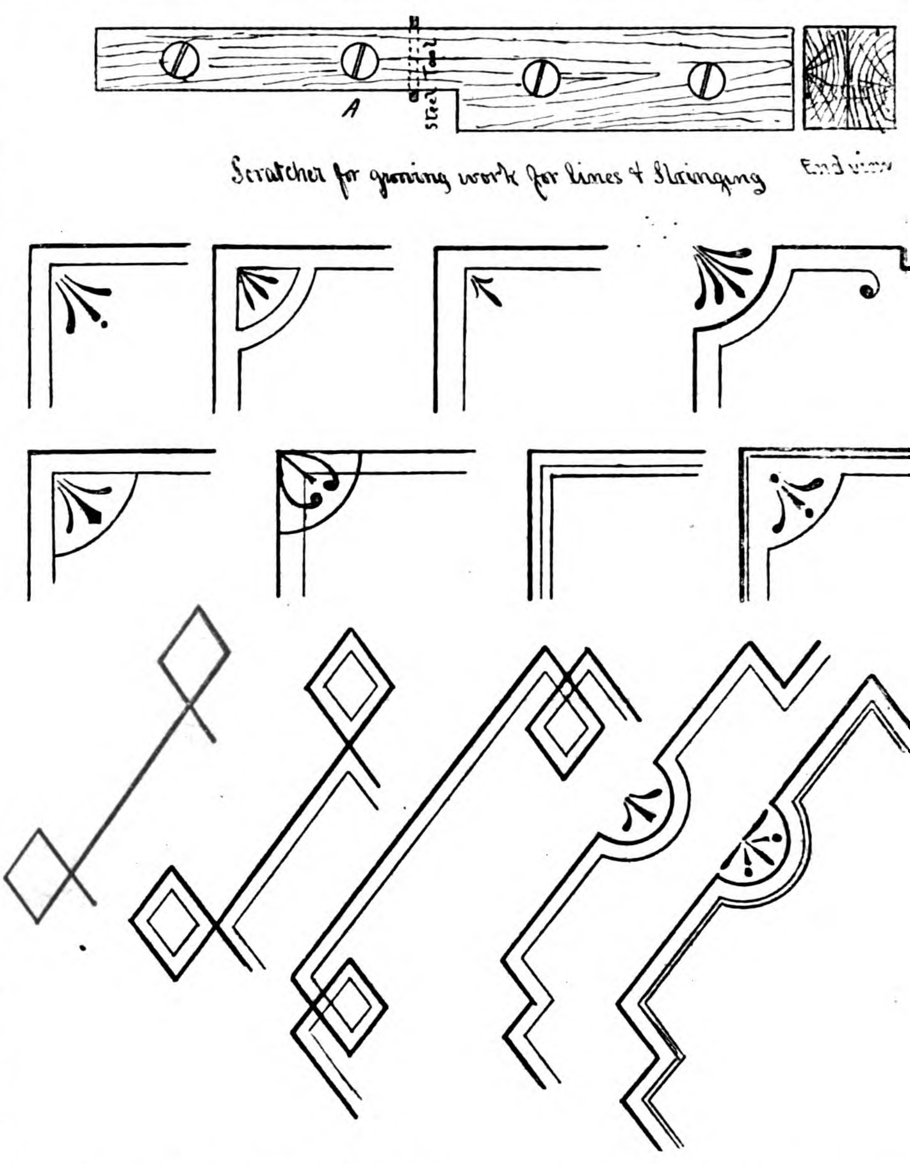
Creased work is greatly enhanced by gilding the lines; the process is simplicity itself. After a partial creasing, the surface of the leather is damped with diluted white of egg; narrow strips of gold leaf are cut on a gild r's cushion, and taken up with a tip. Providing the glair is not too fluid, or too dry, the gold leaf will quickly set itself, and sink into the indentations. The exact condition to be creased with the warm tools will be better determined on spare pieces for practice than from a whole page of written matter; but this may help to overcome any disastrous results. If the iron is too hot, it may work up the leaf if laid on a fluid glair; but that may be avoided by going over the work very gently, increasing the pressure as the gloss appears. But if the leaf ground is too dry it may possibly work up bodily, and be glossy with an entire absence of gold leaf.

When the ornamentation is of the nature of a border as well as lines, it may be advisable to add a little shoemaker's paste to the glue, about three parts glue to one of paste. Opinions vary with respect to gilding; some will maintain that good and bright work cannot be got with glue alone, others again will only use the above reversed—viz, three of paste to one of glue. Where the leather's face is brighter than wanted, a wash can be purchased that will tend to dull it, working the surface in the mean time with a soft shoe-brush. The above wash only applies to black leathers: it is not often resorted to where coloured leathers are varnished, such as writing tables, &c.

The wider the crease line the less is the preliminary creasing or indentation. For it must be borne in mind if the hollows made by the creaser be too deep, there is just a possibility of splitting the gold leaf; if that occurs, apply another narrow strip of gold leaf to cover the imperfection. That should be done before the glair sets; but if it should happen to be too dry, it must be damped down again. If that is attended to, a saving is effected with the gold leaf. After gilding, the surface should be cleansed from the excess glair, and if it is desired to have a slight gloss, then a thin coat of parchment size is passed over the surface of the crease lines; but that should be done quickly, and in a warm room. For panels, or hanging specimens, the after-sizing is a decided acquisition.

A flat piece of cork, with a piece of clean white rag tightly stretched over the face of the cork, when slightly moistened, will quickly wash off the above excess, and tend to preserve the leaf in the creasing. It will be patent to all that to preserve the width of the lines some practical method must be adopted. With a loose rag failure is almost certain.

Before proceeding to the next task, it will be as well to hark back a little, because we have omitted to explain the method employed to let lines, or, as is it generally termed "stringing," into our ground. Where the work is such that the carver's parting tool is not adequate, we resort to scratching them in with a stock and little steel tool of different widths to suit the different widths



of stringing. A rough sketch is given at A, and is simply two pieces of hard wood screwed together as marked, and cut away to form a shoulder or support to guide the tool in its passage of grooving out the channel to receive the lines. Its use will be readily understood. By shifting the piece of saw-blade, which, by the way, makes useful scratchers, any distance from the edge of the work can be obtained. In working round parts, great care is necessary, and that applies to the hollow sweeps as well; but it is invariably an easier task after a little practice. With straight work, rapid progress can be made without much trouble or forethought. Where the confidence is lacking to produce a clean-cut groove, a smaller tool should be used first, widening the groove with a tool the width required.

Where circles, or parts of circles, are required, a fairly stiff pair of compasses will be needed. One leg of the compass can be ground to the size and squared to form a cutter, the other leg can be pointed and used as made or ground to a finer condition. A pair of compasses with a shifting leg will permit of having a number of cutters to suit the different widths, as before stated. Another simple tool is like the above scratcher, without the angle-piece cut out. By using a round point and a square cutter, different diameters of circles can be gained, according to the position they hold in the stock (scratcher). There is one point of importance: If it is found necessary to use the pointed leg of the compass in any part other than a groove, or where a groove may be worked afterwards, then it will be necessary to glue a little piece of hard veneer to hold the centre, while the square leg of the compass works the circular groove. It is an easy matter to remove the veneer when all is done. Do not leave a mass of glue clinging to your work. The wisest plan is to wash the excess with lukewarm water. The better the cleaning, the easier the task of preparing for polishing. If a round dot is used to complete the ornamentation, then the above-mentioned veneer will not be needed. The centre hole will only require enlarging to suit the dot. All lines, stringing, or banding should be an easy fit. If too tight, breakage will assuredly follow. If too loose, it is just possible the lines will rise or bulge here and there. If such should happen, then the flat cauls, as in veneering, should be used, with a piece of clean newspaper intervening, so that when cold the caul should lift without any of the work adhering to it.

The above remarks hold good in the case of small pieces of cutting, whether of wood or metal. The latter must be roughed with a coarse file to gain a tooth, and thus assist the unity of the two bodies. Narrow brass lines should be well cleaned, and will bear a slightly tighter fit, for it must be borne in mind it is not the glue alone that holds.

The designs given under the sketch A are suggestive of either wood, ivory stringing, and can carry a different coloured material between the coarse and fine lines, and can readily be adapted for corners or panels, and can also be used as specimens of creasing, and will bear, also, different coloured leather between lines, or the little panels can be of different coloured leather and creased to suit the taste of the reader. Many others could be given, but the present should form a guide

to any future modification that may be thought of.

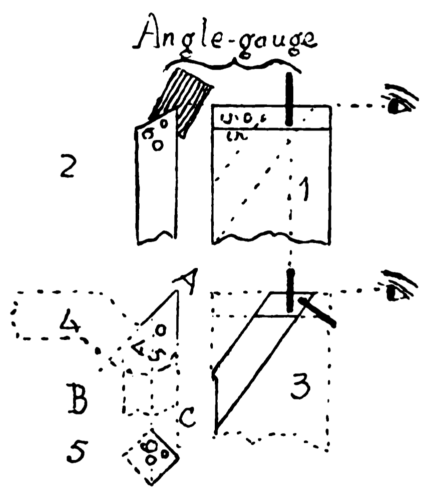
ERRATA.—Fig. 91 was unfortunately reversed; not that it makes much difference, but if it were designed as a hanging or suspended specimen, it would necessitate a slight alteration of the flowers, &c.

ON THE ANGLES OF THE EDGES OF SLIDE-REST TOOLS.—II.

By "D. H. G."

MISAPPREHENSION as to the true angle of an edge often arises from the accident of its shape, or from the position in which it is placed on its stem, or from the fact of one of the two facets required to form an edge being common to more edges than one. But the rule by which the angles of all edges should be measured is very simple, and admits of no exception. An edge, or any point in an edge, is a solid angle made by the intersection of two facets, and the inclination of these to each other determines the angle of the edge. The lines upon which this angle is measured should start from the same point in the line of the edge and pass at right angles to (or square with) this line on *both* facets. When any portion of an edge is rounded, the same rule applies to the *tangent* of any particular point in the curve that it may be desired to measure. For the present purpose this latter rule is sufficiently demonstrated by the foregoing illustration No. 2; for no two tangents to a curve can lie in exactly the same direction, and it has been shown that with a flat upper face no two adjacent points in the edge can be of exactly the same angle. If one facet of the edge were convex and the other concave, the result might be different. But whether the edge be straight or curved, its *shape* is no guide to its *angle*, and this may be experimentally demonstrated in a very simple manner by anyone who cares to do so.

Let Fig. 1 represent the wooden model of, say, a chisel, bevelled to contain an angle of 60°, as shown in the side view, Fig. 2. If it were required to judge of the acuteness of the edge by the eye alone, the chisel would be held sideways, as in Fig. 2, so that the eye might look along the line of the edge, as in Fig. 1. Suppose it were required to test this angle by any simple gauge, such as as a nick cut in a piece of tin or cardboard (shown in the position it would occupy in Figs. 1 and 2 respectively), care should be taken to make the gauge sit square with the lines of the edge on both facets; as, if the gauge were placed askew in any direction, it could not give the true angle of the edge. Now, if two saw-cuts be made obliquely across the face of the chisel, at an angle of 55° with the line of the edge and the same distance apart as the thickness of the model, the "shape" of the diamond-pointed graver will be cut out of the chisel without interfering with the angle of its edge. If it were correct to test the angle of the graver in the way described above, when it formed an integral part of the chisel, the same rule must be applied when it forms only a section of the chisel—viz., that the angle must be tested on lines square with the line of the edge on both facets, without regard to its "shape." To make the illustration more evident, Fig. 1 is repeated in Fig. 3, the only difference being that in Fig. 1 the outline of the chisel is drawn in full lines and that of the graver is suggested in dotted lines, while in Fig. 3 the order is reversed. The "eye" is repeated in Fig. 3 to show that, when the angle of the graver is estimated in this way, the tool should be presented to the eye in the same position which it occupied when it formed an integral part of the chisel; and in the same manner with all straight edges, however they may be formed on their stems. It will be observed that the division of the chisel in this way has given the graver a second cutting-edge on the lower side of Fig. 3, and the angle of this edge must be tested by the same rule as the first, as there cannot be two ways of testing an edge by actual measurement, and the position of the angle-gauge is changed accordingly. If the saw-cuts has been correctly made at an angle of 55° with the line of the edge of the chisel, this second edge will be found to be of the same angle as the first—viz., 60°. Thus the model of the graver will be completed with a square cross-section and two cutting-edges of equal angles. In order to estimate the angle of the *bevel* which has produced the cutting-edges of 60° each, turn the model sideways, as in Fig. 4, and it will be found that the "bevel" is 45°, thus making a difference of 15° between the angle of the bevel and those of the two edges so produced. The lozenge-shaped upper face of the graver being an accident due to facility of construction and convenience in use as a hand-tool, in Fig. 4 only that portion which supplies the cutting-edges is drawn in full lines, while the rest of the outline is completed in dotted lines, and the like arrangement is adopted in Fig. 5, giving the cross-section or "plan angle" of the upper face of the edge. "Holtzapffel" remarks upon the very close resemblance which the edges of V-shaped slide-rest tools bear to those of the graver. To make this more obvious, the stem of a slide-rest is suggested by dotted lines in Fig. 4 to the same cutting-edges as those of the graver, and it will be seen that not only the principle of construction, but also the "shape," are almost identical. If these edges are to work out corners quite square they must be pointed, and the angle on both sides should be of the same degree of acuteness, so that they may work (alternately) on either side of the corner. The angle required for clearance is so low in the case of cutting that it may be practically overlooked in tracing the resemblance. The only points of difference are



that the upper face, as seen in "plan," must be less than 90°, and the "bevel" must be less acute. Reference to the angle B A C in Fig. 4 will show that the so-called "cutting-angle" of the slide-rest edge and the "bevel" of the graver are one and the same thing; and in this case the model will have proved that there is a difference of 15° between the two terms. "J. H." quotes the "cutting-angle" of the Smith and Coventry V-shaped cutters as "embodying an angle of 68°." Here the difference would not be quite so great, for Prof. Willis has shown that in edges of this class the difference between the angles of the "bevel" and the resulting cutting-edges decreases as the "bevel" is made less acute, and *vice-versâ*. It is impossible to be exact without knowing both the *plan angle* and *bevel* of these cutters. But, judging from one of Smith and Coventry's illustrations, the "plan-angle" cannot exceed 70°. Referring to Prof. Willis's table, which shows the various combinations of the "plan" and "bevel" angle, which will produce "cutting-edges" of a given angle, I find that a "plan-angle" of 70° requires a "bevel" of 63° to produce cutting-edges of 75°; and as "J. H." quotes the "bevel" as 68°, it is certain that the edges must be less acute than 75°—probably about 78°. But exactness on this point is rather a question of curiosity than importance. The object has been to prove the fallacious nature of the so-called "cutting-angle" as the standard by which to estimate the angle of the edge employed, and, consequently, of all deductions founded on this basis. In the first example adduced by "J. H.," it has been proved mathematically that, so far from the term "cutting-angle," defining the "constant" angle of the edge, there is only *one single point* in the whole edge which corresponds to this definition; and in the second example it has been shown, on the authority of Prof. Willis, that there is a difference of about 10° between the angle thus described and the real angle of edges which do the work. An error may be stated dogmatically in a few lines which it may take pages to disprove, and this must be my apology for occupying so much valuable space. But if the reasons and references given have warned any novice to distrust such "books" as take the "cutting-angle" for the standard by which to estimate angles, the space will not be altogether wasted. With such a standard, "angles may exist in books, but *cannot* survive in practice."

Having endeavoured to show the fallacy of one theory, I am bound to suggest another if I should be challenged to do so, and in this case I will endeavour to explain the practical application of the principles enunciated by Prof. Willis in the treatise referred to above. I can honestly say that, during a period of almost 40 years, I have derived more practical advantage from the careful study of this treatise than I ever gained from the methods and practice of the machine-shop, though my advantages in this respect were perhaps unusually favourable for an amateur, as it gave the opportunity of practising on work of all diameters.

HOW SCENTS ARE CARRIED.

A CERTAIN vague suggestion of something disagreeable, but imperfectly realised, which has somehow been invading my sanctum, seemingly by the open window, has suddenly assumed definiteness and brought vividly to mind a scene associated with painful recollections.

A large tract of common is burning some three miles to windward, and, though the air without is clear of visible smoke, there assails my olfactory nerves the smell of charred, dry stems of furze. The odour of this wood when burning is utterly unlike that of any other that is to be found in an English faggot-pile, but it sufficiently resembles that of a firewood used extensively in India, and my first experience of the kindling of this was after a forced and fatiguing railway journey of a thousand miles. When arrived at Benares with nerves somewhat jaded, and while being, by way of relaxation, punted by native guides down the Ganges, I was brought up, all unsuspecting, within close range of the horrors of the Burning Ghât. The gruesome reality of that scene is now irresistibly recalled simply by the odour of the smouldering common.

And this opens up one or two interesting inquiries as to the propagation of that impalpable essence that "scents the evening gale." I have to a certain extent been able to carry out some practical investigation in this matter. It had occurred to me that as a distinctive smell may be carried for great distances across country, the same might be conveyed also to considerable heights into the atmosphere. Yet I have never come across any records gathered from balloon voyages confirming this idea, though it is certain that some of our best observers are to be reckoned among balloonists. Assisted by others, however, I have constantly at all reasonable heights endeavoured to notice if, say, the fragrance of the limes or a beanfield in full flower, or even the strong exhalations from gas or chemical works or a tanyard over which we may have passed, have been noticeable from above; but the result has always been negative, chiefly, as I imagine, because of the proximity of the great bulk of gas overhead, which even when not actually obtrusive, probably suffices to mask any other traces of odours in the atmosphere.

It may not be generally known that it is imperative that the neck of a balloon should be kept open as soon as an ascent has commenced, from the fact that as the balloon reaches higher levels the pressure of the external air is diminished, and the expansive power of the imprisoned gas thus being subjected to less constraint, would infallibly burst the balloon but for the open mouth, from which the gas issues to an extent sufficiently appreciated by the occupiers of the car.

A special experience of my own, however, may throw some light on the present question. I was engaged during three or four ascents in carrying out acoustical experiments by means of fog-signals fired at a safe distance below the car. These signals always consisted of one particular type of cartridge, composed of cotton-powder, presumably uniform in character, and were invariably let down to the same distance in the free air below by means of a length of twin wire, and then fired electrically.

On one occasion only was the smell from the powerful explosion detected; but this once it happened that, at the moment of firing, the balloon was descending rapidly, so that we were

almost immediately plunged into the atmosphere of the bursting cartridge, when it was noticed that the products of combustion seemed for a considerable length of time to hang about the car as a cloud of strong-smelling gas. And this, then, is really what the state of the case appeared to be—namely, that an odorous cloud or volume of gas was produced, travelling uniformly with the balloon, but not diffusing itself rapidly—at least, in an upward direction.

With respect to this same view, a correspondent writing to one of the scientific journals a few years ago, states an instance when a boat's crew, four hundred miles from land, had been enveloped in a dense wreath of wood smoke; while in his own experience he had occasionally noticed on the west coast of France, after a westerly gale of exceptional violence, a smell as of primeval forests, which he could only conceive as having been borne across the Atlantic entangled in the bosom of a cyclone.

The writer remembers an occasion early in the "sixties" when, while living at Old Charlton in Kent, he was an observer of a fire that had broken out at some oil-stores near London Bridge, from which the smell of burning fat was carried down the wind on the close air of a November night, so overpoweringly intense, as perceived at the distance of seven miles, that it must have been detected at many miles further away, yet the breadth of the ill-odoured stream was, comparatively speaking, very limited, proving that diffusion in a lateral direction was either very slight or very sluggish. Penetration to a distance was apparently almost entirely due to wind currents.

As lending colour to this view, I may be allowed to quote the laboratory experiments of Prof. Ayrton, by which he showed that when the space through which scent had to pass was screened from draughts, it diffused with surprising slowness. A tube 3ft. long, closed with a cork at one end, and having at its other end a plug of cotton wool saturated with oil of limes, was brought into an odourless room and uncorked, when a momentary smell was transmitted through the tube by the mere act of uncorking; but after this momentary whiff, an interval of eighteen minutes elapsed before the scent became definite and recognisable.

We have all had experience of the difficulty of determining, and yet more of locating, any feeble and ill-defined smell within a building, to account for which there seems a double reason. In the first place, just as the ear becomes quickly fatigued when listening intently for faint sounds, so in like manner does the acuteness of the nose become blunted in the quest of any very feeble cause that appeals to its sensibility. And again, the slight traces of any emanation seem (as in cases just cited of the smell of burning carried on the wind) to be borne on slender streams or currents that are always circulating about a room.

The case is well put by the author of a "Faggot of French Sticks" in a description of his lodging in Paris. He was joyously admiring his chamber when, as he says, "with great velocity there shot past my nose—to tell the truth, it actually hit it—an arrow of air about a foot long, but no thicker than a piece of packthread, that did not smell as it ought to do"; later, "there whizzed by another very little arrow. In less than the twinkling of an eye it had completely passed, and where it had come from, or where it had gone to, I was alike utterly ignorant." But again, "while lying down, there rushed past the uppermost feature of my face, not an arrow, but a javelin."

The author of this graphic, if painful, description: surely stated the case with much perspicacity. Lying awake in the early hours of a still summer morning, with broad daylight in the room, but while as yet there is no disturbance about the house, dust motes may be seen in the level sunbeams careering about the room in most erratic fashion, and if a winged seed of dandelion has been wafted in through the open window, its movements, though only of the same order, will become more definite. It may be slowly climbing down the opposite wall, when suddenly it will be minded to explore the ceiling instead, yet before it has reached this region it has been seized with a fresh freak, and shot out straight into the room after the fashion of the little arrows described above.

It is now easy to see how it comes about that the scent of hunted game is carried readily enough down the wind, though by its slow diffusion it continues to dwell about each spot where it has been once impressed. And it will be equally just to point out that in like manner the tainted breath from any unwholesome source tells its own warning tale to the winds, but at the same time does not otherwise spread itself with any uncontrollable rapidity. And this law as affecting the economy of life in many ways, is far-reaching.

The extent to which the sense of scent can intensify the enjoyment derived from the exercise of other senses can hardly be overestimated. It has long ago been noticed how the flavour of aromatic herbs or spices is largely due to the agreeable perfume belonging to them, and the same is also true in a modified degree with all that we eat and drink; so that, regarded from this point of view, the nurse is justified by sound scientific reasons in holding Master Tommy by the nose when she administers a dose of nauseous medicine.

But there is far more to be said. Who shall tell how much of the charm of some pleasing scene is not due to the fragrance we associate with it? The briny gale is an essential factor in our enjoyment of seaside scenery. The gorse, in our imagination, is the more golden for its perfume, and one half of the delight in all on which we feast our eyes in early summer is brought us by the breeze laden with the scent of hawthorn or fields of new-mown hay. In the self-same manner the murmur of the summer breeze across herbage is music to my ear largely because it reminds me of rambles on the downs, and in imagination I scent the wild thyme and the clover. I am not quite sure that it would be unreasonable to suppose that the feeling of wretchedness connected with a heavy cold is not in some degree due to the sense of smell being blunted, and other contingent enjoyments being impaired thereby.

As to the cultivation of the human nose we are not without suggestive facts. In a large biscuit factory known to the writer it was at one time the practice to test the large number of eggs used by the simple process of breaking them and allowing each palpably to declare its condition of freshness or otherwise. It was, at first, a painful thought that any man should spend all his working hours in this operation, so terrible to contemplate, but in point of fact there was no penance in the work, so instantaneously was each egg as soon as broken either acquitted or placed beyond reach.

It was difficult to conceive a sense more accutely trained and developed, yet we are told of a still more remarkable faculty in the savage. Thus Humboldt asserts that the Indians of Peru are able to determine in total darkness whether an approaching stranger be a European, American, Indian, or negro!

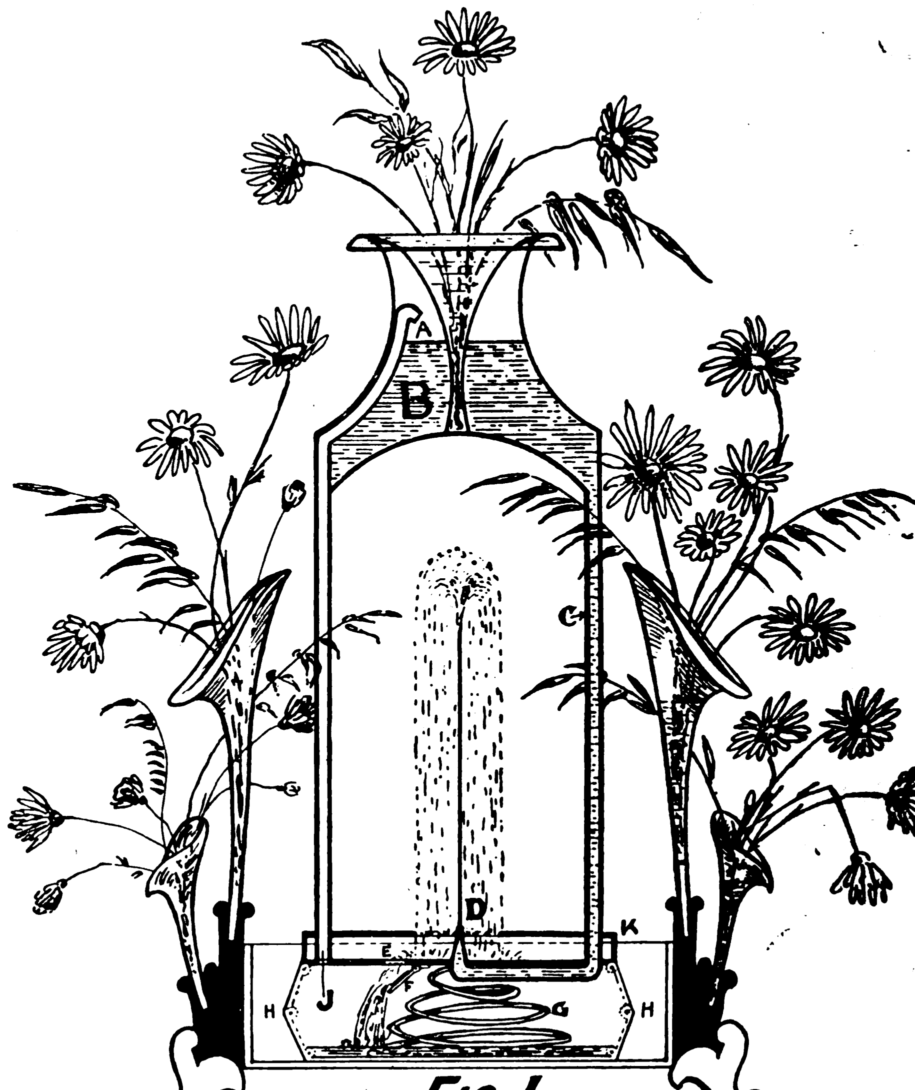

FIG. I.

PNEUMATIC FOUNTAINS.

PNEUMATIC fountains for decorative purposes may be adapted to various forms of epergnes with pleasing effect. The principle on which I construct this class of fountain may be gathered from the two examples illustrated in Figs. 1, 2, and 3. A vessel capable of holding a considerable quantity of liquid is elevated to the highest point in the epergne. Reference being made to Figs. 1 and 2, a vessel, B, rests upon a waterproof cushion, H. This cushion, which is made of rubber, is fitted in its interior with a pair of hinged supports, shown at the dotted lines H H. It has an inlet at E, which at the desired moment is automatically closed by the flap F. A powerful spiral spring, G, supports the vessel B, and at the same time retains the full expansion of the cushion. A pipe, J, is fitted to the upper surface of the lower receptacle, and extends upwards into the top vessel, where its extremity is bent over in the manner shown at A. Another pipe, C, of the same dimensions, is fitted

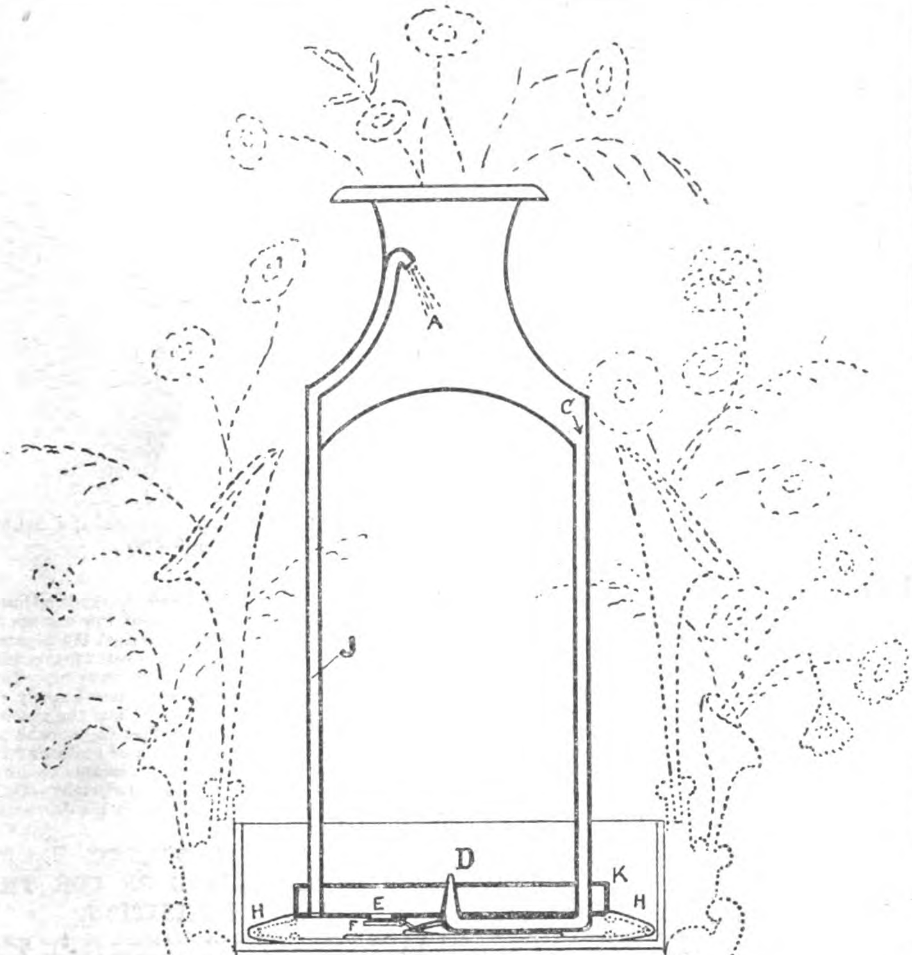

FIG. 2.

to the opposite side of the apparatus. The top end of this tube is flush with the bottom of the top vessel, and its lower end is twice bent at right angles, finishing off with a fine jet at D. The thick line at K represents a shallow basin, into which the water falls previous to draining off into the watertight receptacle through the inlet E. A fountain thus constructed is actuated in the following way :— A suitable quantity of ordinary or coloured water is poured into the basin K, when it will immediately run through E, causing the air to pass out through the pipe J into B, and from thence through C and out of the jet D. When the lower vessel is nearly full of water, the centre portion of the epergne is pressed downward, and the watertight cushion thus made to collapse, as shown in Fig. 2. It is now apparent that by the upward pressure of the water the flap F will be pressed against the inlet E, preventing the escape of water at that particular point; the liquid is thus forced through the pipe J, flows out at A, and is therefore deposited into the top vessel. The pressure of the hand is now taken off the centre portion of the epergne, the spiral spring G expands, forces open the waterproof cushion again, when the centre vase is elevated to its former position. The water deposited into the upper vessel will now commence to flow downwards through the pipe C, and by the force of its own weight spring upward at the jet D in the form of a beautiful fountain.

When the supply of water in the upper vessel is quite exhausted, and the liquid has found its way into the lower receptacle, the fountain is again set to play by applying pressure once more to the centre vase of the epergne. Another design in which the same principle is employed is illustrated in Fig. 3. It will be seen by referring to this figure that the construction of this epergne is somewhat different to that already described. The alterations, however, do not affect the essential method of raising the water from a lower to a higher level. In the present design the supply and exhaust tubes form the stem or support of the centre vase or vases, the upper vessel taking the shape of a globe. The supply-pipe C in this design terminates at the dotted lines A, and is bent over in the manner shown. The exhaust pipe B is of the same dimensions as C, but at its lower end branches off into two smaller tubes terminating on either side with a fine jet.

The accompanying illustrations are given merely as examples of designs to which my pneumatic fountains may be applied; but it is obvious

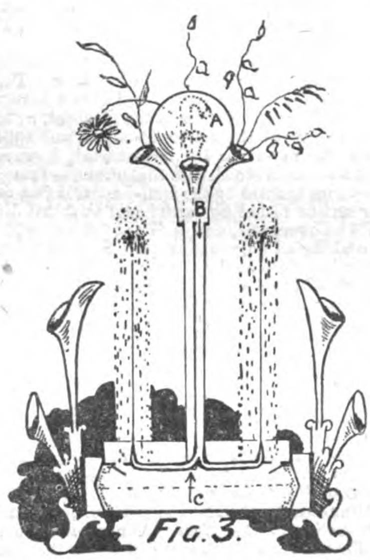

FIG. 3.

that the same principle may be embodied in more elaborate constructions, either for floral decorative purposes or for the aquarium.

Theodore Brown.

TESTS—tensile and crushing—were recently made in Bombay to ascertain the relative strengths of karri wood and teak. They resulted in favour of karri. It was also found that the cost of beams of karri would be rather less than rolled steel beams, while teak would be rather more, and that a solid timber beam 12in. by 16in. would make a more fireproof floor than light rolled beams.

IN QUEST OF THE LEONIDS: A RECORD BALLOON VOYAGE.*

ABOUT midnight on Wednesday we repaired to Newbury, where we were hospitably entertained during the small hours by the Guildhall Club, who kept open house on our behalf. The sky remaining overcast, we followed the advice given us, and shortly after 4 a.m. took our places in the car, and, amid a cheer from many hundred onlookers, quickly mounted to the region where a murky canopy hung overhead. This canopy proved to consist of a dense wetting fog 1,500ft. thick. In traversing it the balloon, which had remained captive in the still, warm air of a mild November night, became heavily charged with condensed vapour, and at the same time greatly chilled. The consequence was that it became necessary to discharge a great quantity of ballast to enable us to penetrate the cloud. Even the balloon again and again sank back into the mist. Only at my earnest entreaty that we should keep well above in view of the stars, and contrary to his better judgment, Mr. Spencer continued to throw out ballast till no less than seven bags had been discharged in twenty minutes. Our observations, which have already been recorded, continued till shortly before six, when, as though at a precise moment, the dawn suddenly flushed out with rapidly-increasing light; the stars paled and, our duties being quickly over, it remained only for us to descend.

But there was the rub. With the earliest beams of sunlight the moisture-laden silk began to dry off, and the gas to grow warmer, and, as though inspired with new life, the balloon began rising into space, mounting up by leaps of 600ft. in every quarter of an hour till, by nine o'clock, it had reached an altitude of 6,000ft., and was still rising. It will, of course, be understood that to have torn open the valve at this elevation would have been to precipitate us to earth. So the unwelcome fact had now to be faced that we were adrift simply at the mercy of the wind, and with not a cloud in sight above us to mitigate the rapidly-increasing power of the sun.

Time brought us no comfort. As breakfast proceeded, we began to hear loud reports overhead resembling small explosions, and we knew what these were. The moist shrunken netting was giving out under the hot sun, and yielding now and again with sudden release to the rapidly-expanding gas. It was, therefore, with grave concern, but no surprise, that when we next turned to the aneroid we found the index pointing to 9,000ft. and still moving upwards. Two miles up above the unseen earth! And was the region below us really earth, or was it already the open ocean? Presently the screech of a locomotive far down relieved our present anxiety, and for some little time the trains on some busy line told us that we must be in the neighbourhood of an important town or junction. Then the crash of big hammers broke in upon us. There are large ironworks at Westbury, but these were scarcely capable, we supposed, of giving out such noisy clamour. It was far more likely that we were approaching Bristol, and a glance at the map showed us that in that case our chances were growing desperate.

Then a brilliant thought occurred to us—let me say that it was due to the lady of the party. Surely there was possible help from people below, and there was a remote chance of communicating with them. We had a pencil, also a thick bundle of Press telegraph forms, ruled one side, plain the other. So with prompt despatch we devised and carried out a system of aërial communication untried in history. The following message was manifolded on some three dozen forms:—

"Urgent! Large balloon from Newbury travelling overhead above the clouds. Cannot descend. Telegraph to sea coast (coast guards) to be ready to rescue. Bacon and Spencer."

These messages were smartly produced and despatched. My daughter was clerk. The folding up of the forms into three-cornered notes was my own task; while each completed missive was labelled "Important" with red chalk by Mr. Spencer and then cast overboard. This busy and practical work afforded great relief to nerves that had long enough been on the stretch. But before it was finished we all suddenly paused and listened with all our ears, for a new sound was in the air. There was no need to exchange thoughts. We rose instinctively and listened over the car. There was the rhythmical plash of waves upon a shingly shore. Resist the thought as we might, it was unmistakable. And as if to end our suspense, up came the wail of a ship's steam siren.

This was repeated once and again, and then for a long space dead silence reigned. But by this time it was 12 o'clock, and on consulting the aneroid we were astonished to find that we had dropped more than 2,000ft., our height now being 7,000ft. only, and apparently we were still descending slowly. It may as well at once be said that it has since been made clear that at the moment just spoken of we were crossing 20 miles of the Bristol

* By the REV. J. M. BACON, in *The Times*.

Channel, and undoubtedly it was some cold current blowing up the estuary of the Severn that first gave the downward motion to the balloon. Moreover, the upper currents must from this point have greatly increased in speed, blowing stiffly up the sea-reach, and eddying in wayward courses above the mountains of South Wales. In half an hour the sounds of earth and open country had returned, and we had drawn down to 1,000ft. above the cloud floor below us, which was now breaking here and there into little black pits, like snowfields beginning to thaw.

Suddenly through one of these tiny openings was seen a far ruddy patch with a white thread running through it. This warm red colour was that of the fields of the south-west corner of England, and the white thread was a roadway. Hopes began to return; yet only to be mocked again and again. Each downward plunge was eagerly watched and timed and recorded, but each ended with a pause and then a re-ascent. Our monster balloon was dying very hard by sheer slow leakage of gas only. If it would but once dip into the cloud layer we knew its end would then be hastened; but, as though aware of this itself, it struggled manfully to keep aloft, and, as every minute sped, we could now watch the country through the openings sliding past us at an ever-increasing speed.

It was 1.30, more than nine hours from the start. The sun, clearly lower in the heavens, began to look at us more aslant. The silk above us, hitherto tense and glistening, showed signs of puckering into wrinkles. Then at last we dipped into the outmost fringe of cloud, and then rose and dipped again. The end was coming near, and it was with a feeling of intense relief that we finally plunged into the darkening mist.

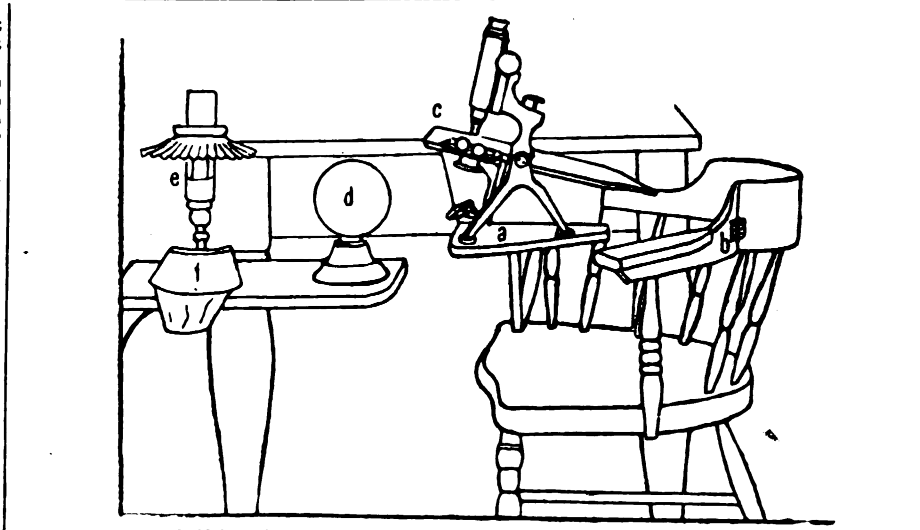
The cloud sensibly chilled the gas, and in less than five minutes we had fallen through below, and a wild romantic country broke upon our view, down on to which, as to a haven of safety, we were now swooping rapidly. But our adventure was hardly yet ended. The wind here was blowing stiffly, sweeping wherever it found egress through the valleys with great violence. This, in addition to our rapid descent, caused us to strike the earth with very considerable force, and the next moment we were breaking madly through all obstacles as the wild gusts caught the bellying silk of the now half-empty balloon. My daughter's forearm was broken with the first rude impact. Then we charged an ugly five-wire barbed fence, every strand of which we snapped like mere packthread. My nether garments were completely torn off my right leg, which, however, sustained only superficial injuries. Still we sped on unchecked till we caught in a dead half-grown oak, the head of which we carried right away entangled in our rigging. A few moments later, however, our anchor got good hold, and by this time help was hurrying up, kindly Welsh folks, cheery and willing and most handy to boot.

SOME HELPFUL LABORATORY APPARATUS.

IN the opinion of the writer, no conveniences are too elaborate for the microscopist who daily spends several hours of exacting labour in the minute and careful observation of details under high-power lenses. Any appliances that give ease to eyes or body not only render the work less arduous, but increase the efficiency of the investigator's powers of observation.

Realising this, the writer has, by degrees, accumulated a number of contrivances that, according to his experience, combine to render observation with the microscope easier and more precise. These different pieces of apparatus may not be new to many, but possibly an account of their combination into working series may suggest to others schemes for greater ease in manipulation, and thus prove of some value. In this hope, a description of the installation is here given.

The principal feature of it is a chair so modified as to carry a microscope and a drawing-board in positions that will require the least strain upon the body and arms. In constructing it, a large chair with the right arm broadened into a slanting writing-surface was employed. The hardwood writing-top was removed, and in its stead was placed a soft pine board of similar size and shape. Below this, at a distance equal to the height of the microscope stage above the table, was fastened a horizontal shelf just large enough to receive the microscope foot. This is sufficiently distant from the seat of the chair to allow the right leg of the observer to rest beneath it. This arrangement places the microscope nearly enough in front of the operator to render access to the eyepiece easy and convenient. At the same time this projection makes it difficult to enter the chair, and accordingly the left arm was cut away and suspended on a hinge so that it might afford a free entrance to the chair, and yet be in a condition to be swung back, to serve as a rest for the left arm of the operator. All the woodwork was then painted black, in order to do away with disturbing reflections.



Explanation:—*a*, shelf for microscope; *b*, swinging arm of chair; *c*, inclined drawing surface; *d*, balloon flask condenser; *e*, Welsbach light; *f*, eye-shade with cloth attached.

When it is desired to use the apparatus, the observer places the microscope on the shelf provided for that purpose, and inclines it until the stage becomes level with and parallel to the drawing-surface. He then swings out the left arm of the chair, seats himself, and returns the swinging arm to its closed position. Thus situated, he finds both arms supported at about the level of the elbows, and the ocular of the microscope at a suitable height for comfortable observation. When the camera lucida is employed, the image is traced upon paper fastened to the pine drawing-board by long, stout pins thrust into the soft wood. The right arm, meanwhile, rests in a comfortable, natural position, and the hand supports and guides the pencil, as in writing. The accompanying cut makes the various details of construction and operation plain.

Illumination.—Ordinary sunlight is, in many ways, unsatisfactory. For accurate comparative work, a more reliable and manageable source of light becomes almost necessary. The writer has found the Welsbach incandescent gas-lamp eminently suited to the requirements of the microscopist. A very excellent method of using it is to cast an image of the glowing mantle upon the mirror by means of a balloon flask filled with ammonio-cupric sulphate solution. The flask acts as a condensing lens, and by mutually arranging it and the lamp, the properly-sized mantle image may be thrown upon the mirror. A turned wooden base, bearing a hole in the centre for the reception of the flask neck, has proven the most satisfactory mounting, although improvised ones, in the form of tumblers or empty fruit-jars, have often served the purpose.

The final character of the light is entirely dependent upon the solution in the flask. This must be of such a nature that it will give a nearly white light, without the yellow of the gaslight, or the blue of an excess of the ammonio-cupric salt appearing. With the most careful adjustment, however, the light has a cold bluish cast that obscures some details in sections stained by the iron-hæmatoxylin method. The writer found by experiment that this difficulty could be overcome, and a beautiful soft white light secured by adding one or two drops of a saturated alcoholic solution of safranin to the litre flask of properly-diluted ammonio-cupric sulphate solution. It has been found necessary to renew the safranin every week or two, since it fades upon exposure. The light thus modified leaves nothing to be desired, and has served in the most delicate work with high powers.

In connection with the chair previously described, a shelf is used for holding the gas-lamp and the flask condenser. This projects from the wall, somewhat below the level of the microscope base, and with the bottom of the incandescent mantle at a height of 7in. from the table, needs to be from 20in. to 24in. long to permit the proper adjustments.

Protection for the Eyes.—Almost as important as the illumination of the object is the prevention of extraneous light from entering the eyes of the observer. Nothing is more trying to the visual organs, or more inimical to accurate observation, than a confusion of lights reflected from half a hundred polished surfaces, supplemented by a general glare from wall, ceiling, and floor. One needs only to protect the eyes for a short time from all light except that coming through the ocular in order to prove the facts stated. With the eyes shaded it will be found that very much less illumination will be required, while at the same time definition of a much higher order will be secured.

To profit by these obvious advantages, the writer adopted the simple device of wearing an eye-shade to which had been fastened a square of black cloth at the upper edge. This cloth is of such a length that when the lower edge is gathered around the top of the microscope tube and the shade adjusted on the head, the eye will be about low enough for observation. The cloth falls against the face and around the eyes, so that all light except that coming from the object is prevented from entering. Thus protected, the eyes can be used continuously for hours without becoming fatigued, and the vision is clear and distinct. I believe that no one who has once employed some such means of protecting the eyes will ever conduct further serious observations without thus conserving his eyesight.—C. E McClung, University of Kansas, in the *Journal of Applied Microscopy*, N.Y.

THE GREAT TELESCOPE FOR THE PARIS EXHIBITION.

WE have given some account of the great telescope which is to be an "object" at the Paris Exhibition next year (see p. 191, April 14, 1899, No. 1,777); but the following particulars from the *Scientific American* may be of interest to some readers:—

"It consists of a horizontal tube, 197ft. long, provided with an objective 4·1ft. in diameter. The image of the moon or stars will be sent through this tube by the aid of a Foucault siderostat—that is to say, by a movable plane mirror. The focal length of the telescope of the Yerkes Observatory is but 65·6ft., so that it will be readily seen that with a telescope whose focal length was 197ft., it would be almost impossible to build a dome and mounting which would carry it. It is estimated that a 210ft. cupola would have been required, so the use of a fixed tube and a movable mirror for gathering the image may be regarded as an excellent solution of a mechanical difficulty. The siderostat is undoubtedly the most interesting part of the instrument. It consists of a large cast-iron frame, and is provided with clockwork and devices for causing the mirror to follow the celestial object which is being viewed. The frame is now under construction at the establishment of M. P. Gautier, a distinguished manufacturer of instruments of precision. It is 26¼ft. long, and the height is the same as its length. It is provided with six levelling screws, which enter into sockets fixed upon a stone base 5·57ft. high. The hour axis is actuated by clockwork through the aid of tangent screws. The part of the instrument towards the south carries the mirror, which is mounted in a cast steel cell, lined with felt in order to prevent any contact of the mirror with the metal. The equilibrium of mirror and cell is obtained by means of levers and counterpoises. The base of this mounting floats in a reservoir 6½ft. in diameter and containing about 16 gallons of mercury. Owing to the application of the principle of Archimedes, the movable parts will be relieved of nine-tenths of its weight. The system of the levers and counterpoises is so well arranged that all of the movable parts can be actuated by hand, even without the aid of mercury. The total weight of the siderostat is 99,000lb.; the movable part weighs 33,000lb., of which the mirror and its cell weighs 14,740lb. A weight of 220lb. is sufficient to actuate the clockwork.

"The mirror has a diameter of 6·56ft., it is 10·63in. thick, and its weight is 7,920lb., and it was, naturally, the most difficult part of the apparatus to construct. The glass was cast at the Jeumont Works, and a special furnace was constructed, capable of holding 22·4 tons of glass. When the time for casting arrived, the mould, 6·72ft. in diameter and 12in. thick, was brought to the furnace upon a truck, and then, after being filled, was introduced into the furnace, which had been raised to a high temperature. It was then walled up in

this furnace, and the cooling required a month. Notwithstanding all the precautions, several of the discs that were cast broke in pieces with a loud noise. The transportation of such a huge disc of glass to Paris was a difficult matter, and a special train carried it there without stopping. A crane deposited the gigantic block on a waggon, and it was

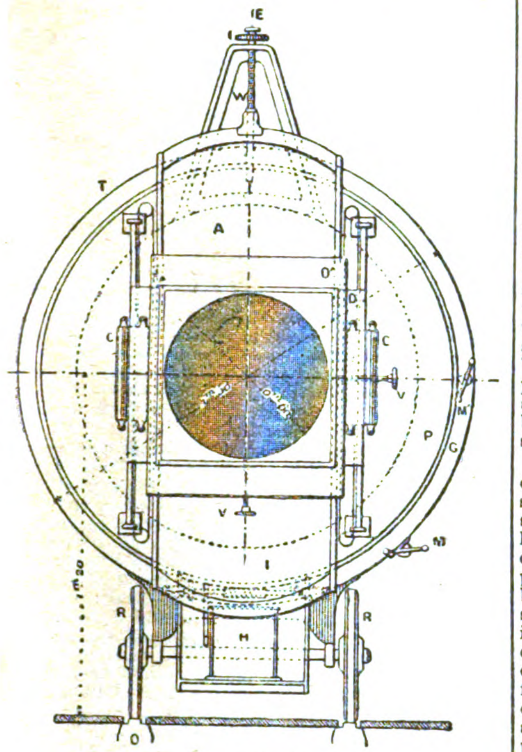


Fig. 1.

carried to the optical establishment at night, in order to have a clear roadway.

"To obtain a fine disc of glass of such dimensions was, of course, difficult, but to give it a perfectly plane surface was a much greater one, and M. Gautier is to be congratulated upon the success which he has attained in performing this difficult operation.

"The polishing-machine, shown in our general and sectional view, was placed in a special shop, protected as much as possible from variations in temperature by a double wooden wall. The grinding apparatus consists essentially of a large cast-iron plate, C, covered with an inch of flannel, upon which the glass disc A (Fig. 2) was carefully laid.

"This plate revolves slowly around a vertical axis by gearing, G, the whole being stepped in a cone. Above there is a stationary circular bronze rubber, B, 47½in. in diameter, which is given a reciprocating motion by a slider, I, thus passing across the face of the mirror travelling in a circle beneath it. The perfect revolution of the plate and the accurate adjusting of the slides and their parallelism resulted in the production of a perfect mirror. It required three months to adjust the slides alone. The grinding of the mirror was done with a mixture of emery and water. During this operation a workman always stood at a respectful distance from the apparatus so as not to change the temperature of it. From time to time he injected a mixture of emery and water by means of a syringe into a channel running through the grinding plate and ending at the centre. This work was carried on generally from 2 to 5 o'clock in the afternoon, the time of day when the temperature does not change perceptibly. The entire morning was devoted to the cleaning of the machine, and to the verification of the parallelism of the grinding plate with the surface of the mirror, an operation which was performed with four scales which were accurate to $\frac{1}{1000}$ of a millimètre.

"As the grinding proceeded, finer and finer emery was used, and the closer the grinding plate was brought to the surface of the glass. With the finest emery the distance between the plate and the glass was 0·008in. The grinding lasted eight months, and was followed by the operation of polishing, which required two months. The lower surface of the polishing plate was covered with a sheet of albumenised paper like that used in photography, but unsensitised. The workmen spread upon this paper a small quantity of the finest Venetian tripoli, and as much as possible was removed with a soft brush. The distance between the rubber and the surface of the glass was 0·0012 of an inch.

"This method of treatment, notwithstanding its delicacy, produces enough heat to render the mirror slightly convex and cause it to draw away more strongly in the centre, so that, upon cooling, it was hollowed at this point. In order to surmount this difficulty the slides were given a curve of which the pitch was 0·4 of an inch. The heat was diminished by operating the machine for a minute and then stopping for a quarter of an hour. When the hand is applied to the mirror, there occurs an extension of 0·0012 of an inch, which is sufficient to distort completely for four or five minutes the image of the flame of a lamp placed at one side of the plate, and observed from the other with a small telescope arranged for the purpose. The next operation to be performed is the silvering, and, of course, it will have to be silvered anew from time to time. The mirror protrudes 5·4in. from its tube or cell, which will be made to swing so as to bring the surface to be silvered underneath. The reservoir containing the bath will be lifted by means of a winch until the mirror enters it at a proper depth. When the operation is finished, the reservoir will be lowered, and the silvered surface turned upwards, and the mirror readjusted in its cell.

"The images of the mirror which are transmitted to the focus of the objective may be examined directly by means of an eyepiece or they may be thrown upon a sensitised plate or projected upon a screen placed in a hall set apart for that purpose so that several thousand people will be able to examine the celestial object at the same time. The tube of the telescope is a steel plate ¼in. in thickness and 5ft. in diameter. It is made up of 24 sections joined with the aid of bolts. These sections when all mounted will rest upon a cast-iron base supported by stone columns. It is arranged so as to slide to take up the expansion and contraction. The tube plays no part in the formation of the images, nor does it serve for supporting the objectives in the eyepiece; but it prevents dust from introducing itself between the essential parts of the apparatus.

"One of the objectives is designed for visual observations, and the other for photographic work. Both are mounted upon a carriage made to roll upon rails, so that either or them may be easily placed in position before the tube. The weight of either of these objectives without its mounting is about 1,295lb., and with the mounting 1,980lb. Each of the crown glasses is carried by rollers, so that it may be separated from the flint glass in order to render the cleaning of each disc easy. The lenses will cost 120,000dol.

"The discs were cast by Mantois, of Paris. Great attention was paid to the casting of the glass. Specimens of the glass were constantly taken out during the heating and examined with a lens under different conditions of illumination, in order to judge of the degree of purity which they have reached. After several specimens have been found to be free from bubbles the temperature is reduced, the glass thickens, the crucible is opened, and a certain portion of the surface is skimmed off to get rid of impurities. The glass is then stirred, and the cooling is allowed to proceed rapidly for five or six hours, until the surface of the glass emits a well-defined sound when it is struck with an iron bar. After this step it is necessary to proceed with annealing. The furnace is walled up and a cooling is allowed to proceed, which requires from four to six weeks. When the crucible is opened the glass is found to have been broken into pieces of varying sizes. In order to obtain a 792lb. flint glass lens it is necessary to find a block which weighs nearly 1,300lb., and such a block having been found among those in the furnace it is removed and placed upon a car. Slabs of glass are sawed from two parallel sides in order to obtain polished surfaces that facilitate a perfect examination of it. The striæ in the surface are removed, and if after this the block exhibits any defects situated at such a depth that they cannot be removed, it is submitted to a moulding which changes its form and brings the chief defects near the surface. The block is placed in a mould of refractory clay and put into a furnace and heated to 800° to 900° Centigrade. By this means it becomes slowly heated and softened until it assumes the form of the mould, but it must not become fused, or the whole operation must be gone over again. If the outcome of the process is successful, the glass is slowly annealed, and is then taken from the mould and examined anew. If any defects deep in the glass are seen, a second operation is begun with a mould of another form. Finally, when the glass is very pure and perfect, another and final moulding produces the plano-convex lens. After this comes another heating and cooling, which takes two or three weeks.

"At this point the glass discs are taken to the establishment of M. Gautier, where the surfaces are polished with a device like that used in polishing the mirror, except that the slides have the curve that is to be given to the disc. A long time is required in polishing out the small imperfections, and finally the lens is entirely corrected and ready for mounting.

"The tube which carries the eyepiece is supported by four wheels rolling upon rails, O. It is attached to the telescope by an adjusting screw, 4·92ft. in length, which serves for putting it in focus. In the interior of this tube another is mounted upon rollers. This inner tube is 3·54ft. in diameter, and is moved circularly by means of clockwork through the medium of a tangent screw which fits into the teeth of a circle fixed to its outer extremity. In this

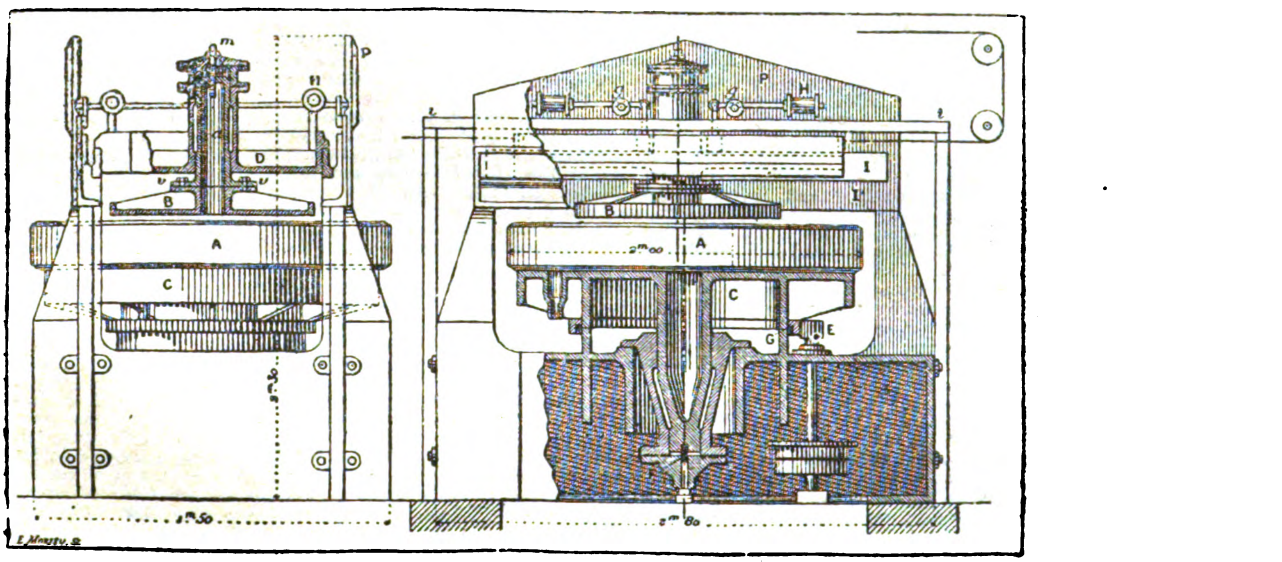

Fig. 2.

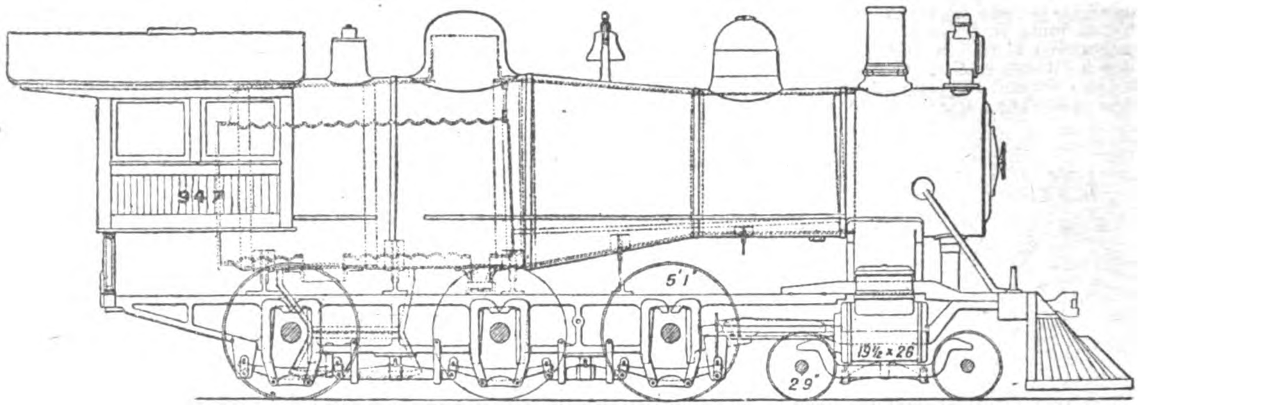

first circle, which moves upon four rollers, is a second circle, which carries two guides, and in which slides a carriage having a travel equal to a little more than two minutes of time. This is actuated by a screw, which causes the motion in another clockwork. This carriage is provided with a system of frames having rectilinear motion that permits of giving the eyepiece different positions. The upper frame is so arranged that it may receive devices for photography, micrometry, spectroscopy, or a projecting apparatus. The exact location of the telescope has not yet been determined upon, but it will be at the service of the Exposition, and will probably be placed somewhere where the atmosphere is purer than that of Paris. We are indebted for most of our engravings and for our particulars to L'Exposition de Paris, 1900, which has had an interesting and scientific series of articles upon the great telescope. The diagrams are from *La Nature*."

The particulars given are from the *Scientific American*, and Fig. 1 shows the eyepiece holder, the other illustration showing the mirror-grinding apparatus in section.

THE VANDERBILT LOCOMOTIVE FIREBOX.

ATTEMPTS have been made at various times to simplify the construction and increase the efficiency of locomotive boilers, by the use of a cylindrical firebox instead of the ordinary rectangular firebox, whose flat surfaces require so much staying, involving a great amount of labour and time in construction and repairs. For various reasons, however, only partial success has attended the experiments, and the system has never yet got beyond the experimental stage.

One of the latest and most promising attempts of this kind has recently been made in the United States. A goods engine of the New York Central Railroad has been fitted with a boiler of somewhat peculiar design, the special feature of which is a corrugated cylindrical firebox, like the furnace of a marine boiler, and having a clear inside diameter of 4ft. 11in. The boiler was designed by Mr. C. Vanderbilt, jun., one of the assistants to Mr. A. M. Waitt, the locomotive superintendent.

The boiler is 29ft. 3in. long over all. The smokebox is 5ft. 7in. diameter and 5ft. 6in. long, and the first barrel course is 5ft. 4in. outside diameter, and 6ft. 3in. in length. This course has plates 11/16in. thick, and fits telescopically into the smoke-box and into the second barrel course. Within it, and near the front end, is riveted the flanged tube sheet, which is slightly inclined backward from the vertical, as the boiler is inclined forward in order to clear the driving wheels. The second barrel course is conical, 5ft. 4in. diameter at the smaller end and 7ft. at the rear, its length being 6ft. 6in. The outer firebox shell is circular, 11ft. 3in. long and 7ft. 1⅝in. diameter, built up of two courses in length. The boiler is thus of circular section from end to end. The corrugated firebox is 4ft. 11in. inside diameter, and 5ft. 4in. diameter at the ends, while its total length is 11ft. 2¼in. It is of ⅝in. steel. In the front is a flanged tube sheet, while the rear end projects through the boiler head, and is riveted to the flanged back-plate of the outer firebox shell. The only firebox stays required are 28 sling stays, arranged in a circle around the front end of the firebox, these being 1⅛in. diameter, with forked ends fitting over T-bar studs.

The dome, 30in. diameter and 20½in. high, is directly over the front end of the firebox. At the back part of the bottom of the firebox is an 18in. opening to the ashpan, while at the front end, beyond the brick bridge wall, is an 8in. opening for cleaning out such ashes as may collect in this combustion chamber between the bridge and the tube sheet. The firebox is, of course, not concentric with the boiler, the steam space above the firebox being 1ft. 6in. high, while the water spaces decrease from 11in. at the sides to 3½in. at the bottom. There are two oval fire-doors, 16in. by 13in., side by side as in some of the wide Wootton fireboxes, for burning small coal of poor quality.

The longitudinal stays for the boiler are shown by dotted lines. In the boiler are 332 tubes, 2in. diameter and 12ft. 6in. long. They are set in vertical rows, staggered horizontally, and are spaced 2 11/16in. centre to centre.

The engine was built in the shops of the railway company, and is of the six-coupled bogie type, known in America as the "ten-wheel" type. It has six-coupled driving wheels, of which the middle pair are the main drivers, while under the smoke-box is a four-wheeled leading bogie. The leading dimensions are as follows:—

Cylinders 20in. by 28in., driving wheels 5ft. 1in., bogie wheels 2ft. 9in., driving journals 9in. by 12in., boiler (diameter of barrel) 5ft. 4in. to 7ft., firebox shell (diameter) 7ft. 1⅝in., firebox (diameter inside) 4ft. 11in., firebox proper (length) 8ft. 2in., firebox and combustion chamber (length) 11ft. 2¼in., steam pressure 185lb., tubes, 332 diameter 2in., tubes (length) 12ft. 6in., heating surface (tubes) 2,165sq.ft., heating surface (firebox) 192sq.ft., heating surface (total) 2,357sq.ft., grate area 34sq.ft., weight on driving wheels 113,300lb., weight on bogie 46,700lb., weight, total tons, English, 71·5.

The boiler steams so freely, or in other words, generates steam so rapidly, that the two 3in. safety-valves were found not to afford sufficient relief, the pressure several times running up to 195lb. when the valves were set to blow off at 180lb. A third valve has since been added. The engine made a trip of 143 miles on its first run, with a train of 50 waggons, and after a stop of three hours returned with a train of 67 empty cars—about 800 to 900 tons. It attained a speed of 25 to 30 miles per hour on this trip, and it was noted that very few cinders were thrown from the smoke-stack or funnel.

The use of corrugated fireboxes in locomotives is by no means new. They were invented by the late John Haswell, of Vienna, about the year 1870, or possibly earlier. They were in use on the Austrian Staates Bahn for many years. Probably most of our readers who are interested in locomotive design will recall the corrugated flue furnaces used in Mr. Strong's singular locomotive, which was tried about ten years ago in the United States, and was described in the *Engineer* at that time. Mr. Strong, however, used two furnaces, side by side, with their ends connected to a third corrugated flue, which formed a combustion chamber, and at the end of which was the tube sheet. This arrangement was specially designed for very long runs, and for inferior fuel, the fires being cleaned and fed alternately. The engine made trips of 440 miles with one train, but it required two firemen to keep the fires in condition. The three corrugated flues were 38½in. diameter, with a 5ft. boiler barrel, and a firebox shell, 5ft. by 9ft. The furnaces were 9ft. 6in. long, the distance from boiler head to tube sheet being 18ft. 6in. The tubes were 11ft. 6in. long, and the total length of boiler, from the back plate of the firebox to the front of the smoke-box, was 33ft. This type of boiler is evidently only adapted to engines of special design.

In 1890 Mr. Gustav Lentz, formerly managing director of the Hohenzollern Locomotive Works, in Germany, designed a locomotive boiler, having a corrugated cylindrical furnace. His boiler was of larger diameter at the middle than at the ends, and the rear part of the furnace was inclined downwards. This part formed the furnace proper, a brick wall with a semicircular opening being built at the end, and the horizontal portion of the furnace forming a combustion chamber. A six-coupled goods engine, with cylinders 17¾in. by 24⅞in., and wheels 4ft. 4⅜in. diameter, was fitted with a Centz boiler, the weight of the engine being about 32½ tons. The furnace was 3ft. 9in. diameter, with 6ft. of its length as a firebox, and 4ft. 11in. as a combustion chamber. The tubes were only 10ft. long. In 1892 a four-coupled bogie express engine, for the Prussian State Railways, was built according to the designs of Mr. Lenz. It had cylinders 17in. by 23⅝in., driving wheels 6½ft. diameter, and weighed 50 tons. This engine is said to have been successful as a steam generator, and for complete combustion of fuel, but was very wasteful of the heat. The smoke-box temperature, in fact, reached 768°, while in the ordinary engines it was about 526°.

The Vanderbilt boiler is of much simpler design and easier of construction than either the Strong or the Lentz boilers, and it appears to promise good results in service. Whether it will effect any practical change or revolution in locomotive design remains to be seen. At present the one goods engine is in regular service, and a record is being kept of its performance. The general results of one of the trips with a goods train were as follows:—

Distance 140 miles, total time 8 hours 15 minutes, running time 6 hours 51 minutes; speed, average for running time, 20 4 miles per hour; speed, maximum, 30·2 miles per hour; weight of train, behind tender (gross tons 2,240lb), 826 tons; weight of train, engine and tender (gross tons 2,240lb.), 940 tons; coal consumed 12,390lb., water consumed 107,571lb., water evaporated per pound of coal 8·60lb., water evaporated from and at 212° Fahr. 10·30lb., coal per car per mile 1·43lb., coal per 100 tons per mile 9·40lb. tons hauled one mile per pound of coal 10·40 tons, tons hauled one mile per pound of water 1·23 tons.—*The Engineer.*

THE COLOURING OF LANTERN SLIDES.

IN the *Bolletino della Soc. Fot. Ital.* Roster points out that in colouring slides the best results are obtained with aniline colours, and that it is important that the colours should not destroy one another, and he suggests the following as satisfactory. Blue: Indigo carmine. This is the best colour for the sky. Green: (*a*) Malachite green. This is very brilliant, and must be sparingly used, and it is difficult to spread it evenly on large surfaces, and it is not suitable for plants and foliage. (*b*) A mixture of tropælin O and indigo carmine is the best for foliage, and, according to the proportion of these two, a cold, a brilliant, or a yellowish green is obtained, and also the colour of dead leaves. Yellow: (*a*) Tropælin O for bright yellow, mixed with eosine it gives flesh tints. (*b*) Mixtures of tropælin O and orange for darker and golden yellow. (*c*) Orange alone. Red: (*a*) Eosine for a bright red. (*b*) Mixture of eosine and orange for brilliant fiery red. For brown: (*a*) Bismarck: brown or vesuvin; the former is to be preferred for warm brown tones. (*b*) Mixtures of Bismarck brown and indigo carmine for cold brown tones.

The separate colours, as well as the mixtures, may be kept in stock in stoppered bottles. A retouching desk should be used with a sheet of white paper as a reflector, and the plate slightly tilted. The reflector should be about 4in. from the plate.

The transparency should be allowed to thoroughly soften by soaking in water for half an hour, then blotted off with blotting-paper, and placed on the retouching desk. The colours should be applied with a camel's-hair brush in a very dilute state, and the operation repeated to obtain the necessary intensity. After every application the excess of colour should be removed with a sheet of blotting-paper. When colouring large surfaces, it is advisable to pass over it a broad brush dipped in plain water before blotting off; this evens the colour. In working up the sky the transparency should be turned upside down, and the colour applied from the landscape; a natural gradation will thus be obtained.—*British Journal of Photography.*

THE electric railway power stations in America use larger units than in Europe; 1500-kilowatt, 2000-kilowatt, 3000-kilowatt machines may now be regarded as common American practice.

THE "NEW DEPARTURE" AUTOMATIC COASTER.

We have from time to time published descriptions of novel forms of bicycle devices. We take pleasure in publishing herewith a new form of coaster hub which possesses novelty of construction in several particulars. It will be noticed from the description given below that in going down hill the wheels may be allowed to run freely with the pedals remaining in a stationary position, while the brake may be applied by simply bringing the weight to bear upon the rear pedal.

The coaster uses 36 straight spokes, and can be furnished with any size or thickness of sprocket from 7 teeth by $\frac{3}{16}$in. up. No fitting or adjusting is necessary, for the hub, when it leaves the factory, is in perfect order, ready to be placed on the wheel. It has the advantage of being no larger than the regular bicycle hub, and has its coasting device assembled compactly and securely within the hub shell. Anyone can apply the coaster in a few moments to any form of wheel.

When the rider desires to coast, the feet are simply held still, thereby releasing the driving mechanism and allowing the wheel to coast freely. By a slight downward pressure on the rear pedal the brake is brought into action and adjusted as required. When it is desired to go ahead, it is necessary simply to pedal forward in the usual manner. There is no back-pedalling; the pedal cannot jump, either forward or backward; and there is no strain or twist whatever upon the machine.

What is probably the greatest advantage, and one peculiar to this device, is the fact that the rider always has a tight pedal under foot, which feature is of itself of paramount importance in any free-wheel device. The best rider will naturally feel nervous and insecure if the pedals hang loosely under foot; but in this improved device there is no point where the pedals are not in thorough contact either with the coasting or driving mechanism.

Second only to this point is the fact that the wheel may be trundled backward or forward, allowing easy racking, whether the coasting be on or off. In walking alongside of the machine the pedals may remain stationary, so that they will not interfere with the limbs or clothing.

The method of obtaining these advantages will be noted by referring to the cuts. Fig. 1 shows the coaster hub assembled as shipped from the factory. Figs. 2 and 3 show the manner of assembling the interior mechanism.

The chain, when pulled forward, causes the sprocket G to rotate. This sprocket, being fast upon the driver E causes it to rotate forward, thereby drawing the cone D over into contact with the clutch F, which, being fast in the hub, causes the hub to rotate and the wheel to move forward.

When the rider holds the feet still upon the pedals, the driver E stops rotating, thus drawing the cone D out of engagement with the clutch F, and carrying it across into the brake-clutch C. The brake is not yet applied; but the wheel is free to coast with the feet upon the pedals. If it be desired to brake, simply press lightly upon the rear pedal; and the brake is instantly in operation, and can be graduated to any degree desired. When it is required to propel the wheel, merely pedal ahead; the mechanism does all the adjusting. There is no "kick-off."

The device is manufactured by the New Departure Bell Company, Bristol, Conn., which is represented by John H. Graham and Company, No. 113, Chambers-street, New York, N.Y. — *Scientific American.*

STEEL CASTINGS.

At a recent meeting of the Manchester Association of Engineers, Mr. J. E. Fletcher read a paper on "The Manufacture of Steel Castings." The chief difficulty, he said, was in the manufacture of steel castings in connection with their contraction. The contractional coefficient being roughly double that of cast iron, very special means were necessary in order to release castings of large dimensions rapidly and successfully whilst cooling. With regard to hydraulic cylinders, Mr. Fletcher recommended that these should always be cast mouth upwards. By this means the weakest portion—viz., the closed end of the cylinder, was most likely to be perfectly sound, as it was subjected to the pressure of the whole of the cylinder body and casting-head above it. Again, the crystallisation of the steel in the cylinder base was regular, and the contraction more uniform. With regard to the casting of engine, boiler, and pipe connections, he said that in the Navy the introduction of the Belleville boiler had led to the use of steel castings of most intricate form, some of which had been produced successfully; but in the case of others, waster after waster had rewarded the founders' efforts. He believed he was perfectly correct in saying that on several occasions the completion of warships had been delayed simply on account of the difficulty in obtaining delivery of steel boiler castings of the intricate order above mentioned. From experience gained the following conclusions had been arrived at:—Pipes, tees, bends, and valve-bodies of over 4in. bore should not be less than $\frac{5}{8}$in. thick; under 5in. bore, $\frac{1}{2}$in.; 6in. to 8in., $\frac{3}{4}$in.; 8in. to 10in., $\frac{7}{8}$in.; 10in. to 12in., 1in. The holes in all flanges should be drilled; the junction of two boxes should be well rounded, and the coupling flanges kept as small as possible. In casting for locomotive purposes several articles had given considerable trouble, notably wheel centres, motion-plates, and bogie-frame castings of more or less intricate form. The greatest difficulty was in the production of wheel centres having heavy balance weights. It was true that steel founders, had overcome the difficulty partially, and such wheels could be cast free from flaw, but it was extremely doubtful whether they were ever free from the severe strains set up during contraction, however well the castings were annealed. Dealing with the casting of spur and bevel wheels for millwrights' use, Mr. Fletcher said the thickness of arms and rims should be as nearly as possible uniform. Wheels over 4ft. 6in. diameter should have their shaft bosses or eyes split, and afterwards hooped. The Continental plan of adopting an odd number of arms was recommended, such wheels as a rule being more truly circular than wheels with an even number of arms. Wheels in halves should be cast in one piece, afterwards being sawn or drilled apart at the rim. The arms of bevel-wheels should be of H section, and where the wheels had very flat faces the rims should be stiffened. Steel wheels with disc centres were not recommended, fracture in cooling being of constant occurrence. In conclusion, the author remarked that in considering various representative castings, the question of crystalline structure played an important part. In fact, wherever in a casting, weak zones of crystallisation occurred, there was a risk, to a greater or less extent, of fracture. The risk might be minimised by annealing only, and he was strongly of opinion that all steel castings should be well annealed. The demand for very mild steel castings giving high ductility had in some cases been carried too far, intricate forms of rapidly changing section, when cast in steel of this character, being very likely to fail; indeed, it might be taken as certain that mild qualities of steel developed cracks more readily than the harder ones. The production of steel castings would be carried on more successfully as the laws of cooling in relation to crystalline structure became more widely known, but steel founders, with all other metal founders, were seriously hampered by the appalling general ignorance—on scientific subjects—of the moulder.

In the discussion

on the paper, Mr. James Saxon agreed with the author as to the advisability of splitting the bosses of wheels for millwrights' use, and also the advantage of having an odd number of arms.—Mr. Parry said the most difficult locomotive casting to deal with was the radial axle-box.—Mr. Whittaker expressed the opinion that 25 per cent. of bad steel castings were due to the steel being badly melted in the furnace.—Mr. Alfred Saxon said that, for certain classes of engine-work, engineers would not adopt steel castings unless they were produced lighter than cast iron.—Mr. Mitton thought there was no virtue in having an odd number of arms in wheels for millwrights' requirements.—Mr. Hodgson said the foreman moulder ought to be taken more into confidence by those who were designing the work.—Mr. Daniels considered hydraulic castings were best when cast with the head down.—Mr. Whitehead thought a good deal of trouble in steel-casting arose from the hard sand or compound of which the mould was made.—Mr. Fletcher, in replying, said the different results obtained in castings when they used the same method of moulding, casting, and releasing, were largely due to the difference in the temperatures at which the castings set. In the case of large or vital defects, he would not recommend electric welding; but in making good small defects that could be readily got at, it was perfectly satisfactory.

TEMPERING COPPER.

The art of tempering copper and bronze tools is supposed to be a lost art; but announcements are frequently made about the discovery of a method of putting a hard edge on copper. They are generally misleading; but this seems definite, and, as a patent has been applied for, the truth will soon be known:—

Martin L. Shevlin, of Elizabeth, Pa., employed at Lohrey's pork-packing establishment, on East-street, Allegheny, is the inventor of a process for
